Summary

Up to 80% of *BRCA1* and *BRCA2* genetic variants remain of uncertain clinical significance (VUSs). Only variants classified as pathogenic or likely pathogenic can guide breast and ovarian cancer prevention measures and treatment by PARP inhibitors. We report the first results of the ongoing French national COVAR (cosegregation variant) study, the aim of which is to classify *BRCA1/2* VUSs. The classification method was a multifactorial model combining different associations between VUSs and cancer, including cosegregation data. At this time, among the 653 variants selected, 101 (15%) distinct variants shared by 1,624 families were classified as pathogenic/likely pathogenic or benign/likely benign by the COVAR study. Sixty-six of the 101 (65%) variants classified by COVAR would have remained VUSs without cosegregation data. Of note, among the 34 variants classified as pathogenic by COVAR, 16 remained VUSs or likely pathogenic when following the ACMG/AMP variant classification guidelines. Although the initiation and organization of cosegregation analyses require a considerable effort, the growing number of available genetic tests results in an increasing number of families sharing a particular variant, and thereby increases the power of such analyses. Here we demonstrate that variant cosegregation analyses are a powerful tool for the classification of variants in the *BRCA1/2* breast-ovarian cancer predisposition genes.

Introduction

Identification of the *BRCA1* (MIM: 113705) and *BRCA2* (MIM: 600185) genes 25 years ago opened up a new field

in cancer genetics and *BRCA1/2* testing is now a paradigm in predictive medicine. Pathogenic germline *BRCA1/2* monoallelic variants are associated with a high risk of breast and ovarian cancer.¹ They are classified as

pathogenic when they have a putative loss-of-function effect, usually when a stop codon is introduced by nonsense substitutions, frameshift insertions/deletions (indels), complete splice defects, or large gene rearrangements (LGRs).^{2–6} However, many numerous identified variants, such as missense, synonymous, or variants surrounding coding exons even at canonical splicing positions, are difficult to classify without complementary analyses and, in many cases, remain unclassified.^{7–11} An international effort to classify *BRCA1/2* variants was initiated in 2009 through “The Evidence-based Network for the Interpretation of Germline Mutant Alleles” (ENIGMA) and has recently been extended to other breast cancer predisposition genes.¹²

In view of the increasing genetic testing capacity due to the use of next generation sequencing (NGS) and with the advent of PARP inhibitors (PARPi) for the treatment of individuals affected with a tumor driven by *BRCA1/BRCA2* inactivation, the number of affected individuals tested and the number of variants detected are continuously increasing.^{13,14} In April 2021, about 40,000 and 25,000 *BRCA1/BRCA2* different germline variants have been reported worldwide in the BRCAexchange and ClinVar databases, respectively, of which nearly 80% and 50%, respectively, are unclassified in term of their pathogenic effect¹⁵ (Table S1). However, due to the individual impacts of PARPi prescriptions and prophylactic decisions such as mastectomy and oophorectomy, a reliable

classification of variants as either pathogenic or non-pathogenic is of utmost importance. In a survey of 3,672 women who underwent *BRCA1*/*BRCA2* testing in 2014–2015, Kurian et al. reported that 51% of women carrying a variant of uncertain significance (VUS) underwent bilateral prophylactic mastectomy even in the absence of family history of cancer.¹⁶ In March 2016, the journalist Jeremy Lange reported in The New York Times the case of a woman whose doctors had conflicting information on her *BRCA1*/*BRCA2* test result. “The situation is ripe for overinterpretation and misinterpretation,” said a geneticist interviewed.

The large size of the *BRCA1* and *BRCA2* proteins, the complexity of their functions, and the lack of reliable surrogate markers of their activity, such as pathological immunohistochemistry or a comprehensive functional assay, have led to the VUS classification approach based on a multifactorial model, which has been validated for *BRCA1*/*BRCA2* variant classification in previous studies.^{11,17,18} For each VUS, this model comprises a prior probability (PriorP) of pathogenicity based on Align-GVGD prediction score and combined likelihoods of pathogenicity derived from measurements of associations between VUS and cancer: personal and family cancer history, breast tumor pathology, co-occurrence of VUS with a known pathogenic variant of the same gene, and cosegregation data.^{11,17,19–21} Plon et al. proposed a classification of cancer predisposition gene variants based on five levels of likelihood of pathogenicity, known as the IARC-5-tier classes: (1) benign (BV), (2) likely benign (LBV), (3) of uncertain significance, (4) likely pathogenic (LPV), and (5) pathogenic (PV).²²

The COVAR (cosegregation variant) study has been set up within the French Unicancer Genetics Group (UGG) which brings together cancer genetics clinics and laboratories. Here, we report the first results of the COVAR study showing the value of cosegregation analyzes for classification of *BRCA1*/*BRCA2* variants. In addition, by comparing the COVAR results to the variant scoring obtained by following the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) guidelines, we demonstrate the power of the COVAR approach.

Subjects and methods

UGG cancer genetics clinic and laboratory network, FrOG (French OncoGenetics) Database

The French UGG (see [Web resources](#)) was established in 1991 to contribute to the identification of cancer predisposing genes and estimation of cancer risks based on national (GENEPSO, GEMO, GENESIS) and international (IBCCS, CIMBA) genetic epidemiological studies and to define recommendations for genetic testing and management of individuals at risk.^{1,2,5,23–28} In 2020, the UGG consists of a network of 148 public/private cancer genetics clinics throughout France and 26 academic molecular genetics laboratories, 17 of which routinely perform breast-ovarian cancer genetic testing.

Between 1994 and 2018, about 260,000 index cases (ICs) were sequenced for *BRCA1*/*BRCA2* in the UGG cancer genetics clinic and laboratory network. The sequencing was performed by specific gene analyzes until 2017 and by multigene panel thereafter.^{26,29} ICs correspond to the first case to be tested in their families and are mostly women with a personal history of breast and/or ovarian cancer. Sequencing technologies evolved during this period, but genetic testing always included the search for substitutions and indels on all *BRCA1*/*BRCA2* coding exons and exon/intron boundaries, as well as the search for LGR. All identified variants (except for common polymorphisms) were reported in a dedicated *BRCA1*/*BRCA2* database initially called UMD-*BRCA1*/*BRCA2*⁵ (*BRCA*Share³⁰) and now called FROG (French OncoGenetics) database. This database is a helpful everyday tool for molecular geneticists and an essential resource for the classification of variants. Affected individuals are pseudonymously registered in the database by means of a family ID assigned by the submitting laboratory.⁵ Patients can therefore be mapped back through their family ID for variant classification updates and research study invitations.

A working group composed of the UGG molecular geneticists is in charge of the classification of variants. The curation is under the responsibility of S.M.C. Systematic classification criteria have been introduced in the framework of the IARC-5-classes of pathogenicity.²² The principles of classification are reported in [Figure 1](#) and in Béroud et al.³⁰

In April 2021, of the 3,389 distinct *BRCA1* variants reported, 1,112 variants were classified as LPV/PV (class 4/5), 583 as BV/LBV (class 1/2), and 1,694 as class 3 (VUS), this last class representing 50% of all variants ([Figure 2](#)). A similar class distribution was observed for *BRCA2*: within 5,081 distinct *BRCA2* variants reported, 3,062 were classified as class 3 (60%).

The COVAR study and variant selection

The COVAR study was initiated in order to increase the proportion of classified variants by using cosegregation data within families. The study was designed to focus on sampling available relatives of the ICs and testing whether or not they carried the variant found in the IC with reference to their cancer phenotype. The model used here includes the absence/presence and age at diagnosis of *BRCA*-associated cancers (breast, ovarian, pancreas for *BRCA1* and *BRCA2*, and prostate for *BRCA2* only).^{1,33–35} The model compares the probability of observing the pedigree phenotypes and variant genotypes under the hypothesis that the variant is pathogenic with that under the hypothesis that the variant is benign with respect to risk.^{17,19} If this likelihood ratio (LR) is greater than 1, this indicates evidence in favor of a pathogenic effect of the variant and, conversely, if it is less than 1 this provides evidence that the variant is benign. For a given variant, combined cosegregation likelihood of pathogenicity is calculated by multiplying the LR obtained from families sharing the same variant (or different variants when the same impact at the mRNA and/or protein level has been demonstrated for each variant).

Variant selection is discussed by the variant classification working group according to the expected classification power. It is based on the number of families carrying the same variant, the number of potential participants among the relatives, and the level of PriorP, because a lower level of evidence is required to reach a final classification of PV or LPV when PriorP is high ([Figure 1](#)). A variant may be selected in the COVAR study when it has been identified in at least three families, whatever

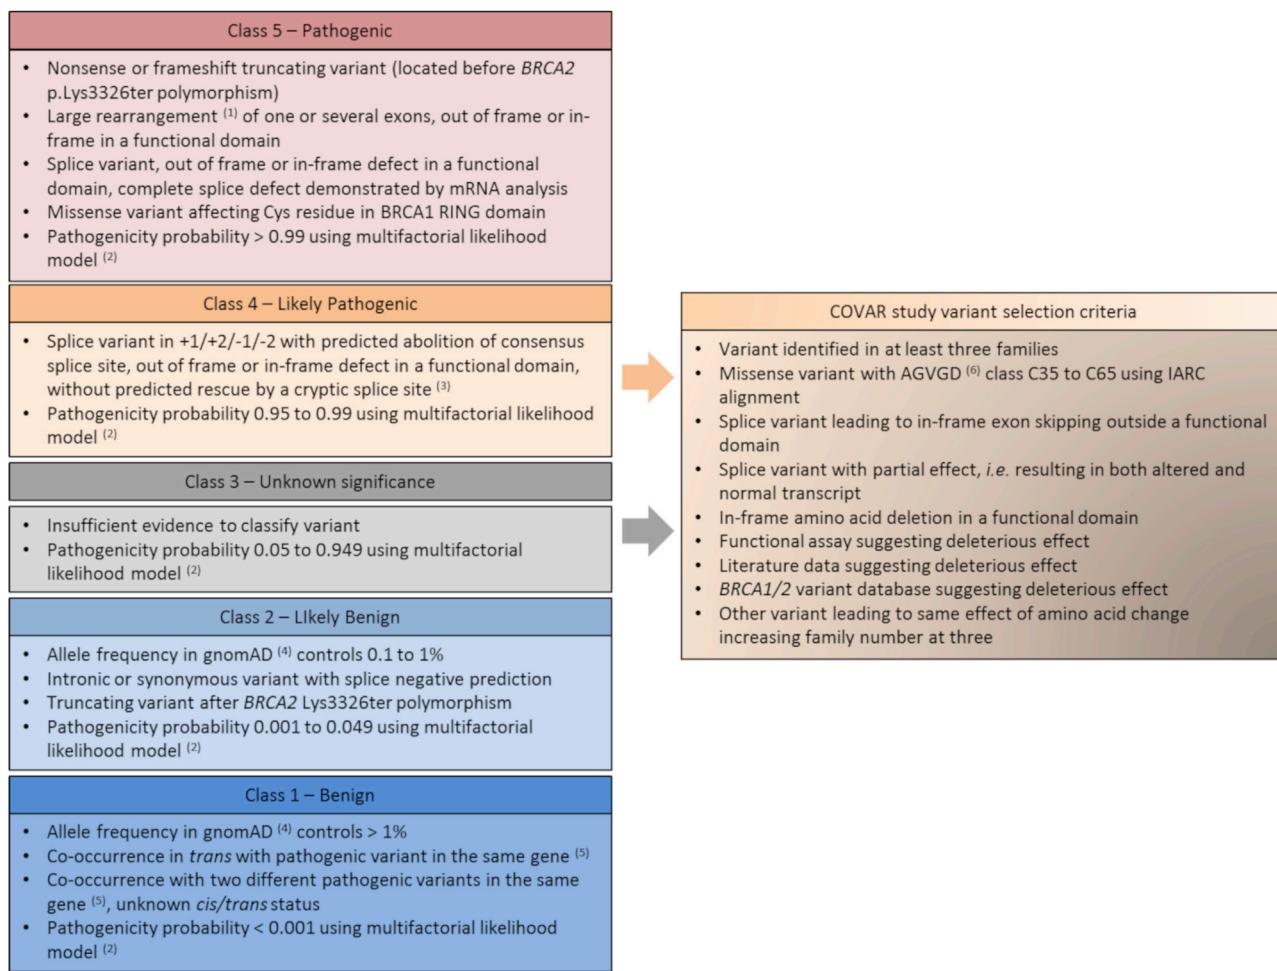

Figure 1. Variant classification criteria in the framework of the 5 classes of likelihood of pathogenicity and COVAR study variant selection criteria

The variant classification or selection for COVAR study relies on the presence of at least one of the listed criteria.

(1) For large duplications, tandem status disrupting the gene must be demonstrated by mRNA analysis or breakpoint sequencing, otherwise this variant should be considered to be a VUS.

(2) Multifactorial likelihood model proposed by Goldgar et al. ¹⁷

(3) This classification criterion has been used since January 2019. Before 2019, these splice variants were classified in class 5 and were confirmed by mRNA analysis.

(4) Total gnomAD cohort or subpopulations except for Finnish, Ashkenazi Jewish, and “Other” groups due to the possibility of a founder effect and/or the small number of subjects. gnomAD started to be used as the control database for classification criteria in July 2017. Between December 2014 and June 2017, allele frequency was determined from the ExAC database, with the same thresholds and population groups for classification. Between 2012 and November 2014, allele frequency was determined from the 1000 Genomes Project and Exome Sequencing Project databases, with only one threshold, allele frequency > 1% for classification in class 1 variant, and only the total cohort of both projects.

(5) With no clinical or biological signs of Fanconi anemia.

(6) Align-GVGD prediction algorithm classifies variants from C0 to C65 classes; C0 corresponds to the least likely functional variants and C65 corresponds to the most likely functional variants.³¹ The last species of IARC alignment, purple sea urchin, is removed for Align-GVGD prediction when it is the only species with an amino acid change; in this case, the inclusion criterion corresponds to Align-GVGD class C35 to C65 AND deleterious prediction by SIFT algorithm.³²

IARC, International Agency for Research on Cancer.

its PriorP. A minimum PriorP of 0.66 is sufficient to select a variant, even if it has been identified in only one family; the threshold of 0.66 corresponds to the Align-GVGD C35 to C55 prediction classes. LPVs are rare and systematically selected. Most selected variants are VUSs. Splice variants with equivocal effect are also selected, e.g., the deep intronic variant *BRCA2* c.6937+594T>G.^{36,37} Variant selection is an ongoing process; thus, a variant not initially selected may be subsequently

selected based on identification of new families carrying the same variant.

Ethics declaration

The COVAR study was authorized by Ethics Committee in 2011 (Comité de protection des personnes Ile de France III, Ref: Am5677-1-2940) and is registered in the international clinical

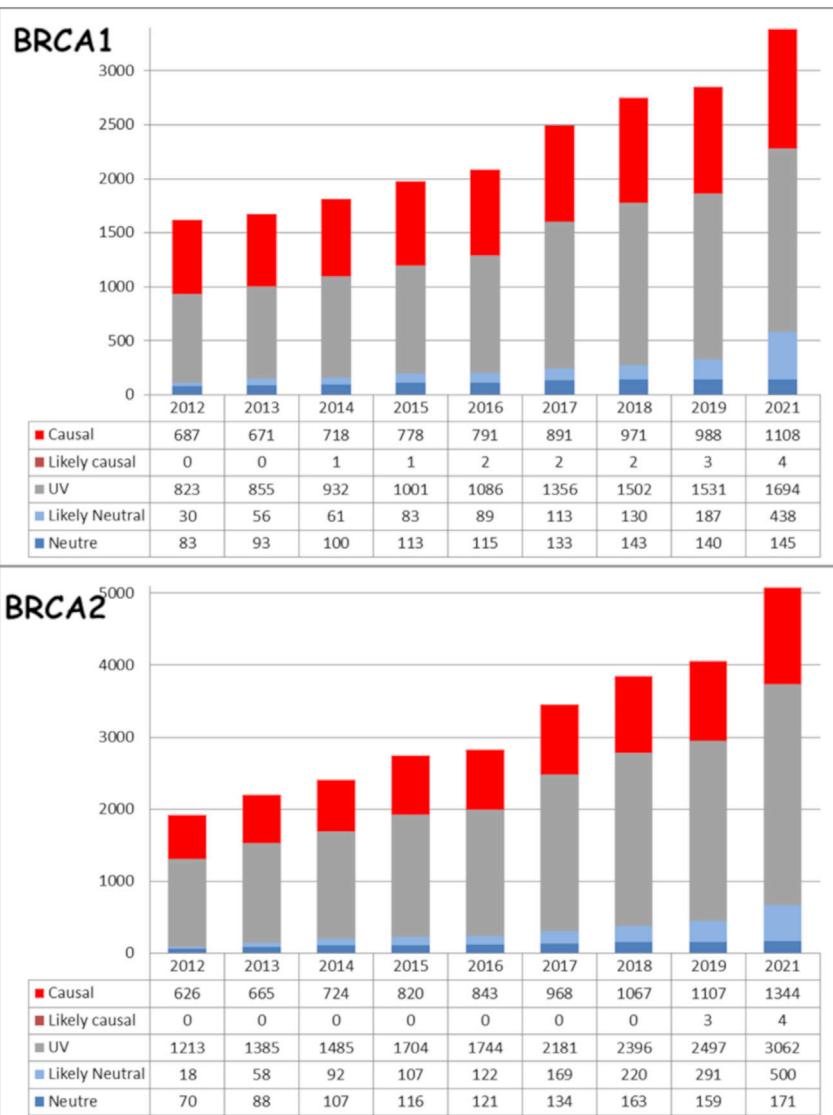

Figure 2. Increase of the number of *BRCA1* and *BRCA2* variants in the FrOG database since 2012, not including the result of the COVAR study classification

rectomy. They provide their permission to access medical files in order to retrieve pathology reports. Breast cancer details are collected.³⁸ For relatives not included in the study and whose cancer status is useful for cosegregation analysis, efforts are made to obtain cancer validation by pathology report, medical record, or *bona fide* clinical history. When a variant has been classified as BV or LBV, the ICs concerned are informed by mail and are invited to inform their relatives; when classified as LPV or PV, all study participants, regardless of individual test results, are invited to attend a cancer genetics clinic to perform diagnostic testing on a second sample.

Statistical model

Cosegregation LR is assessed using the statistical model developed by Thompson et al.¹⁹ and implemented in the COOL-webserver based on an improved penetrance model, developed by Belman et al.³⁹ In addition to the cosegregation LRs derived in this way, the multifactorial LR for each family includes LR co-occurrence,¹⁷ personal and family cancer history,^{40,41} and breast pathology LRs³⁸ as previously published.¹¹ All these LR are multiplied to obtain the “combined LR.” As previously mentioned by Goldgar et al., since analysis of cosegregation is conditional on the phenotypes in the family, the data on cosegregation can be considered independent of the data on family history.¹⁷ Combined LRs of families

sharing the same variant are multiplied. The PriorP of each variant is based on the Align-GVGD prediction class score determined by phylogenetic conservation of the modified amino acid, physico-chemical change score for missense variants, and the MaxEntScan splicing site prediction tool for suspected splicing defects.²¹ PriorP and LRs are combined to calculate posterior probabilities using a Bayesian formula:^{11,17,18}

$$\text{Combined LRs} = \text{LR}_{\text{coseg}} \times \text{LR}_{\text{co-occurrence}} \times \text{LR}_{\text{fam-Hist}} \times \text{LR}_{\text{pathology}}$$

$$\begin{aligned} \text{Posterior Odds} &= \text{Combined LRs} \times \\ &\quad [\text{Prior Probability}/(1 - \text{Prior Probability})]. \end{aligned}$$

$$\begin{aligned} \text{Posterior Probability of pathogenicity} \\ &= \text{Posterior Odds}/(\text{Posterior Odds} + 1). \end{aligned}$$

For in-frame indels located in the same functional domain, the highest Align-GVGD PriorP is chosen.¹⁸ Combined LR (or LR causal) thresholds used are those defined by Goldgar et al.: >1,000:1

trials platform (see [Web resources](#)). Informed consent for genetic testing was obtained from all individuals undergoing testing.

Affected individual inclusion and study participation

ICs carrying a variant selected in the COVAR study are invited to participate in the study by medical geneticists during the test result disclosure consultation, or later if the variant has been selected subsequently. Inclusion of relatives is prioritized as follows: individuals with a personal history of breast and/or ovarian cancer, older cancer-free women/males when they can be useful to infer genotypes. Potential participants receive invitation letters from the cancer genetics clinic that manage them. Relatives agreeing to participate in the study receive full information about the study by mail and can receive oral information from a genetic counselor upon request. After providing their written consent, they receive a salivary kit for DNA testing (Oragene, DNA Genotek) and a short clinical questionnaire that includes sex, cancer status (site and age at diagnosis), age at interview for unaffected relatives, and age at possible prophylactic mastectomy and ooph-

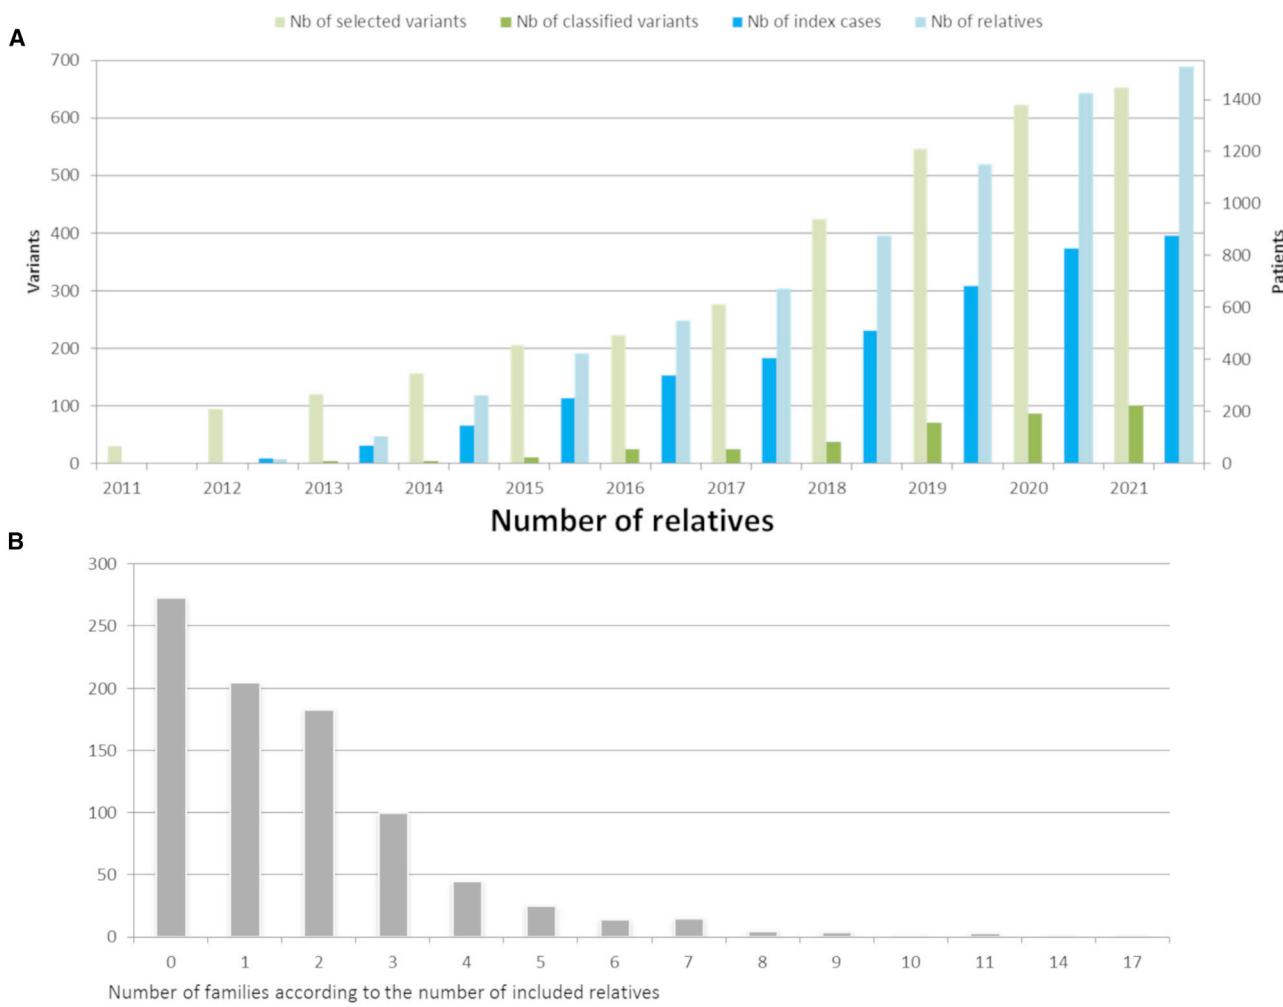

Figure 3. Patients and variants in the COVAR study from December 2011 to November 2019

(B) Number of families participating in the COVAR study according to the number of relatives included.

considered to be pathogenic (class 5) and <1:100 considered to be benign (class 1).¹⁷ It means that the Posterior Probability of pathogenicity is calculated only when the combined LR is greater than 1,000:1 or lower than 1:100. Variant classification is based on the Posterior Probability of pathogenicity, with values <0.001, between 0.001 and 0.049, between 0.95 and 0.99, or >0.99 corresponding to BV, LBV, LPV, or PV, respectively.²²

Results

Variant selection and patient inclusion

From December 2011 to April 2021, 645 VUSs (214 *BRCA1* and 431 *BRCA2*) and 8 LPVs (4 *BRCA1* and 4 *BRCA2*) were selected for the COVAR study (Figure 3A). These 653 variants included 518 missense, 53 intronic, 34 in-frame deletions/insertions, 22 synonymous, 14 nonsense or frame-shift indels, and 12 in-frame LGR.

By April 2021, 876 ICs carrying a selected variant (283 *BRCA1* and 593 *BRCA2*) and 1,525 relatives had been included (Figure 3A). Among the 876 participating ICs, no relative was included for 273 ICs, one relative was

included for 205 ICs, and more than one relative was included for 398 ICs (Figure 3B).

Variant classification

At the time of the study report, COVAR allowed the classification into clinically useful categories of 101 variants (15% of the selected variants) shared by 1,624 families registered in the UGG clinics network. Thirty-four variants (17 *BRCA1*, 17 *BRCA2*, 34%) were classified as PV; 4 *BRCA1* variants (4%) as LPV, and 63 variants (25 *BRCA1*, 38 *BRCA2*, 62%) were classified as BV or LBV (Tables 1, S2, S3, S4, and S5). Table 1 reports LRs calculated for each component of each variant and its class with or without including cosegregation data. Of note, 29 of the 38 (76%) COVAR-classified PVs/LPVs and 37 of the 63 (59%) COVAR-classified BVs/LBVs, overall 66 of the 101 (65%) COVAR-classified variants would have remained VUSs without cosegregation data. Classified variant types were 74 missense, 11 intronic, and 8 synonymous variants, 6 in-frame indels, and 2 LGRs (Figure 4A). Each type

Classifications without or with cosegregation data are in bold. See Table S3 for details of ClinVar, BRCAexchange and ACMG classification.

^aThis variant was also classified by BRCAexchange.^bThis variant was also classified by ClinVar.^cBoth variants were always observed altogether. Their cosegregation in 4 meiosis supports that they are in c/s.

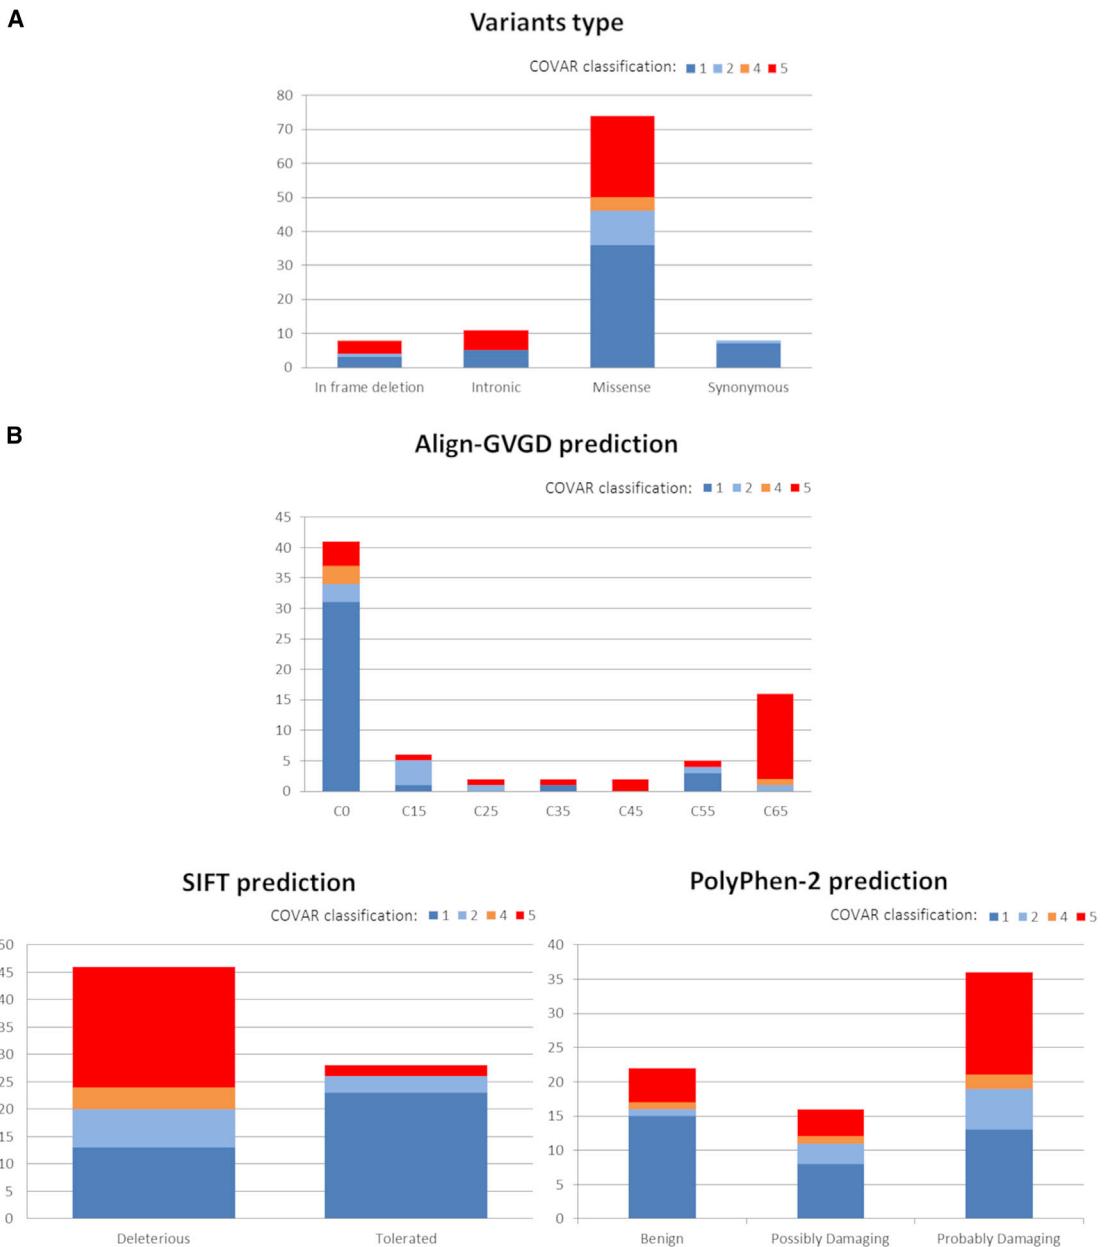

Figure 4. Classified variants type and *in silico* prediction

(A) Classified variants according to the type of variation.

(B) Classified variants according to the *in silico* predicted protein effect: Align-GVGD, SIFT, or PolyPhen-2.

contained variants classified either as pathogenic or benign, except for synonymous variants that were all classified as BV or LBV. Although 8 LPVs were selected for analysis, none of them were re-classified.

Variant classification and pathogenicity prediction tools

A good concordance was observed between the Align-GVGD prediction tool for extreme classes and the COVAR study classification concerning amino acid changes, i.e., most C65 variants were classified as pathogenic and C0 variants as benign (Figure 4B). However, six variants with a predicted pathogenic effect ranging from Align-GVGD class C35 to C65 were demonstrated to be benign or likely

benign: *BRCA1* c.92T>A (p.Ile31Asn) located in the RING domain and c.5071A>G (p.Thr1691Ala) and c.5117G>C (p.Gly1706Ala) located in the BRCT1 domain; *BRCA2* c.7481G>A (p.Arg2494Gln) located in the Helical domain and c.9104A>C (p.Tyr3035Ser) and c.9275A>G (p.Tyr3092Cys) located in the oligonucleotide binding 2 and 3 (OB2/3) domains, respectively. Conversely, nine variants with Align-GVGD class C0 to C25 were demonstrated to be pathogenic: *BRCA1* c.4963T>G (p.Ser1655Ala) and c.5062G>T (p.Val1688Phe) located in the BRCT1 domain, c.5254G>C (p.Ala1752Pro) and c.5255C>A (p.Ala1752-Glu) located in the linker between BRCT1 and BRCT2 domains, c.5309G>T (p.Gly1770Val), c.5309_5310delinsTT

(p.Gly1770Val), and c.5434C>G (p.Pro1812Ala) located in the BRCT2 domain; *BRCA2* c.8009C>T (p.Ser2670Leu) and c.8009C>G (p.Ser2670Trp) located in the OB1 domain. Poor concordance was observed between the COVAR study classification and SIFT and PolyPhen-2 prediction tools, especially for variants with a predicted pathogenic effect, almost half of which were classified by the COVAR study as BVs or LBVs (Figure 4B).

Specific variants

The *BRCA2* c.6937+594T>G deep intronic variant previously reported to be associated with a cryptic exon inclusion between exons 12 and 13 was classified as a BV, like the *BRCA2* c.9501+3A>T variant leading to partial exon 25 skipping.

Some variants were classified as pathogenic by combining pathogenicity likelihoods, as they have the same putative protein effect: *BRCA1* c.5309G>T and c.5309_5310delinsTT that both result in Gly 1770 to Val substitution (a splice defect was excluded for both of these variants); *BRCA2* c.68–?_316+?del (corresponding to exon 3 deletion), c.156_157insAlu, c.316+1G>T, c.316+2T>C, c.316+4del, c.316+5G>A, and c.316+5G>G that all lead to the complete loss of the in-frame exon 3.

Some variants located in the same codon but resulting in different amino acid changes were classified in different classes, e.g., three variants in *BRCA1* 1706 codon located in BRCT1 domain: *BRCA1* c.5116G>A (p.Gly1706Arg), c.5117G>A (p.Gly1706Glu), and c.5117G>C (p.Gly1706Ala) were classified as PV, LPV, and BV, respectively.

Two *BRCA2* variants were systematically identified in *cis*: *BRCA2* c.927A>G (p.Ser309=) and c.7759C>T (p.Leu2587Phe), classified as BV and LBV, respectively.

Comparison of COVAR and ACMG/AMP classification

We compared the COVAR-classification results with ACMG/AMP scoring by using two bioinformatics tools, Varsome and InterVar (Tables 1 and S3).^{42,43} All variants could be compared with Varsome, but only 82 of the 101 COVAR classified variants could be assessed with InterVar, as InterVar does not process all variant types (indels, LGRs, intronic variants). Among the 34 variants classified as PV by the COVAR study, only 4 (11.8%) variants were classified in this category by Varsome and none by InterVar. As cosegregation data can be included in Varsome, we subsequently compared our results for the 34 COVAR-classified PVs with Varsome integrating cosegregation data. The number of Varsome-classified PVs increased from 4 (11.8%) to 18 (52.9% of the COVAR-classified PVs). The other COVAR-classified PVs were classified as LPV by Varsome or InterVar or remained VUSs. At the other extreme, among the 51 variants classified as benign by the COVAR study, two were classified similarly by Varsome, and only one was classified as benign by InterVar. The majority of the other COVAR-classified BVs remained VUSs or LBVs with both tools. In addition, it should be noted that nine COVAR-classified BVs were classified as LPVs by Varsome or InterVar.

Discussion

COVAR classification or the power of cosegregation analysis

Among the 653 *BRCA1/2* variants selected for the COVAR study, 101 (15%) variants identified in 1,624 families had been classified at the time of this first report; 38% were classified as PVs or LPVs and 62% were classified as BVs or LBVs. Most of the selected and classified VUSs were missense variants, but other variant types were also classified: in-frame indels, LGRs, and synonymous and intronic variants. Among the 101 classified variants, 5 had never been previously reported, 13 were new for ClinVar and not reviewed in BRCAexchange, and 79 (78.2%) were present but not reviewed in the BRCAexchange database. Twenty-three (32.7%) and 59 (58.4%) variants were also reported in ClinVar as VUSs or “conflicting interpretation,” respectively (Table S3).

A very wide range of cosegregation LR values was observed (1.4E+23 to 9.4E−08), illustrating the power of cosegregation analyzes in variant classification provided that sufficient data have been collected. No other measurement of association between VUSs and cancer was more powerful in our dataset (Tables 1 and S3). Indeed, 66 of the 101 (65%) variants classified by COVAR would have remained VUSs without cosegregation data.

Specific variants

Combining data for different genetic variants with a common protein impact allows the classification of a greater number of variants by increasing the statistical power of cosegregation. However, mRNA analyses must be performed before combining variant data in order to ensure that all variants have a similar splicing profile. We confirmed that the two *BRCA1* variants leading to the amino acid Gly1770 to Val substitution did not result in a splicing defect. Moreover, in order to classify the *BRCA2* exon 3 deletion, we combined only *BRCA2* variants leading to complete loss of exon 3.⁴⁴

Conversely, variants located on the same codon but leading to different amino acid changes were classified as pathogenic or benign, e.g., *BRCA1* variants located on codons 1691 or 1706. The class of each *BRCA1* 1691 or 1706 codon variant was concordant with previously published functional assays.^{45–49} Similarly, there was a good correlation between our classification of *BRCA2* missense variants and functional assay results when available.^{50–52}

Prior probability

Although cosegregation analysis is a powerful variant classification tool, the multifactorial model of pathogenicity that includes cosegregation data may have a number of limitations, especially the major influence of PriorP on posterior probability, as the better concordance observed between our classification and Align-GVGD prediction than SIFT or PolyPhen-2 prediction could be explained

by the high weight of PriorP, because the Align-GVGD prediction score was used to determine PriorP. However, interestingly, some missense variants predicted as pathogenic by Align-GVGD were classified as benign and some variants predicted as benign were classified as pathogenic after cosegregation analysis. Lindor et al. pointed out that PriorP should not be used alone but combined with other arguments such as cosegregation, in a multifactorial model.¹⁸ Re-evaluation of these PriorP is ongoing.⁴¹

An example of the impact of PriorP on variant class is the observation for the two variants systematically identified in *cis*, *BRCA2* c.927A>G (p.Ser309=) and c.7759C>T (p.Leu2587Phe), classified as BV and LBV, respectively. As all data and consequently all evidence of pathogenicity for these two variants are identical (since they always occur together), the only difference in posterior pathogenicity probability calculation for these variants was their PriorP (C0 versus C15).

Combined LR thresholds to estimate posterior probability

Combined LR thresholds used for classification of variants were those defined by Goldgar et al. in 2004,¹⁷ a combined LR greater than 1,000:1 for PV and lower than 1:100 for BV. The calculation of posterior probability was not performed when combined LR were between these thresholds, to ensure a sufficient level of evidence from observational data. Recent studies used the multifactorial model with prior probability truncated at 0.10 and 0.90 for minimum and maximum prior probability, respectively, which leads to combined LR lower than 0.5 or greater than 2 to reach class 2 or class 4, respectively; in these studies the estimation of posterior probability was not performed only for combined LR between 0.5 and 2.^{11,21} We could have classified 100 additional variants toward causality or neutrality if posterior probability had been calculated outside the range of 0.5–2 instead of the range of 1:100–1,000:1. However, it may lead to variant misclassification because of a low level of observational data and an increased weight of prior probability. This misclassification, especially in the PV or LPV classes, can have clinical consequences leading to inappropriate prophylactic surgery decisions for carriers and unsafe surveillance discontinuation for non-carriers.^{7,53}

Multifactorial model parameters

A last limitation is that the model does not consider the possibility of *de novo* variants and may therefore classify a variant as benign because of the absence of a family history of cancers although it is pathogenic. However, this constitutes a minor limitation, as the *BRCA1/2 de novo* variant rate is estimated to be only 0.3% [0.1%; 0.7%] and *de novo* status should be detected by genetic testing of both parents when available.⁵⁴

Note that the scoring for cosegregation data used in this study was designed for high penetrance variants. Some *BRCA1/2* PVs with moderate penetrance could remain classi-

fied as VUS. This class uncertainty for moderate penetrance variants has been previously reported for the *BRCA1* c.5096G>A (p.Arg1699Gln) PV, which was demonstrated to be associated with intermediate breast and ovarian cancer risks on the basis of the large volume of cosegregation data collected: using the standard multifactorial model for high penetrance variants, the *BRCA1* c.5096G>A (p.Arg1699Gln) would have remained classified as a VUS; Spurdle et al. integrated in the model a lower level of *BRCA1* variant penetrance so this variant could be classified as pathogenic.^{55,56} Adaptation of the cosegregation statistical model developed by Thompson et al., modifying the value of cancer risks and introducing polygenic risk scores for breast cancer risk and subsequent ovarian cancer risk, should improve the classification of variants with moderate penetrance.⁵⁷ Adaptation of the statistical model will be no doubt required for VUSs of genes such as *CHEK2* and *ATM* that are associated with moderate risk. The multifactorial likelihood model of pathogenicity could also be improved by incorporating a complementary LR to the LR-pathology based on tumor status of a germline variant, as somatic loss of the wild-type allele would suggest pathogenicity and conversely loss of variant non-pathogenicity (S.M.C., E.R., and D.S.-L., unpublished data).⁵⁸ A parameter called somatic to germline ratio (SGR) has recently been used for *TP53* variant classification.⁵⁹ Increasing indications for *BRCA1/2* gene analyses of tumors in order to guide PARPi therapy, thereby increasing the information regarding the wild-type allele, will allow the introduction of this information into the likelihood model.

ACMG/AMP classification

In 2015, the ACMG/AMP published general guidelines for gene variant classification based on various types of evidence, including population data, bioinformatics prediction tools, functional data and, when available, cosegregation data.⁶⁰ We compared our results to the ACMG/AMP classification using Varsome and InterVar, the bioinformatics tools that were developed to standardize scoring. Many discrepancies were observed between our classification and the ACMG/AMP classification and between variant scoring by the two tools. This observation was expected as recent studies already showed discrepancies between classification based on the multifactorial model used in our study and ACMG/AMP classification.^{61,62} Most variants classified as pathogenic in our study remained classified as LP or VUSs while most BVs remained LB or VUSs. The greatest classification discrepancy concerned the 12 COVAR-classified BVs that were classified as LPVs by Varsome or InterVar. Three of these 12 variants were in-frame amino acid deletions classified as LPVs by Varsome. The weight applied to this variant type may be excessive in the ACMG/AMP scoring. Six other COVAR-classified BVs were also classified as LPVs by InterVar because it took into account reporting of the variant as pathogenic in public databases with no available evidence of pathogenicity as a supporting element for pathogenicity. Uncurated public database classification should not be used as a classification criterion to avoid misclassification

based on insufficient data. Counting meiosis has been proposed for ranking of supporting evidence of pathogenicity based on cosegregation data in the ACMG/AMP classification.^{60,63} It allowed us to input cosegregation data in the Varsome-tool after counting meiosis, resulting in better concordance for our 34 classified PVs, increasing the number of Varsome-classified PVs from 4 (11.8%) to 18 (52.9%). We used the same levels of cosegregation as proposed by Jarvik and Browning in 2016⁶³ to consider cosegregation data as supporting, moderate, or strong evidence of pathogenicity for ACMG/AMP classification. We could not include cosegregation data for comparison of BV classification, as counting meiosis is unable to generate any evidence in favor of a benign effect.⁶⁴ The ACMG/AMP scoring system is globally based on discrete variables with somewhat subjective ranking of evidence. Cosegregation data computed in a quantitative multifactorial model, as performed in this study, allow more robust classification.

Functional assays

A large-scale functional assay based on cell survival after BRCA1 disruption has been recently developed to classify nearly 4,000 known or possible *BRCA1* variants located in RING and BRCT domains.⁴⁷ All variants were generated by saturation genome editing with CRISPR-Cas9 system in human haploid cell lines, allowing an identical genomic background for all tested variants. This functional assay is very promising: it gives accurate results for a large number of variants. However, because the reporting test is cell survival, a surrogate marker of the BRCA1 role in DNA repair by homologous recombination, other BRCA1-altered functions could be missed. Moreover, *in vitro* data alone should not be used as the basis for medical advice until they have been clinically validated.⁶⁵ Such functional assays can be used to prioritize variants selected for clinical and genetic studies such as the COVAR study. A “LR functional assay” would be helpful to implement functional data in the multifactorial model but there is no international consensus yet on which assays and which weights should be used.

Artificial intelligence

Finally, artificial intelligence (AI) is being developed for more and more clinical applications including genetic variant classification. At the present time, algorithms are being developed to integrate literature data, gene and protein structure, and species alignment (Corona-AI, REVEL,...). Using machine-learning on the ClinVar *BRCA1/2* variant database, Favalli et al. developed an interesting variant classification algorithm. However, AI variant classification still requires critical examination by geneticists, especially with regard to the quality of the data on which AI tools are trained.⁶⁶

Conclusion

In conclusion, the first series of results of the COVAR study show that cosegregation is a highly powerful tool for

BRCA1/2 variant classification. Cosegregation studies, i.e., linkage studies, for VUS classification may be as useful as they were 25 years ago for the identification of a large of disease-related genes, including *BRCA1/2*. However, in order to be feasible, such studies must be organized by clinical and laboratory networks at a nationwide or even worldwide level such as ENIGMA. Although the initiation and organization of these studies requires considerable effort, the growing number of available genetic tests results in an increasing number of families sharing a particular variant, thereby increasing their power. Here we demonstrate that variant cosegregation studies, i.e., “linkage studies 2.0” for reference to the linkage studies which led to the localization of the *BRCA1* and *BRCA2* genes 30 years ago,^{67,68} are a powerful tool for the classification of variants in the *BRCA1/2* breast-ovarian cancer predisposition genes.

Data availability

The dataset in support of the current study has not been deposited in a public repository because it is composed of patient data including pedigrees which are indirectly identifying. The data are available on request from the corresponding author. A large part of the variants have been deposited in BRCAShare (<http://www.umd.be/>), and all variants will be annotated in the upcoming FrOG (French OncoGenetics) database, as listed in Table S4 and all material and data supporting this study is included within the manuscript (or by request to the authors if this is the case).

Supplemental information

Supplemental information can be found online at <https://doi.org/10.1016/j.ajhg.2021.09.003>.

Acknowledgments

This article is dedicated to the memory of Olga Sinilnikova. S.M.C., L. Golmard, M. Léone, F.D., M. Guillaud-Bataille, F.R., E.R., N.D., A. Buisson, N. Basset, M.S., P.V., C. Garrec, M.P., M. Gay-Bellile, T.N.N.T., O. Caron, C. Lasset, A. Remenieras, N.B.-K., and L. Castéra are members of the variant classification working group. The authors thank the clinicians and biologists (Table S6) involved in the UGG. This work was funded by grants from the French National Cancer Institute (2013-1-BCB-01-531_ICH-1) and the French Ligue contre le cancer 92. The COVAR study is supported by the GENETICANCER and “Cercle Olympique” associations and AstraZeneca.

Declaration of interests

D.S.-L. and the Institut Curie have received honoraria for her participation in education meetings organized by AstraZeneca or Tesaro. The remaining authors declare no conflict of interest.
