Abstract: Cholangiocarcinomas are rare tumors originating at any point along the biliary tree. These tumors often pose significant challenges for diagnosis and treatment, and often carry a poor prognosis. However, in recent years, studies have identified significant molecular heterogeneity with up to 50% of tumors having detectable mutations, leading to the guideline recommendations for molecular testing as part of the diagnostic workup for these tumors. In addition, better classification of these tumors and understanding of their biology has led to new drugs being approved for treatment of this resistant tumor. This manuscript will provide a comprehensive review of the epidemiology, risk factors, diagnostic approach, molecular classification, and treatment options for patients with advanced cholangiocarcinomas.

Keywords: cholangiocarcinoma, chemotherapy, targeted therapy, molecular, detectable mutations

Introduction

Cholangiocarcinomas (CCA) are a rare, heterogeneous group of malignancies originating from biliary tract epithelium. They can emerge at any point along the biliary tree and are classified accordingly as intrahepatic or extrahepatic depending on their anatomical location. Intrahepatic cholangiocarcinomas (iCCA) are located within the hepatic parenchyma proximal to segmental bile ducts, while extrahepatic cholangiocarcinomas (eCCA) can occur anywhere along the extrahepatic bile duct (Figure 1).¹ Although these tumors differ in clinical presentation and staging, they are generally aggressive and most often diagnosed in advanced stages, resulting in a very poor prognosis.

Epidemiology and Risk Factors

Cholangiocarcinomas represent about 3% of gastrointestinal malignancies in the United States, with approximately 1–2 cases per 100,000.² Incidence of CCA varies throughout the world, reflecting the geographic distribution of risk factors. In the US and Europe, the main identifiable risk factors are fibropolycystic disease (e.g., choledochal cysts) and Primary Sclerosing Cholangitis (PSC). In Asia, the leading identifiable cause is chronic infection with liver flukes. Other identified risk factors include hepatolithiasis, chronic liver disease (e.g., viral hepatitis, cirrhosis), alcohol, smoking, obesity, fatty liver disease, diabetes, inflammatory bowel disease, and certain toxic exposures (e.g., dioxin, thorotrast). Several genetic conditions have

Figure 1 Cholangiocarcinoma subtypes.

also been associated with CCA, including Lynch syndrome, BAP-1 tumor predisposition syndrome, cystic fibrosis, and biliary papillomatosis. However, a specific risk factor cannot be identified in approximately 90% of patients with CCA.^{3–8}

CCA is more common in men than women, which may be associated with the higher incidence of PSC in men. In PSC patients, CCA is generally diagnosed at a younger age (30–50 years) and is often unresectable.⁹ Otherwise, the incidence generally increases with age with the average age of diagnosis between ages 60–70.^{10,11} Surveillance, Epidemiology, and End Results program (SEER) data have shown a slight increase in the incidence of eCCA and a dramatic increase in the incidence of iCCA (4.4% over the last decade), which has also been noted across North America, Europe, Asia, and Australia over the last 20 years.^{12,13} This may be due to changes in classification and increases in certain risk factors. Some have suggested this trend reflects improvements in diagnosis. However, there has not been a corresponding increase in diagnosis of smaller lesions or earlier stage disease; rather, mortality rates have been increasing worldwide.^{5,10}

Tumor Subtypes

About 90% of CCAs are extrahepatic (50% perihilar, 40% distal) and 10% are intrahepatic. Perihilar tumors (pCCA), also known as Klatskin tumors, occur at or near the confluence of the right and left hepatic ducts, and are the most common type of CCA. Distal cholangiocarcinomas (dCCA) occur along the common bile duct and proximal to the ampulla of Vater. Intrahepatic CCA is further classified by morphologic subtypes, which reflect the tumor growth pattern – mass forming, periductal, intraductal, or mixed.^{14,15} Histologically, over 90% of CCAs are adenocarcinomas.^{1,16,17} Rare histological variants include mucinous, adenosquamous, squamous,

clear cell, sarcomatoid, and lymphoepithelial carcinomas (Table 1).¹⁸

Clinical Presentation, Diagnosis, Challenges, and Prognosis

Diagnosis of CCA is clinically challenging due to its anatomic location. In its early stages, CCA is usually asymptomatic and generally found due to abnormal liver function tests or incidentally on imaging as an isolated intrahepatic mass. Once symptoms occur, they are usually non-specific or related to biliary obstruction, at which point nearly 70% of patients have unresectable, locally advanced, or metastatic disease.^{19,20}

Patients with eCCA generally present with symptoms of biliary obstruction, such as jaundice, pruritus, dark urine, and clay-colored stool. Abdominal pain, hepatomegaly, weight loss, and fever are also common signs and symptoms. In contrast, patients with iCCA often present late with non-specific symptoms, such as weight loss and dull right upper quadrant abdominal pain; biliary obstruction and associated symptoms are uncommon as these tumors do not usually involve the common bile duct. Metastasis usually occurs in local lymph nodes, the peritoneum, and liver. Less commonly, CCA can metastasize to the lungs and bone.²¹ Brain metastases have also been reported with CCA, though they are very rare.^{21,22}

Initial workup includes liver function tests, which usually have a cholestatic pattern with elevated bilirubin, alkaline phosphatase, and gamma-glutamyltransferase. Carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) levels should be obtained as a baseline; however, these are non-specific and are not used to confirm the diagnosis. Moreover, CA 19-9 may be falsely elevated in the setting of jaundice.²³ Used together, these tumor markers can be helpful for monitoring treatment effect.

Table I Features of Subtypes of Cholangiocarcinoma

Feature	Intrahepatic Cholangiocarcinoma (iCAA)	Extrahepatic Cholangiocarcinoma (eCCA)	
		Perihilar (pCCA)	Distal (dCCA)
Percent of CCA	10–20%	50–60%	20–30%
Location	Intrahepatic bile ducts	Left, right common hepatic ducts	Common bile duct
Growth pattern	Mass forming or peri-ductal infiltrating or intraductal growth	Peri-ductal infiltrating or intraductal growth	
Risk factors	Risk factors seen more commonly in eCCA: <ul style="list-style-type: none"> • Cholelithiasis • Chronic Pancreatitis • Primary Sclerosis Cholangitis Risk factors seen more commonly in iCCA: <ul style="list-style-type: none"> • Cirrhosis • Viral Hepatitis (HBV, HCV) • Liver Flukes (<i>Opisthorchis viverrini</i>, <i>Clonorchis sinensis</i>) • Alcohol consumption • Asbestos General Risk factors: <ul style="list-style-type: none"> • Diabetes Mellitus type 2 • Obesity • Cigarettes smoking 		
Presentation	Weight loss, abdominal pain, nonspecific symptoms	Biliary obstruction, jaundice, abdominal pain, weight loss	
Detectable genetic abnormalities (* = FDA-approved targeted therapy)	FGFR Alterations (10–20%)* IDH1 Mutations (15–20%)*	KRAS mutations (30–45%) ERBB2 (HER2) and ERBB3 alterations (10–15%)	
	BRAF alterations (3–5%) Homologous Recombination Deficiency – DNA Repair Genes (<i>ATM</i> , <i>BRCA</i> , <i>PLAB2</i> , <i>BAP1</i> , <i>ARID1A</i> , etc) (5–15%) MSI-high/dMMR (2–5%)*		

Alpha-fetoprotein (AFP) testing may be helpful to distinguish iCCA from hepatocellular carcinoma (HCC) in patients with chronic liver disease. Serum IgG4 testing should be considered in patients with possible eCCA to evaluate for IgG4-related cholangiopathy.²⁴

For patients presenting with these symptoms or imaging findings concerning for CCA, multiphase contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis is indicated for diagnosis, staging, and assessment of resectability.²⁵ CT imaging of the chest is also recommended to complete staging. Positron emission tomography (PET) is not routinely used, as it has limited sensitivity in detecting small, non-metastatic tumors as compared to CT and MRI; however, there is some

evidence that it may be most useful for assessing lymph node and major vessel involvement, distant metastases, and recurrent disease in cases where CT and/or MRI are equivocal.²⁶

In addition to CT and MRI imaging, magnetic resonance cholangio-pancreatography (MRCP) allows for non-invasive evaluation of the biliary tree, tumor spread, and local invasion; however, it can be difficult at times to differentiate between benign and malignant strictures.²⁷ In such cases and with more distal lesions, endoscopic retrograde cholangiopancreatography (ERCP) can be used for tissue sampling via brush cytology and biopsies, and to alleviate an obstruction if therapeutic intervention is necessary.^{24,28} When ERCP is unsuccessful or does not sufficiently visualize the biliary tree, percutaneous hepatic

cholangiography (PTC) can be performed to sample more proximal and perihilar lesions.²⁵ Endoscopic ultrasound (EUS) is useful in localizing strictures and allows for more accurate fine needle aspiration (FNA), including regional lymph node sampling; however, it is still limited by sampling error and limited ability to visualize proximal extrahepatic or peripheral lesions. For that reason, EUS is frequently combined with ERCP; together, EUS-ERCP has increased accuracy for diagnosis than either alone.^{25,29,30} Peroral cholangioscopy (POCS), which is performed during ERCP, can also be useful for establishing a diagnosis in indeterminate strictures. It is a safe adjunctive diagnostic technique that allows for direct visualization of the biliary tract and has a higher diagnostic yield than biopsies with ERCP alone.^{31,32}

Notably, brush cytology has a high specificity but is limited by low sensitivity, particularly in patients with significant strictures, such as patients with PSC. Fluorescence in situ hybridization (FISH) analysis is now routinely used as part of the diagnostic evaluation as it significantly increases the sensitivity of cytology.^{33–37} Biopsy is usually not necessary for patients with localized disease undergoing resection. Patients with non-metastatic disease must be evaluated for resection or liver transplant prior to biopsy or biliary drainage, especially those with pCCA, in whom trans-peritoneal biopsy can lead to tumor seeding and may preclude them from transplantation.³⁸

Diagnosis of eCCA can be particularly challenging due to biliary strictures, difficulty identifying a lesion on cross-sectional imaging, and potential complications with invasive procedures, including cholangitis and tumor seeding within the biliary tree.^{33,39} In general, the degree of biliary obstruction can often present a difficult clinical challenge, limiting the options for therapeutic intervention, as well as the use of chemotherapy and radiation.

Staging

Staging of CCA is necessary for determining the extent of local invasion and resectability, as well as nodal involvement and distant disease. In recent years, significant changes have been made to the staging criteria for CCA. The 7th edition of the American Joint Committee on Cancer (AJCC) Staging Manual included the first unique staging classifications for iCCA, which was previously staged as HCC. This edition also introduced separate staging systems for pCCA and dCCA, which were previously grouped together as eCCA. The most recent 8th edition, published in 2017, further expanded the tumor (T)

category in iCCA staging to include more information on size and degree of local invasion. Several studies have subsequently demonstrated that this edition allows for better prognostic stratification.^{40–42} The 8th edition also includes more detail about depth of tumor invasion for dCCA and lymph node involvement for pCCA.⁴³

Prior to these AJCC staging editions, two independent staging systems were developed for pCCA. The modified Bismuth-Corlette staging system classifies pCCA into four patterns based on extent and location of hepatic duct involvement alone. It does not include other clinical or pathologic features such as vascular invasion, lymph node involvement, or metastatic disease.⁴⁴ Unlike the AJCC and modified Bismuth-Corlette systems, the Blumgart staging system is used for preoperative staging and has been shown to predict resectability and likelihood of metastatic disease.⁴⁵ Those tumors that are classified as unresectable are often treated initially with systemic chemotherapy similar to that used in the metastatic setting, with the option for localized treatment in the setting of response.

Molecular

Cholangiocarcinomas demonstrate significant molecular heterogeneity and up to 50% have detectable mutations, with available or emerging therapeutic targets.²⁰ Studies have identified differences in the mutational profiles of iCCA and eCCA, with implications on therapeutic interventions and prognosis. For this reason, molecular testing is recommended at the time of diagnosis of these tumors in order to inform therapeutic approach.⁴⁶ Significant variability is found with regard to mutation frequencies described in the literature, which reflects differences in patients' gender, ethnicity, geography, and risk factors, as well as different identification methods and tumor classification between studies.¹

In recent years, iCCA has been identified as a complex group of tumors that carry unique molecular abnormalities, some of which have new therapeutic implications. Specifically, mutations, fusions, and alterations in *IDH1*, *IDH2*, *FGFR1*, *FGFR2*, *FGFR3*, Eph receptor 2 (*EPHA2*), *BAP1*, and *MET* genes are found more commonly in iCCA.⁴⁶ In perihilar and distal tumors, genetic alterations in *ERBB2*, *ARID1B*, *ELF3*, *PBRM1*, cAMP Dependent Protein Kinase (*PRKACA*, *PRKACB*) are more prevalent.^{47,48} Mutations in *KRAS*, *BRAF*, *PIK3CA*, and *CDKN2A/B* are found with nearly equivalent frequency in both intrahepatic and extrahepatic subtypes.^{20,49}

Approximately 13% of iCCA carry an Isocitrate Dehydrogenase (*IDH1*, *IDH2*) mutation, which is associated with a poor prognosis. More than 65% of these mutations are seen in women and are almost never found in eCCA (<1%).⁵⁰ Activating Fibroblast Growth Factor Receptors -2 (*FGFR2*) fusions occur in about 20% of iCCA and may be associated with a favorable prognosis. Mutations in Chromatin Remodeling Genes *BAP1* and *BRAF* are also more common in iCCA.^{8,19,29} On the other end, *ERBB2* overexpression is more common in eCCA and gallbladder cancer, occurring in 15–20% of cases. Mutations in *KRAS* and *TP53* have also been identified more commonly in eCCA, but can also be found in iCCA, especially those derived from large bile ducts.^{8,20,29} *NTRK* fusions are found in <1% of patients with biliary tract cancer, but when identified carry significant therapeutic implication.

The National Comprehensive Cancer Network (NCCN) guidelines recommend molecular testing as well as testing for microsatellite instability (MSI) or mismatch repair (MMR) as part of the diagnostic workup for both iCCA and eCCA.⁵¹ Microsatellite instability (MSI - high) or mismatch repair deficiency (dMMR) is found in 2–3% of biliary tract cancers.²⁹ The finding of dMMR CCA has therapeutic implications regarding the use of immunotherapy. In addition, these patients, as well as those with a family history suggestive of BRCA1/2 mutation carriers, should be referred to a genetic counselor and considered for germline testing. Notably, 1–7% of all biliary tract cancers harbor a germline or somatic BRCA mutation.^{19,52} Tumor Mutational Burden (TMB) has also been identified as a predictor for response to immunotherapy and thus, should be routinely tested in these cases.⁵³

Recently, the European Society of Medical Oncology (ESMO) Precision Medicine Working Group issued recommendations for the use of multi-gene next-generation sequencing (NGS) in patients with metastatic cancers, including CCA.⁵⁴ In CCA, they recommend testing for mutations considered to be level I, which are actionable mutations with a validated targeted therapy, stating that larger panels are unlikely to be cost-effective. The level I mutations according to this group are *IDH1*, *FGFR2*, and *NTRK*. As noted, the NCCN guidelines recommend molecular testing in patients with unresectable or metastatic CCA but does not specify which mutations should be tested for or which platforms are appropriate.⁵¹ Some advocate for testing in early-stage CCA as well, as this may guide future treatment considering the very high rate

of recurrent disease following resection.⁵⁵ Based on the current data, we would recommend using comprehensive NGS molecular profiling that includes testing for *IDH1*, *FGFR2*, *NTRK*, TMB, MSI/MMR, *KRAS*, *TP53*, *BRCA 1/2*, *BRAF*, *CDKN2A/B*, *BAP1*, *PIK3CA*, and *HER2*. Notably, there are data demonstrating a high failure rate of tissue biopsies in patients with CCA, with over 26% of samples inadequate for molecular profiling.⁵⁶

Prognosis

Surgical resection remains the only potentially curative treatment for CCA; however, 70% of patients present with advanced stage disease and only 25% of patients with localized disease are candidates for resection.²⁰ The 5-year overall survival (OS) in patients following resection is 25–35% due to high relapse rates (68–86%).¹⁹ For patients with advanced, unresectable disease, the median OS is 11.7 months²⁰ and poor performance status (ECOG ≥ 2) is the strongest prognostic factor.⁵⁷

Treatment of Advanced Cholangiocarcinoma

For patients with unresectable or metastatic CCA, systemic therapy is offered with palliative intent. The landscape of therapeutic options has been rapidly evolving over the past decade with the advent of novel targeted therapies. While combination chemotherapy remains the standard frontline option for such patients, an improved understanding of the molecular characteristics of CCA has allowed for the identification of therapeutic targets.

Systemic Therapy

CCA has been associated with a poor overall prognosis which can be marginally improved with standard cytotoxic chemotherapy (Table 2). Prior phase 2 trials have demonstrated response rates of 10–34% with 5-fluorouracil (5-FU), and 17–36% with single-agent gemcitabine.⁵⁸ Several combination regimens have been investigated and have shown response rates of 19–24% with 5-FU/platinum therapy, 25% with gemcitabine/capecitabine combination, 50% with gemcitabine/oxaliplatin, and 30% with gemcitabine/nab-paclitaxel regimens.^{58,59}

The landmark ABC-02 phase 2 trial published in 2010 established the combination of gemcitabine with cisplatin as the standard frontline therapy for advanced CCA. In this study of 410 patients with locally advanced/metastatic hepatobiliary tumors, patients in the combination therapy arm achieved an

Table 2 List of Completed and Ongoing Clinical Trial Evaluating Selected Targeted Agents in CCA

Target	Agents	Available Data from Completed Trials	Ongoing
FGFR (FGFR-2 fusion/re- arrangement)	Pemigatinib*	Phase 2 FIGHT 202 trial: ORR - 35.5% mOS - 21.1 mos	FIGHT-302 – [NCT03656536] Phase 3 – front line vs gemcitabine + cisplatin

Abbreviations: ORR, objective response rate; mPFS, median progression free survival; mOS, median overall survival; ATR, ataxia telangiectasia and RAD3 related (ATR) kinase.

OS advantage of 3.6 months as compared to treatment with single-agent gemcitabine (median OS 11.7 months in the combination arm vs 8.1 months in the gemcitabine arm).⁶⁰ With regard to response rates, 81.4% of patients in the combination arm had a complete/partial response or stable disease, while 71.8% of patients who received single-agent gemcitabine achieved such outcomes.^{60,61} A phase 2 trial of 60 patients investigating the efficacy of the addition of nab-paclitaxel to gemcitabine/cisplatin demonstrated a similar disease control rate of 84% with an improved median OS of 19.2 months.⁶² Based on this data, a phase 3 trial is ongoing using this triplet combination in the frontline setting [NCT03768414]. Similarly, a phase 3 study comparing a combination of gemcitabine, cisplatin, and an oral

fluoropyrimidine (S1) to the gemcitabine/cisplatin backbone showed a small but statistically significant improvement in median OS (13.6 months with the triplet therapy vs 12.6 months with gemcitabine/cisplatin).⁶³ A recent report from the AMEBICA PRODIGE 38 study did not show any benefit with the use of 5-FU/irinotecan/oxaliplatin (FOLFIRINOX) over gemcitabine/cisplatin in the front-line setting (median OS 11.7 months vs 14.3 months, respectively, [95% confidence interval (CI) 11.3–16.5]).⁶⁴

After progression on frontline gemcitabine/cisplatin therapy, 5-FU-based systemic regimens remain the current standard of care, though targeted therapies are evolving in this space as discussed below. The phase 3 ABC-06 trial studying the efficacy of second-line therapy with 5-FU/oxaliplatin

(FOLFOX) showed that active symptom control in addition to FOLFOX improved OS when compared to active symptom control alone (median OS 6.2 months in the combination arm vs 5.3 months in the active symptom control arm).⁶⁵ There are limited data for the use of 5-FU with irinotecan (FOLFIRI) in the second-line setting. A small retrospective study including 12 patients treated with this regimen showed a median OS of 5 months.⁴⁹ Recently, Yoo et al presented the results of the Korean NIFTY study which randomized patients to 5-FU/Leucovorin with or without liposomal irinotecan after progression on gemcitabine/cisplatin. The study demonstrated improvement in progression-free survival (PFS) and OS with the addition of liposomal irinotecan (PFS 7.1 months vs 1.4 months, HR 0.56, $p=0.0019$; OS 8.6 months vs 5.5 months, HR 0.68, $p=0.034$).⁶⁶

Role of Radiation Therapy and Liver Directed Therapy

At present, radiation is only used for palliative purposes for patients with unresectable or metastatic CCA for treatment of painful metastatic sites or in attempt to achieve local control for locally advanced tumors. Patients with liver predominant disease who have partial response or stable disease following 6 months of chemotherapy may be considered for liver directed therapy with trans-arterial radioembolization (TARE) or yttrium-90 (Y-90), although prospective data supporting this approach are limited.⁶⁷ One systematic review of Y-90 treatment for iCCA reported a median OS of 15.5 months with 28% of patients having partial radiographic response and 54% with stable disease.⁶⁸ The use of external beam radiation or stereotactic radiation (SBRT) for iCCA has been sparsely evaluated. A study by Hong et al reported a 2-year OS rate of 46.5% in 37 patients with iCCA who received high-dose hypofractionated proton therapy.⁶⁹ The ongoing ABC-07 study is a multicenter clinical trial evaluating the addition of SBRT to 6 cycles of gemcitabine/cisplatin versus 8 cycles of chemotherapy only for localized unresectable CCA. The use of hepatic arterial infusion of chemotherapy was also tested in the setting of unresectable localized iCCA in a small phase 2 trial, showing 84% of patients having disease control at 6 months, with a median OS of 25 months.⁷⁰

Immunotherapy

The use of immunotherapy with checkpoint inhibitors has been tested in advanced CCA with disappointing results. The phase 2 KEYNOTE-158 trial which studied the

efficacy and safety of pembrolizumab (an anti-PD-L1 monoclonal antibody) in refractory solid tumors included 104 patients with biliary tract primary tumors. The study found an overall response rate of 5.8% and a median OS of 9.1 months in these patients. Response rates were slightly higher for patients with PD-L1 combined positive score (CPS) ≥ 1 ; these patients had an overall response rate of 6.6%. However, this did not translate into improved overall survival advantage.⁷¹

Currently, immunotherapy is only approved for CCA patients with dMMR tumors based on a study evaluating the efficacy of pembrolizumab in dMMR tumors. The study was comprised of patients with 12 different tumor types including CCA and reported a 53% objective response rate with 21% of patients achieving a complete response.⁷² This study led to the site agnostic approval of pembrolizumab for dMMR tumors. Similarly, CCA tumors with high TMB would be candidates for immunotherapy based on a similar agnostic approval.⁷² Ongoing trials are attempting to establish the role of immunotherapy in combination with chemotherapy in this disease such as ABC-09 study [NCT03260712] evaluating the combination of pembrolizumab with gemcitabine/cisplatin.⁷³ Similarly, the TOPAZ-1 study is a phase 3 trial testing the combination of gemcitabine/cisplatin with or without durvalumab, an anti-PD-L1 monoclonal antibody [NCT03875235].⁷⁴

Targeted Therapy

The advent of tumor genomic sequencing and the development of targeted therapeutics directed at mutations at the molecular level has greatly expanded the therapeutic arsenal for biliary tract tumors.⁴⁷ In fact, there are data to suggest that as many as 38.9% of patients with biliary tract cancers may harbor a potentially targetable mutation.⁷⁵ Other studies have shown that 11–15% of patients with biliary tract cancers have mutations in cancer risk genes, and experts have suggested that routine germline genetic testing may therefore be advantageous from a clinical standpoint in the care of these patients.⁷⁶

Several trials have been completed investigating the role of targeted therapies after progression on standard chemotherapy. Notable trials that have led to FDA approval of targeted agents include the ClarIDHy and FIGHT-202 trials targeting *IDH1* and *FGFR2*, respectively.^{77,78} The phase 3 ClarIDHy trial investigating the use of ivosidenib in patients with *IDH1*-mutated CCA who had previously progressed on up to 2 prior chemotherapeutic regimens found that patients

derived a substantial PFS benefit of 6.9 months as opposed to 1.4 months in the placebo arm (HR 0.37, 95% CI 0.25–0.54, $p < 0.0001$). Median OS was 10.8 months for ivosidenib versus 9.7 months for placebo (HR 0.69, 95% CI 0.44–1.10), which was not statistically significant due to cross over of patients in the control arm.⁷⁷ Additional agents are under development in this space including IDH305 (NCT02381886), FT-2012 (Olutasidenib) (NCT03684811), BAY-1436032 (NCT02746081), and LY3410738 (NCT04521686).^{79,80} These newer agents may offer treatment options for patients who have progressed on treatment with ivosidenib.

One of the most studied targets in CCA is *FGFR*, with multiple agents under evaluation for management of patients with *FGFR2* fusion/rearrangement (Table 2). The phase 2 FIGHT-202 trial of the selective *FGFR1-3* inhibitor, pemigatinib, in patients with advanced CCA enrolled 3 cohorts of 107 patients with *FGFR2* fusions or rearrangements, 20 patients with other *FGF/FGFR* alterations, and 18 patients with no *FGF/FGFR* alterations who have progressed on at least one line of therapy. Patients with *FGFR2* fusions/rearrangements demonstrated a 35.5% objective response rate (ORR), while no responses were seen in the other cohorts. Within this group, a PFS of 6.9 months was seen and median OS was noted to be 21.1 months.⁷⁸ Pemigatinib is now approved by the FDA for the treatment of patients with advanced iCCA with *FGFR2* fusion in the second-line setting. Recently, data from the FOENIX-CCA2 phase 2 study testing the *FGFR* inhibitor, futibatinib, in patients with advanced CCA. The study enrolled 103 patients with iCCA harboring *FGFR2* fusions/rearrangements that progressed on at least one prior line of therapy and reported an ORR of 37.7%, disease control rate of 82%, and median PFS of 7.2 months.⁸¹ Based on these data, the FDA granted breakthrough therapy designation to this agent that is now added to the treatment arsenal. Infigratinib (BGJ398) is another *FGFR* inhibitor that is currently in clinical trials.⁸² The results of the phase 2 trial with infigratinib with 108 patients with *FGFR2* fusions/rearrangements were recently presented, demonstrating an ORR of 23.1%, median PFS of 7.3 months, and median OS of 12.2 months.⁸³ Based on these results, infigratinib has been recently approved for use in the second-line setting.

Initial reports are now emerging of an acquired resistance to these inhibitors, often associated with secondary *FGFR2* kinase domain mutations. Goyal et al reported four cases of patients who responded to futibatinib

following progression on other *FGFR* inhibitors.⁸⁴ These reports suggest the potential benefit of sequencing these agents and evaluation of acquired mutations using circulating tumor DNA (ctDNA) at the time of disease progression. These agents are now being tested in large randomized clinical trials in the front-line setting in comparison to standard chemotherapy – FIGHT-302 trial (pemigatinib) [NCT03656536], PROOF trial (infigratinib) [NCT03773302], FOENIX-CCA3 trial (futibatinib) [NCT04093362]. Multiple additional agents are under development at various stages for tumors harboring an *FGFR* alteration (Table 2) offering the promise of multiple treatment options for these patients.

Like *FGFR* and *IDH*, *NTRK* fusion-directed therapy is also considered standard of care for eligible patients. Three separate phase 1 or 2 trials investigating the use of entrectinib in patients with advanced or metastatic cancer with *NTRK* fusions across 19 tumor types showed a cumulative 57% response rate with 7% of patients achieving a complete response.⁸⁵ Larotrectinib was evaluated in a phase 1/2 study of patients with malignancies harboring *TRK*-fusion and showed a 75–80% response rate.⁸⁶ Although the rate of these mutations is low in CCA tumors, the significant clinical benefit for those patients with tumors harboring this alteration is significant and supports the wide testing of all patients for this molecular marker.

Several studies investigated other molecular targets and pathways central to the pathogenesis of CCA. For example, EGFR- and VEGF-directed therapies have shown limited efficacy in this setting thus far, although importantly, these studies were performed in patients regardless of mutational status.^{87–101} HER2/neu genomic alterations (overexpression or mutations) are also found in some CCAs, more commonly in eCCA, and have shown some response to HER2 blockade with trastuzumab plus pertuzumab or neratinib in early small clinical trials.^{102,103} An ongoing phase 2 study of Trastuzumab Deruxtecan (DS8201) will evaluate the efficacy of this agent in HER2 positive biliary tract cancers.¹⁰⁴

Overexpression of the proto-oncogene MET has been found in 34% of biliary tract cancers, and a small phase 1 trial evaluating the efficacy of a MET inhibitor in combination with gemcitabine reported that 46% of patients had stable disease and 20% achieved a partial response.¹⁹ Treatment with the dabrafenib (*BRAF* inhibitor) and trametinib (MEK inhibitor) has been evaluated for patients with *BRAF* V600E mutated CCA as part of the ROAR basket study showing an ORR of 51% in this

population.¹⁰⁵ Cabozantinib, which inhibits both VEGFR2 and MET, demonstrated significant toxicity with limited clinical benefit.¹⁰⁶ Other tyrosine kinase inhibitors including vandetanib, sorafenib, sunitinib, cediranib, and selumetinib have been studied either alone or in combination with other agents with variable efficacy.¹⁹

While the aforementioned therapies targeting *IDH1*, *FGFR2*, and *NTRK* remain the only interventions currently approved for use, many other targeted therapies have been investigated or are currently under investigation for use in this disease. Table 2 outlines the prominent completed and ongoing trials in this area. Given the heterogeneity of this disease, we should expect to see an evolution in its care, with classification of tumors based on their molecular subtype, and utilizing this to personalize therapy.

Future Directions

Cholangiocarcinomas are highly heterogeneous clinically and molecularly and thus additional research is warranted in order to better define the optimal treatment approach for each subtype. Considering close to 50% of these tumors harbor some identifiable mutation, molecular profiling is recommended for all patients to help guide treatment decisions. While research continues in this disease, we will see additional trials evaluating combination treatments for known targets, as well as new modalities towards novel targets. Furthermore, as we start to use these targeted therapies more widely, resistant mechanisms will emerge and studies guiding us on how to sequence these drugs will be of high importance. In addition, studies are also evaluating new chemotherapy agents and combinations for this cancer such as acelarin (NUC-1031, a first-in-class nucleotide analog with greater intracellular concentration), which is being studied with cisplatin in the phase 1 ABC-08 study and in a phase 3 trial compared to gemcitabine/cisplatin [NCT04163900].¹⁰⁷ There are also ongoing trials investigating the efficacy and tolerability of nanoliposomal irinotecan (Onivyde) with 5-FU as compared to gemcitabine/cisplatin in the front-line setting [NCT03044587] and trifluridine/tipiracil hydrochloride for previously treated advanced CCA [NCT04076761]. The active and vibrant research in this disease allows for increased hope for improved outcomes in patients diagnosed with this aggressive cancer.

Disclosure

Dr Efrat Dotan reports grants and/or personal fees from Pfizer, Lilly, Incyte, AstraZeneca, MedImmune, Boston Biomedical (SDP), QED, and Basilea, outside the

submitted work. The authors report no other conflicts of interest in this work.

Cancer Management and Research

Dovepress

Publish your work in this journal

Cancer Management and Research is an international, peer-reviewed open access journal focusing on cancer research and the optimal use of preventative and integrated treatment interventions to achieve improved outcomes, enhanced survival and quality of life for the cancer patient.

The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/cancer-management-and-research-journal>
