ABSTRACT

Objectives

This is a protocol for a Cochrane Review (intervention). The objectives are as follows:

The aim is to assess, using network meta-analysis (NMA), the effectiveness and safety of interventions for preventing relapse-recurrence of depression in adults in a primary care setting. NMA is a technique for comparing three or more interventions simultaneously in a single analysis by combining both direct and indirect evidence across a network of studies.

The objectives are to:

1. estimate the relative effectiveness of pharmacological, psychological and other interventions to prevent relapse-recurrence, compared with each other and controls (e.g. pill placebo, treatment as usual) on relapse-recurrence outcomes and adverse events;
2. assess the effect of interventions on quality of life outcomes and social and occupational functioning;
3. estimate the relative ranking of included interventions on relapse-recurrence, quality of life, and adverse events;
4. summarise availability and principal findings of eligible economic evaluations.

BACKGROUND

Description of the condition

Depression is now the leading cause of disability worldwide (WHO 2017), with a prevalence in excess of 264 million people globally (GBD 2017). It results in significant morbidity for patients and exerts a high societal and economic cost (Richards 2011). Rather than being a phenotypically homogenous condition (i.e. presenting in the same way in all people who experience depression), clinical presentation and trajectories vary across patients. Some people with depression experience a single, time-limited episode, and no further episodes beyond that (Monroe 2011). Depression for others, however, is a recurrent condition, with patients experiencing the re-emergence (relapse or recurrence) of depressive symptoms after a period of relative wellness (Beshai 2011). There is some evidence to suggest that the risk of relapse and recurrence increases with a greater number of depressive episodes experienced, but decreases as the period of recovery gets longer (Beshai 2011; Solomon 2000). The economic burden of depression is also significantly higher in those who experience a relapse or recurrence compared to those who do not (Gauthier 2019). Therefore, intervening to prevent relapse and recurrence of depression is likely to improve the overall course of illness for individual patients.

Relapse and recurrence of depression are usually defined with respect to three further terms: response, remission and recovery. According to most recent recommendations (Frank 1991; Rush 2006), response is an initial improvement of symptoms, usually after treatment initiation and usually attributable to the treatment. After three weeks of minimal symptoms, a patient can be said to have entered remission. Any subsequent re-emergence of depressive symptoms after this point is described as a relapse (a return to the index episode of depression). If a relapse has not occurred by four months after remission, a patient is said to have entered recovery, after which point any re-emergence of depressive symptoms is termed a recurrence (a new episode of depression separate from the index episode).

The original description of relapse, recurrence and the other change-points by Frank 1991 presented a consensus view of how these terms should be used to facilitate a more consistent application in research. There is also probably a meaningful clinical distinction to be made between a relapse back to the index episode of depression before full recovery and the recurrence of depression in the form of a new and discrete depressive episode, following recovery. Subsequent efforts to validate the dichotomy (or contrast between the two terms) have been few, but are broadly supportive of the distinction (Beshai 2011; Riso 1997), although the precise temporal cut-offs have not been empirically derived and remain inconsistently operationalised in the literature (Bockting 2015). Therefore, for the purpose of this review, we will use the term 'relapse-recurrence', which has been used in previous reviews of interventions (Cox 2012; Vittengl 2007), to mitigate for inconsistencies in how the terms are applied in the included studies.

The majority of work exploring the scope of the problem of depressive relapse-recurrence has been done in secondary care settings and is likely to be of limited applicability to primary care (Buckman 2018), which is where the vast majority of patients with depression are managed (Rait 2009). Relapse-recurrence rates, and longer-term outcomes generally, tend to be worse in speciality

settings, compared to primary care settings (Ormel 2020). One primary care cohort study that followed up people with remitted depression found that 37.1% of participants relapsed within one year (Lin 1998). It is worth noting that this study was relatively small ($n = 251$) and followed up participants from randomised trials (all of whom had been prescribed antidepressant medication); therefore, this study's findings are potentially not generalisable to all primary care populations. A more recent UK-based cohort study followed up patients who had received low-intensity cognitive behavioural therapy (CBT) through the Improving Access to Psychological Therapies (IAPT) service of the UK National Health Service NHS. Conducted in a community care setting, this study found that 53% of participants experienced a relapse-recurrence within one year, and that the majority (79%) of those participants did so within the first six months (Ali 2017). This study is also not necessarily representative of a typical primary care population, as not all patients with depression in primary care would be referred to the IAPT service.

Potentially more useful information can be gained from non-clinical, naturalistic cohort studies. Two systematic reviews have examined studies with naturalistic cohorts (Steinert 2014; Van Weel-Baumgarten 2000). One review estimated primary care relapse-recurrence rates to be between 30% and 40% (Van Weel-Baumgarten 2000). The other review found that 35% to 60% of participants experienced stable recovery (Steinert 2014). A study of trajectories of depression in primary care suggests that the majority of patients with depression in primary care follow a mild trajectory of illness (Gunn 2013).

In addition to patients who experience single or recurrent episodes of depression, there is a further group of patients who have a more chronic and persistent form of depression. An estimate from a review of naturalistic cohorts suggests that between 10% and 17% of depressed patients in primary care follow a chronic rather than episodic course of illness (Steinert 2014). The concepts of relapse and recurrence are less easily applied to these patients, although this group of patients can include those with recurrent depression, with incomplete remission between episodes. Indeed, Monroe 2011 cautioned against excluding patients with chronic or persistent depression from studies of relapse and recurrence; the majority of these patients do in fact still remit or recover at times and can therefore be said to experience a relapse and recurrence, despite the longer duration of index episodes. In summary, the cohort of patients seen in primary care is different from those in secondary care, and the studies discussed here have limitations that prohibit us from making definitive statements about relapse-recurrence rates in primary care settings.

Description of the intervention

There are three recognised treatment phases for depression: treatments implemented before any symptomatic improvement, with a view to achieving remission (acute phase); those employed after symptomatic improvement but before recovery (continuation phase); and those that extend past the point of recovery (maintenance phase) (Bockting 2015). Interventions to prevent relapse-recurrence might be targeted at patients who are in the continuation or maintenance phases, having had symptomatic improvement; or might be implemented during the acute phase, with the intention of exerting a protective effect against relapse or recurrence in the future (Bockting 2015).

Pharmacological and psychological interventions are comparable in terms of efficacy for acute phase depression (Cuijpers 2013; Kamenov 2016), and combination therapy is superior to either type of intervention given singly (Kamenov 2016). Like the acute phase interventions, interventions for preventing relapse-recurrence of depression can broadly be considered pharmacological (i.e. antidepressant medications (ADMs)) or psychological. Other kinds of non-pharmacological therapies might include social interventions (befriending, financial support), service-level interventions (for example, collaborative care), and combination interventions. Physical interventions such as electroconvulsive treatment (ECT) can be used to prevent relapse in some patients, although ECT is almost exclusively a secondary care intervention, evidence for its efficacy is of low quality and there are concerns around harm caused by ECT (NICE 2018).

There is reasonable evidence that compared with placebo, ADMs prevent depression relapse-recurrence; there do not appear to be major differences in this effect across different ADMs, or even different classes of ADMs (Geddes 2003; Glue 2010; Hansen 2008; Kaymaz 2008). A recent systematic review supported the pre-existing evidence that compared to placebo, continuation of ADMs for at least six months after remission significantly improved relapse-recurrence rates, and that this was true for selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs) and other newer agents (Kato 2020). Absolute benefits from ADMs are greater for those at higher initial risk of relapse-recurrence (Geddes 2003), and the effect may decrease after a number of depressive episodes, as patients appear to develop resistance to their prophylactic properties (Kaymaz 2008). There are some limitations in the available literature around the effect of ADMs on relapse-recurrence, which prevent us from drawing firm conclusions about their effects in primary care populations. The studies included in existing reviews have all been undertaken in secondary care populations, where outcomes are generally poorer; the included studies, on the whole, have not adjusted for potential withdrawal effects upon stopping ADMs, which are likely to be a significant confounding factor when estimating rates of relapse-recurrence (Cohen 2010; Hengartner 2020; Recalt 2019). ADMs are also not without their drawbacks:

- adverse effects are common (including sleep disturbance, gastrointestinal disturbance and sexual dysfunction, among others) (Van Leeuwen 2020), and can be worse in elderly people (Coupland 2011);
- concerns about dependence and withdrawal symptoms (which can often be confused with relapse, although these generally occur much sooner after ADM discontinuation than relapse, and can be severe and long-lasting (Davies 2019; Van Leeuwen 2020));
- reluctance by patients to take medication;
- poor concordance (i.e. not taking the medication as prescribed or recommended); and
- high financial cost to the health service (Maund 2019).

The other issue with ADMs is that any prophylactic or protective effects disappear when the medication is discontinued (Bockting 2015), whereas the effect from some types of psychological therapy, like CBT and problem-solving therapy (PST), can endure beyond the point at which the therapy is actually being administered (Cuijpers 2013; Vittengl 2007).

Psychological therapies for preventing relapse-recurrence include CBT, mindfulness-based cognitive therapy (MBCT), PST, and interpersonal therapy (IPT) (Clarke 2015). CBT aims to modify thoughts and behaviours, such as reducing avoidance, increasing activities and challenging negative thoughts. CBT also involves the teaching of cognitive skills which focus on challenging underlying dysfunctional beliefs (cognitive content) that can persist after remission or recovery despite a non-depressed state, presenting a vulnerability that might be more easily triggered by, for example, life events or stress (Beshai 2011; Bockting 2015; Clarke 2015). MBCT was developed specifically as an intervention to prevent relapse-recurrence (Kuyken 2015) and, in addition to cognitive content, also focuses on cognitive processes. MBCT teaches patients to experience thoughts without judgement and to recognise that negative thoughts are transient and do not have to guide feelings or behaviours. IPT focuses on interpersonal and societal role problems, which can be implicated in the onset and recurrence of depressive symptoms (Clarke 2015).

The UK National Institute for Health and Care Excellence (NICE) currently recommend that patients starting ADM for depression should continue treatment for a minimum of six months after remission to reduce the risk of relapse. People "at risk of relapse" are advised to continue ADM for a minimum of two years (this includes people who have had two or more episodes of depression, have residual symptoms, have a history of severe or prolonged episodes or inadequate response, or for whom "the consequences of relapse are likely to be severe"). Recommendations for relapse prevention psychological therapies are: individual CBT for people who have relapsed despite ADM, or for people with a significant history of depression and residual symptoms despite treatment; and MBCT for patients who have had three episodes or more of depression (NICE 2009). In more severe cases, patients are usually referred for specialist treatment where relapse prevention interventions can include further high-intensity psychological treatment, lithium augmentation of ADM and ECT. The Canadian Network for Mood and Anxiety Treatments (CANMAT) depression guideline concurs with NICE that evidence to support maintenance therapy for longer than two years is less well-established, but that certain risk factors (early depression onset, ongoing psychosocial adversity, older age, and comorbid medical or psychiatric conditions) might justify extended maintenance ADM treatment (Lam 2009). The American Psychiatric Association (APA) guideline recommends continuation treatment with ADM and depression-focused psychological treatments. For those with three or more previous depressive episodes, chronic depression or other risk factors (including family history of mood disorder), the APA advises maintenance treatment with the ADM treatment that produced and maintained remission during the acute and continuation phases, and for ECT to be considered beyond that. They recommend regular monitoring for "signs of relapse" throughout (Van Kempen 2010).

How the intervention might work

One route by which interventions for preventing relapse-recurrence might work is through modifying neural pathways; ADMs primarily exert their pharmacological effects on the serotonergic, dopaminergic and noradrenergic pathways (Healy 1997). A comprehensive overview of these neurobiological processes is beyond the scope of this review, but one mechanism by which ADMs are thought to prevent relapse-recurrence through this

route is by reducing the presence of residual depressive symptoms (those that are sub-threshold and persist after remission), which are strongly associated with increased risk of relapse-recurrence (Buckman 2018; Lin 1998). While neurotransmitters are likely to be implicated in some patients with depression, and modification of these pathways is a sound theoretical basis for explaining some of the effectiveness of ADMs at preventing relapse-recurrence, it is widely accepted that depression is multifactorial. Indeed, a recent study reports that for this reason, doctors increasingly avoid giving overly simplistic biological explanations to patients (Tickell 2020).

Psychological therapies exert their effect by modifying a broader range of therapeutic targets. Most psychological therapies for preventing relapse-recurrence are designed to be provided during the continuation or maintenance treatment phases; although, as discussed, these can be given during the acute phase and exert a longer-term benefit. As well as aiming to reduce residual depressive symptoms (like ADMs) psychological therapies additionally target cognitive and information processing mechanisms (specifically those involved in integrating affective and cognitive information; processing negatively valenced stimuli; social skills and the ability to use social support; problem solving skills; and degree of negative self-concept) and interpersonal stress pathways. Relapse of depression is associated with negative thinking styles, such as rumination (Buckman 2018). CBT specifically targets these thoughts and aims to educate patients on how to modify and transform such thoughts into more positive thoughts (Clarke 2015). MBCT focusses on teaching patients to improve their awareness of and relationship to such thoughts, rather than on modifying the thoughts (Kuyken 2015). Psychological therapies also focus on being aware of and planning for early warning signs of relapse-recurrence, and also focus on healthy lifestyle behaviours. In summary, there are a range of mechanisms by which the interventions eligible for inclusion in this review might work to improve relapse-recurrence outcomes.

Why it is important to do this review

We have discussed the burden associated with depression in terms of patient morbidity and quality of life, as well as the wider cost to society as a whole. Despite scientific progress and an increased understanding of the biological and psychological underpinnings of mental health conditions, there is no evidence of a decrease in morbidity or mortality from depression, in contrast to physical health conditions such as cardiovascular disease, stroke and cancer (Insel 2009). Furthermore, the vast majority of people with depression are managed in primary care (Ramanuj 2019), yet the majority of research on depressive relapse-recurrence has been undertaken in a secondary care context. There is a need for feasible and scalable interventions that can be implemented in a primary care clinical setting and, by better understanding what interventions and intervention components work best, this review could inform such efforts.

Other Cochrane Reviews have looked at similar interventions and outcomes. One review assessed the effectiveness of continuation and maintenance treatments for persistent depressive disorder, mainly in a secondary care context (Machmutow 2019), and found that the paucity and moderate/high risk of bias in the available studies meant it was uncertain whether pharmacological or psychological therapies were effective for preventing relapse-recurrence. There has been a Cochrane Review of relapse prevention interventions in children and adolescents (Cox

2012) and an ongoing review is exploring the effectiveness of interventions aimed at teaching patients to recognise early warning signs (EWS) of depression to prevent recurrence (Lenora 2019). These will form part of a larger body of evidence looking at relapse prevention more generally.

There has been only one previous systematic review of relapse prevention strategies, specifically in a primary care setting (Gili 2015); this review identified only three studies. There have been a number of new primary care-based RCTs of relapse prevention interventions since the publication of that review. A synthesis of available evidence is needed to guide the allocation of interventions in primary care to prevent relapse-recurrence and improve disease trajectories for patients. As we have seen, it is not well understood which interventions work best for which patients, and national guidelines differ in terms of risk stratification and treatment recommendations. This speaks to the fact that depression is complex and centred in a biopsychosocial context. Furthermore, there are multiple kinds of interventions available. Patient preferences and individual patient circumstances will always be important in guiding treatment decisions through discussion with healthcare professionals. An ability to be able to inform patients about the relative effectiveness of the range of different treatment options is an essential part of this decision-making process. This review aims to provide a robust summary of the available evidence to support such discussions.

OBJECTIVES

The aim is to assess, using network meta-analysis (NMA), the effectiveness and safety of interventions for preventing relapse-recurrence of depression in adults in a primary care setting. NMA is a technique for comparing three or more interventions simultaneously in a single analysis by combining both direct and indirect evidence across a network of studies.

The objectives are to:

1. estimate the relative effectiveness of pharmacological, psychological and other interventions to prevent relapse-recurrence, compared with each other and controls (e.g. pill placebo, treatment as usual) on relapse-recurrence outcomes and adverse events;
2. assess the effect of interventions on quality of life outcomes and social and occupational functioning;
3. estimate the relative ranking of included interventions on relapse-recurrence, quality of life, and adverse events;
4. summarise availability and principal findings of eligible economic evaluations.

METHODS

Criteria for considering studies for this review

Types of studies

We will include all RCTs (including cluster- and cross-over RCTs) that include direct comparisons between two or more eligible interventions and/or usual care, control or placebo. The latter are useful for NMA, as placebo can be a common comparator and therefore can be an important component of a network of interventions. All studies must have taken place in a primary care or community setting. A primary care setting is the first

point of contact for a patient accessing health services (e.g. in a general practitioner's clinic) and interventions are usually delivered by a generalist. By community settings, we mean interventions delivered outside of a traditional primary care setting (e.g. those delivered in community centres or community clinics) but not requiring a specialist referral to a secondary care setting. Community settings include nursing and residential care settings, as long as there is no specialist or secondary care involvement. Services providing first-line psychological treatments (for example, the UK's IAPT service (Clark 2011)) are also often termed community rather than primary care, and their cohorts are likely to be directly applicable to a primary care setting. These will be all included, but setting (primary or community care) will be explored as a potential source of heterogeneity.

Types of participants

Adults (age 18 years and over) with major depressive disorder (MDD), diagnosed in line with Diagnostic and Statistical Manual of Mental Disorders (DSM-V) criteria, either through diagnostic interview or using a validated diagnostic questionnaire, who have entered remission or recovery before receiving the intervention. Participants with remission or recovery would be defined as those patients who had met diagnostic criteria for MDD at baseline but no longer met these diagnostic criteria. In this review, we will not include interventions delivered during the acute phase of depression. It is likely that the majority, if not all, of the included studies will have tested interventions in participants with recurrent depression.

We will not include participants with severe mental illness (for example, bipolar affective disorder or schizophrenia), as these participants would not represent a population comparable with those with only MDD and therefore would be a potential threat to the transitivity assumption (similarity of the direct and indirect evidence) of the network meta-analyses. We will include participants with other psychological co-morbidities which are routinely managed in primary care (for example, anxiety, post-traumatic stress disorder, obsessive-compulsive disorder). We will also include participants with physical co-morbidities and long-term conditions, and will explore this as a potential source of heterogeneity if appropriate to assess whether this may contribute to intransitivity. In addition, criteria for comparing the similarity of participant characteristics of included studies is outlined in "Assessment of clinical and methodological heterogeneity within treatment comparisons" below.

Types of interventions

RCTs of any intervention specifically aimed at preventing relapse or recurrence of depression in a primary or community care setting. These could be pharmacological, psychological or social (e.g. collaborative care, community outreach, befriending). We expect that some RCTs may compare different interventions (e.g. psychological versus pharmacological approach) rather than a control arm. As discussed, physical therapies such as ECT are not relevant to a primary care setting and therefore will be excluded from this review.

The following are interventions of clinical relevance (decision-set interventions).

- Pharmacological interventions: Previous reviews have not suggested significant differences in the effectiveness of different

ADMs on relapse and recurrence across primary and secondary care settings, but there may be a dose-related effect (Hansen 2008). Where different doses or drug classes have been trialled, we will merge classes (e.g. SSRI, TCA, serotonin-norepinephrine reuptake inhibitor (SNRI)) and will split these by dose (low, medium and high strength), according to equivalent doses per the British National Formulary.

- Psychological interventions will be categorised by type (for example: CBT, MBCT, IPT), and intensity (for example, high-versus low-intensity CBT, as defined by the authors of primary studies). Group and individual psychological interventions will be treated a separate nodes in the NMA.
- Other interventions: as discussed, interventions that aim to prevent relapse-recurrence, but which are not either pharmacological or psychological will be included, as long as they meet the other inclusion criteria.

The following are supplementary-set interventions and are included to give greater power and to connect up the network, but are not themselves of clinical relevance:

- Placebo, control, or 'treatment as usual' arms. These can be defined as deemed appropriate by the trial authors. We will extract information about the content of these arms to ensure that they are directly comparable.

Types of outcome measures

Primary outcomes

- Time to relapse-recurrence

Time to relapse-recurrence provides a more detailed picture of intervention effectiveness than a binary outcome (i.e. relapse-recurrence or no relapse-recurrence). We will define participants with relapse-recurrence as those who had previously met the definition for remission or recovery but subsequently met the diagnostic criteria for MDD.

The primary harm outcome is adverse events (for example, discontinuation due to side effects, self-harm, suicide, or hospitalisation).

Secondary outcomes

- Binary relapse-recurrence outcome
- Antidepressant medication dose changes (change in dose after intervention, to enable us to assess whether interventions led to increased or decreased ADM prescription)
- Quality of life measures (e.g. EQ-5D, SF-36, or any other instrument)
- Social and occupational functioning (e.g. Global Assessment of Function Scale (GAF), Occupational Functioning Scale (OFS), or any other instrument)

Timing of outcome assessment

We will analyse outcome data at the following time points: short-term (less than six months), medium-term (six to 12 months) or long-term (greater than 12 months).

Hierarchy of outcome measures

Due to the great likelihood of more than one reported eligible outcome, we will include data as per the following rules.

- In case of available data from both observer-rating scales and self-report questionnaires, we will prioritise data from observer-rating scales. For the remission/recovery and relapse-recurrence outcomes, we will give preference to diagnostic interview or HAM-D and for the self-reporting scale, we will give preference to the PHQ-9 or BDI.
- In case of several outcome measures of the same hierarchy level used in one trial, we will select the outcome measure most frequently used across all trials.
- In case of several outcome measures of the same hierarchy level and the same availability across trials, we will randomly select the outcome measure.
- Where applicable, if diagnostic interview, HAM-D or BDI were not reported, we will select the outcome measure most frequently used across all trials.

Economic commentary

We will develop a brief economic commentary based on current methods guidelines (Aluko 2020) to summarise the availability and principal findings of trial-based full economic evaluations (cost-effectiveness analyses, cost-utility analyses, cost-benefit analyses) that compare psychological or pharmacological relapse prevention interventions with each other or with controls for depression. This commentary will focus on the extent to which principal findings of eligible economic evaluations indicate that an intervention is judged favourably (or unfavourably) from an economic perspective, when implemented in different settings. A separate search will be conducted to identify economic evidence, including: screening the reference lists and conducting forward citation tracking from eligible studies of effects identified for inclusion in the main review; a search of NHS Economic Evaluation Database (NHS EED); and the use of specialist search filters to sets of records retrieved by searches of one or two selected general electronic biomedical literature databases searched for the main review of intervention effects (as recommended by the Cochrane Economics Methods Group).

Identified economic evaluations will be screened against the inclusion criteria by one review author (ASM). Data will be extracted including: basic details of the characteristics of each identified economic evaluation (including analytic framework and type of economic evaluation, analytic perspective and time horizon, main cost items included in each analysis, and setting); and brief text extracts that summarise their principal findings (verbatim text on conclusions drawn by the authors of each economic evaluation and text that summarises uncertainty surrounding authors' principal conclusions).

The findings of the brief economic commentary will be incorporated into the 'Discussion' section and will include a brief narrative summary of: the electronic health economics literature databases searched; the number of relevant economic evaluations identified for each eligible comparison (each eligible intervention/comparison combination); the descriptive information collected from each study; principal conclusions as reported by the authors of each analysis (with respect to the base case analysis); and principal sources of uncertainty regarding authors' principal conclusions (based on the results of any sensitivity analyses conducted).

Search methods for identification of studies

Electronic searches

An Information Specialist with the Cochrane Common Mental Disorders Group (CCMD) will run searches on the following bibliographic databases and trial registers using relevant subject headings (controlled vocabularies) and search syntax, appropriate to each resource.

- Cochrane Common Mental Disorders Controlled Trials Register (CCMDCTR) (all available years).
- The Cochrane Central Register of Controlled Trials (CENTRAL) (the Cochrane Library, latest issue).
- Ovid MEDLINE (1946 to date) (Appendix 1).
- Ovid Embase (1974 to date).
- Ovid PsycINFO (all available years).
- ISI Web of Science: Conference Proceedings Citation Index-Science (CPCI-S) (1990 to date).
- ClinicalTrials.gov (www.clinicaltrials.gov) (all available years).
- World Health Organization International Clinical Trials Registry Platform (apps.who.int/trialsearch/) (all available years).

There will be no restrictions on date, language or publication status applied to the searches.

Searching other resources

The Information Specialist will also search the following sources of grey literature (primarily for dissertations and theses).

- Open Grey (www.opengrey.eu).
- ProQuest Dissertations & Theses Global (www.proquest.com/products-services/pqdtglobal.html).
- DART-Europe E-theses Portal (www.dart-europe.eu).
- EThOS - the British Libraries e-theses online service (ethos.bl.uk).
- Open Access Theses and Dissertations (oatd.org).

Reference lists

We will check the reference lists of all included articles and relevant systematic reviews to identify additional research missed from the original electronic searches (e.g. ongoing studies, unpublished or in-press citations).

Personal communication

We will contact authors and subject experts for information on unpublished or ongoing studies, or to request additional data.

Data collection and analysis

Selection of studies

All abstracts will be independently screened by two review authors (from among AM, LR, FM, NC), with any disagreements to be referred to a third review author (NM). The same process will apply to full-text screening. We will identify and exclude duplicate records and we will collate multiple reports that relate to the same study, so that each study, rather than each report, is the unit of interest in the review. We will record the selection process in sufficient detail to present an adapted PRISMA flow chart of study selection and 'Characteristics of excluded studies' table.

Data extraction and management

We will extract data using a pre-prepared and pre-piloted data collection form. Two review authors (from among ASM, LR, FM, NC) will independently extract data, and any disagreements or discrepancies will be resolved by referral to a third review author (NM). We will extract the following study intervention and population characteristics that may act as effect modifiers:

- methods: study design, total duration of study, number of study centres and location, study setting (primary care, community), withdrawals, and date of study;
- participants: number, mean age, age range, gender, baseline severity of condition, diagnostic criteria, number of previous episodes, length of index episode, recurrence status, anxiety symptoms; inclusion criteria, and exclusion criteria, suicide-related behaviours; level of suicide ideation; risk of suicide; co-morbid chronic physical illness, psychiatric co-morbidity; socio-economic status;
- interventions: type and duration of acute phase intervention; type of relapse-recurrence prevention intervention; comparison; dose (including intended and actual dose received); duration of treatment; concomitant medications; concomitant psychosocial interventions (including type, duration, who delivered the intervention, whether it was delivered to groups or individuals, was manualised, actual number of sessions attended); and excluded medications;
- outcomes: primary and secondary outcomes specified and collected, and time points reported;
- notes: funding for trial, and notable conflicts of interest of trial authors.

Outcome data

We will extract from each included study arm-level data about relapse-recurrence rates and time to relapse-recurrence, the duration of the intervention, the number of participants, the drop-out rates, the authors' definition of relapse-recurrence, the number of patients that experienced a relapse-recurrence and the interventions being compared. When extracting data about type and duration of acute phase interventions, we will also extract information about how the individual studies have controlled for withdrawal confounding ([Hengartner 2020](#)).

Other data

We will extract and report a narrative summary of any cost-effectiveness analyses taking place alongside the RCT. If outcome data are not reported in a usable way (e.g. missing standard deviations (SD) or 95% confidence intervals (CIs)), we will note this in the 'Characteristics of included studies' table. We will resolve disagreements by consensus or by involving a third review author (NM). One review author (ASM) will transfer data into the Review Manager 5.4 file ([Review Manager 2020](#)) or RevMan Web ([RevMan Web 2019](#)). We will double-check that data are entered correctly by comparing the data presented in our review with the study reports. A second review author (from LR, FM or NC) will spot-check study characteristics for accuracy against the study report.

Assessment of risk of bias in included studies

Two review authors (ASM, LR, FM, NC) working independently will undertake risk of bias assessment, using version 2 of the Cochrane risk of bias tool for randomised controlled trials (RoB 2) ([Higgins](#)

[2021](#); [Sterne 2019](#)), with respect to effect of assignment. We will do this for the two primary outcomes (time to relapse-recurrence within 12 months; adverse outcomes at any timepoint). A third review author will resolve any disagreements. We will use the methods described in the ROB 2 guidance for Cluster RCTs. We will assess the risk of bias according to the following domains:

- random sequence generation;
- allocation concealment;
- blinding of participants and personnel;
- blinding of outcome assessment;
- incomplete outcome data;
- selective outcome reporting;
- other bias.

We will judge each potential source of bias as either high, low or unclear, and will provide a supporting quotation from the study report together with a justification for our judgment in the 'Risk of bias' table. We will summarise the 'Risk of bias' judgements across different studies for each of the domains listed. We will use the RoB2 excel tool to manage assessments and will store documentation of judgements and assessments on a data repository website for scientific data, where they will be available to readers of the full review. Where necessary, we will contact the trial authors for further information. Where information on risk of bias relates to unpublished data or correspondence with a trial author, we will note this in the 'Risk of bias' table. We will present all 'Risk of bias' data graphically and in the text.

Measures of treatment effect

Relative treatment effect

Where time to relapse-recurrence has been assessed, we will use hazard ratios (HRs). We will express dichotomous outcome data as risk ratios (RRs) with 95% CIs. We will express continuous data as standardised mean differences (SMD) with 95% CIs. To aid interpretation of SMDs we will back-transform estimates to the most commonly reported scale for that outcome. Results from the NMA will be presented as summary relative effect sizes (SMD or RR) for each possible pair of treatments.

Relative treatment ranking

Where appropriate, we will also estimate the ranking probabilities for all treatments of being the most effective treatment using P values, which take into account effect estimates and precision ([Chaimani 2020](#)). However, if we identify too much uncertainty we will not rank treatments.

Unit of analysis issues

Cluster-randomised trials

Cluster-RCTs involve the randomisation of participants as groups (or clusters) rather than as individuals. If we include cluster-RCTs, but reported data have not been appropriately adjusted for the correlation between participant outcomes within clusters, we will contact trial authors to obtain an estimate of the intra-cluster correlation coefficient (ICC); or impute the ICC using estimates from the other included trials, or from similar external trials. We will inflate the reported standard errors by the square root of the design effect, using the estimated/imputed ICC ([Higgins 2020](#)). We

will undertake sensitivity analyses to assess the robustness of the combined intervention effects to assumptions regarding the ICCs.

Cross-over trials

If we include cross-over trials (trials where participants receive a sequence of different interventions), we will only use data from the first cross-over period, due to the risk of carry-over effects.

Studies with multiple treatment groups

For multi-arm trials, we will use graph-theoretical methods (using the R software package 'netmeta', R) to account for between-arm correlations. The netmeta package treats multi-arm trials as a complete subgraph with known variances. For each comparison within the trial, variances are back-calculated adjusting for correlation between arms (Rucker 2012).

Dealing with missing data

We will attempt to obtain any missing data (data necessary for our analysis that is not reported in the trial paper) from study authors. If we are unable to obtain missing SDs from study authors, we will estimate these from P values, t-statistics, CIs or standard errors, if reported in the paper.

If a vast majority of SDs are available and only a minority of SDs are unavailable or unobtainable, we plan to use the method devised by Furukawa and colleagues to impute SDs and calculate percentage responders (Furukawa 2005; Furukawa 2006). If we use this method, we will interpret data with caution and will take into account the degree of observed heterogeneity. We will also undertake a sensitivity analysis to examine the effect of the decision to use imputed data.

If additional figures are not available or obtainable and it is not deemed appropriate to use the Furukawa method as described above, we will not include the trial data in the comparison of interest.

We will pool 'last observation carried forward' (LOCF) data and other data from other imputation methods, such as multiple imputation or mixed effect models (rather than mix LOCF and observed case (OC) data). We will also undertake sensitivity analyses using OC data, where available.

Assessment of heterogeneity

Assessment of clinical and methodological heterogeneity within treatment comparisons

Heterogeneity and transitivity are related. Heterogeneity results from variation of effect modifiers within a treatment comparison, while intransitivity results from variation of effect modifiers across treatment comparisons (Efthimiou 2016). To evaluate the presence of clinical heterogeneity we will generate and compare descriptive statistics for trial and study population characteristics across all eligible trials that compare each pair of interventions.

When we find heterogeneity, we will attempt to determine potential reasons for it by examining individual study and subgroup characteristics. We expect the following characteristics to potentially introduce clinical heterogeneity and intransitivity.

- Study setting (primary care or community).
- Type of depression (first-episode; recurrent; chronic).

- Age of participants.
- Comorbid anxiety.
- Physical comorbidity (long-term conditions).
- Gender.
- Socio-economic status.
- Length of follow-up/timing of relapse.
- Dose of treatment (e.g. milligram dosage of ADMs, length and number of sessions with for psychological interventions).

Assessment of statistical heterogeneity

Assumptions when estimating the heterogeneity

In NMAs, we will assume a common estimate for the heterogeneity variance across the different comparisons.

Measures and tests for heterogeneity

We will assess statistical heterogeneity using the I^2 statistic and its 95% CI and τ^2 (between-study variance). I^2 quantifies heterogeneity across studies by measuring the percentage of variability that cannot be attributed to random error. The *Cochrane Handbook for Systematic Reviews of Interventions* provides the following rule of thumb for interpreting I^2 values (Deeks 2020):

- 0% to 40%: might not be important;
- 30% to 60%: may represent moderate heterogeneity;
- 50% to 90%: may represent substantial heterogeneity;
- 75% to 100%: considerable heterogeneity.

The I^2 will be interpreted in light of its magnitude and direction of effects and the strength of evidence for heterogeneity (width of 95% CI).

Assessment of transitivity across treatment comparisons

As described, transitivity assessment is related to heterogeneity assessment, with transitivity being specifically applicable to NMA and relating to differences in the distribution of different effect modifiers across different comparisons. We will assess transitivity by comparing the distribution of effect modifiers across the different comparisons for each outcome.

Assessment of statistical inconsistency

Inconsistency (also called incoherence) is the statistical manifestation of intransitivity in the data. Inconsistency occurs when direct and indirect evidence for a particular relative effect are in disagreement, and is only possible to detect when there are evidence loops (sources of direct and indirect evidence for the same comparison).

Local approaches for evaluating inconsistency

Local approaches focus on a particular comparison and usually involve assessing the absolute difference between the two summary estimates in the form of an inconsistency factor (IF). We will use a loop-specific approach (a loop of evidence is formed when at least three pairs of treatments have been compared and form a closed path). An IF will be calculated by contrasting direct estimates with indirect estimates. The magnitude of the IFs, their 95% CIs and a loop-specific Z-test will be used to infer about the presence of inconsistency in each loop. We will extend analysis to all closed loops assuming a loop-specific heterogeneity and examine

the estimates of inconsistency together with 95% CIs for each loop, using a graphical representation. We will assume a common heterogeneity estimate within each loop and will be cautious deriving conclusions from this approach. Netmeta software also provides pairwise meta-analyses estimates as part of the analyses and we will informally compare these estimates with the results found in our network meta-analyses.

Global approaches for evaluating inconsistency

We will also perform a global assessment of inconsistency to check the assumption of consistency in the entire network. We will model inconsistency using the design-by-treatment interaction model (Higgins 2012), which accounts for different source of inconsistency that can occur when studies with different designs (two-arm trials versus three-arm trials) give different results as well as disagreement between direct and indirect evidence.

Assessment of reporting biases

We will use a framework described in the *Cochrane Handbook* (Page 2019) that proposes an assessment be made for each comparison regarding the risk and potential impact of missing data from studies ("known-unknowns") and risk of missing studies ("unknown-unknowns"). We will use this framework in our GRADE assessments to guide our judgements on 'undetected' or 'suspected' reporting bias.

For our primary outcome, we will be guided by our risk of bias assessments, as well as by comparison-adjusted funnel plots (extensions of funnel plots for use in network meta-analyses), if there are a minimum of ten studies (Chaimani 2012). Where there is evidence of funnel plot asymmetry, we will adjust for small-study effects using WinBUGS/OpenBUGS (Mavridis 2016).

Data synthesis

Assuming that we have a connected network of treatments, we will perform NMAs using the netmeta package in R for all outcomes. Feasibility will be assessed in terms of the number of data points, heterogeneity of treatment and outcome characteristics as well as the patient and study characteristics (Cipriani 2013). We will illustrate network geometry using network plots. If we identify relevant interventions that we are not aware of at the Protocol stage, we will consider them as eligible and we will include them in the network after assessing their comparability with the pre-specified set of competing interventions. They will be included in the meta-analysis so long as they fulfil the transitivity assumptions as follow: that they are in principle jointly randomisable along with the other included interventions (that is, they have the same indication and could be meaningfully compared head-to-head with one another). We will also include contour-adjusted funnel plots for our primary outcomes to assess the potential impact of small studies on findings, if there are 10 or more included studies in these analyses.

Subgroup analysis and investigation of heterogeneity

If we find important heterogeneity or/and inconsistency (see above), we will explore the possible sources. If sufficient studies are available, we will also perform an NMA with meta-regression analyses on the primary outcome in Stata (Stata) for the following factors.

- Study setting (primary or community).

- Type of depression (first-episode; recurrent; chronic), as defined by the authors.
- Age of participants (< 65 years and > 65 years).
- Comorbid anxiety (presence or absence, using an appropriate validated instrument, e.g. GAD-7).
- Length and number of sessions for psychological interventions.
- Funded by pharmaceutical company (yes or no).

Sensitivity analysis

We will undertake sensitivity analyses for the primary outcomes to investigate how effect estimates are affected by the following.

- Definition of relapse/recurrence: we will assess effects only in recurrent depression (i.e. exclude studies focusing on a single episode of depression).
- Drug classes: as there may be heterogeneity within drug classes we will also conduct NMAs including individual drugs as nodes.
- Dose: our primary analyses propose to include different doses as separate nodes in the network, we will assess the impact of combining doses of the same drug as a single node.
- Study bias: we will perform a sensitivity analysis excluding all studies assessed to be at high overall risk of bias and comparing the results.
- Provided there is sufficient information in the primary studies, we will compare relapse-recurrence rates in those studies that adequately controlled for withdrawal confounding (those that continued acute phase pharmacological management or those that documented this was weaned appropriately (NICE 2009)), versus those that did not (i.e. where ADM was stopped abruptly prior to the relapse prevention intervention, or where the approach was not documented)).
- Missing data: we will conduct analyses including analyses with OC data in addition to LOCF and other imputed data.

Summary of findings and assessment of the certainty of the evidence

We will present 'Summary of findings' tables, based on the template provided in Table 2 in Yepes-Nunes 2019 (but we will not report a column for ranking and will include a column for comments), for the following primary outcomes:

1. Time to relapse-recurrence (within 12 months)
2. Adverse outcomes (at any timepoint)

The 'Summary of findings' tables will include all interventions.

For the relapse-recurrence related outcomes (time to relapse-recurrence or binary outcome), we will assess our certainty in the evidence from the NMA using the Confidence In Network Meta-Analysis (CINeMA) approach (CINeMA; Nikolakopoulou 2020; Papakonstantinou 2020). CINeMA is based on the GRADE framework for assessing the certainty of the body of evidence and involves assessing the following six domains: within-study bias (i.e. the impact of risk of bias of the included trials); reporting bias (i.e. the impact of missing studies, outcomes and results); indirectness; imprecision; heterogeneity; and incoherence. Each domain (except 'reporting bias') is judged to have no concerns, some concerns or major concerns. 'Reporting bias' is judged as 'suspected' or 'undetected'. Judgements across the six domains are summarised to obtain four levels of confidence for each relative treatment effect:

very low, low, moderate or high. We will assess our certainty in all comparisons formed by treatment groups in the decision and supplementary sets. Here we provide some further detail of the criteria we will use to inform our judgements for the domains.

Within-study bias

This domain concerns risk of bias within the included studies. In judging the certainty of the evidence for each relative effect estimate in this domain, we will consider the percentage contribution from studies judged to be at a low risk of bias, with some concerns, or a high risk of bias. Specifically, we will calculate a weighted average of the risk of bias, where the risk of bias judgements are assigned scores of -1 (low), 0 (some concerns) and 1 (high), and these scores are weighted by the proportion contributed from studies at each level. We will use these weighted averages to classify the certainty of evidence for each estimate. We may choose to override some of the judgements based on the findings from our sensitivity analysis that excludes trials at a high risk of bias.

Indirectness

In judging the certainty of the evidence for each relative effect estimate in this domain, we will consider for each study how directly it addresses the research question in combination with the percentage contribution the study makes to the estimate. In considering directness, we will consider population, intervention and outcome characteristics that are potential effect modifiers (e.g. age).

Reporting bias

We will use the results from our investigation of reporting bias (see 'Assessment of reporting biases', above) in judging the certainty of evidence for each relative effect estimate. This will involve considering the contribution that each direct comparison makes to each relative effect estimate (i.e. network estimate).

Imprecision

In judging the certainty of the evidence for each relative effect estimate in this domain, we have set a "margin of equivalence" for relapse-recurrence outcomes. The margin of equivalence corresponds to clinically unimportant differences between groups. Our margin of equivalence for relapse-recurrence outcomes

corresponds to a risk ratio of between 0.8 and 1.25. We have derived this by assuming a comparator risk of 0.5, based on expected baseline relapse rates, and a risk difference of 0.1, based on agreement among the research team that a 10% improvement would be clinically meaningful in this cohort.

Heterogeneity

We will use the clinical equivalence ranges specified for the 'imprecision' domain in combination with prediction intervals, to determine whether heterogeneity in the results affects our certainty in the evidence.

Incoherence

We will take into account both global and local approaches to inconsistency. For local approaches, we will use the clinical equivalence ranges specified for the 'imprecision' domain in combination with the 95% CIs of direct and indirect relative treatment effects to determine if incoherence between these estimates affects our certainty in the evidence.

ACKNOWLEDGEMENTS

We thank the editorial team of the Cochrane Common Mental Disorders (CCMD) Group including Jessica Hendon (Managing Editor) and Sarah Dawson (Information Specialist). Sarah Dawson helped develop the search strategies.

The authors and the CCMD Editorial Team are grateful to the following peer reviewers for their time and comments: Mieke van Driel, Ellen van Leeuwen, Jean Sellar-Edmunds and Gill Worthy. They would also like to thank Cochrane Copy Edit Support for the team's help.

The National Institute for Health Research (NIHR) is the largest single funder of the CCMD Group. Andrew Moriarty is funded by a NIHR Doctoral Research Fellowship for this research project (NIHR Doctoral Research Fellowship, Dr Andrew Moriarty, DRF-2018-11-ST2-044). This publication presents independent research funded by the NIHR. Appendix 2. Glossary of terms

Recovery: follows an extended period of remission; at this point, patients are said to be no longer in episode.

Recurrence: a new episode of depression, separate from the index episode.

Relapse: a return to the index episode of depression.

Relapse-recurrence: a hybrid term used to describe the re-emergence of depressive symptoms after a period of relative wellness, to account for inconsistencies in how relapse and recurrence are operationalised in the literature.

Remission: a period of time, following a response to treatment, during which patients have minimal depressive symptoms but are still "in episode".

Response: an initial improvement of symptoms, usually after treatment initiation and usually attributable to the treatment.

CONTRIBUTIONS OF AUTHORS

ASM: Contributed to the conception of the review and lead author of the protocol. Wrote the first draft of the protocol and response to peer review.

LR: Commented on the background and contributed to the methodology of the protocol.

FM: Commented on the background and contributed to the methodology of the protocol.

NC: Commented on the background and contributed to the methodology of the protocol.

SG: Contributed to the conception of the review and the background and methodology of the protocol.

DM: Contributed to the conception of the review and the background and methodology of the protocol.

CCG: Contributed to the conception of the review and the background and methodology of the protocol.

SA: Contributed to the conception of the review and the background and methodology of the protocol.

SH: Commented on the background and contributed to the methodology of the protocol.

RC: Commented on the background and contributed to the methodology of the protocol.

NM: Commented on the background and developed the methodology of the protocol.

DECLARATIONS OF INTEREST

ASM: No conflicts of interest.

LR: No conflicts of interest.

FM: No conflicts of interest.

NC: No conflicts of interest.

SG: No conflicts of interest.

DM: No conflicts of interest.

CCG: No conflicts of interest.

SA: No conflicts of interest.

SH: is the Joint Co-ordinating Editor of the Cochrane Common Mental Disorders Group. She is funded by the Auckland Medical Research Foundation and CureKids.

RC: Leads and has responsibility for Cochrane Common Mental Disorders, which has supported parts of the review process and is largely funded by a grant from the National Institute for Health Research (NIHR) in the UK.

NM: is the Deputy Co-ordinating Editor of the Cochrane Common Mental Disorders Group.

SOURCES OF SUPPORT

Internal sources

- University of York, UK
- Hull York Medical School, UK
- University of Auckland, New Zealand

External sources

- National Institute for Health Research (NIHR), UK

LR, RC & NM contribution to this protocol is supported by Cochrane Infrastructure funding to the Common Mental Disorders Cochrane Review Group.

ASM is funded by a NIHR Doctoral Research Fellowship for this research project. This publication presents independent research funded by the NIHR. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR or the Department of Health and Social Care.
