Abstract

Mitochondria dysfunction occurs in the aging brain as well as in several neurodegenerative disorders and predisposes neuronal cells to enhanced sensitivity to neurotoxins. 3-nitropropionic acid (3-NP) is a naturally occurring plant and fungal neurotoxin that causes neurodegeneration predominantly in the striatum by irreversibly inhibiting the tricarboxylic acid respiratory chain enzyme, succinate dehydrogenase (SDH), the main constituent of the mitochondria respiratory chain complex II. Significantly, although 3-NP-induced inhibition of SDH occurs in all brain regions, neurodegeneration occurs primarily and almost exclusively in the striatum for reasons still not understood.

In rodents, 3-NP-induced striatal neurodegeneration depends on the strain background suggesting that genetic differences among genotypes modulate toxicant variability and mechanisms that underlie 3-NP-induced neuronal cell death. Using the large BXD family of recombinant inbred (RI) strains we demonstrate that variants in *Ccnd1* - the gene encoding cyclin D1 - of the DBA/2J parent underlie the resistance to 3-NP-induced striatal neurodegeneration. In contrast, the *Ccnd1*

variant inherited from the widely used C57BL/6J parental strain confers sensitivity. Given that cellular stress triggers induction of cyclin D1 expression followed by cell-cycle re-entry and consequent neuronal cell death, we sought to determine if the C57BL/6J and DBA/2J Ccnd1 variants are differentially modulated in response to 3-NP. We confirm that 3-NP induces cyclin D1 expression in striatal neuronal cells of C57BL/6J, but this response is blunted in the DBA/2J. We further show that striatal-specific alternative processing of a highly conserved 3'UTR negative regulatory region of *Ccnd1* co-segregates with the C57BL/6J parental *Ccnd1* allele in BXD strains and that its differential processing accounts for sensitivity or resistance to 3-NP. Our results indicate that naturally occurring *Ccnd1* variants may play a role in the variability observed in neurodegenerative disorders involving mitochondria complex II dysfunction and point to cyclin D1 as a possible therapeutic target.

Keywords

3-nitropropionic acid; mouse; neurodegeneration; striatum; BXD; cell cycle; Cyclin D1

1. Introduction

Mitochondrial respiratory chain complex II dysfunction is associated with neuronal degeneration in several diseases, including Huntington's disease (HD) and multiple system atrophy (MSA), and is likely to play a pivotal role in the progression of these disorders (Reiner et al., 2011; Stefanova and Wenning, 2016; Arun et al., 2016). Livestock poisoning by either plants or fungi containing 3-nitropropionic acid (3-NP), a naturally occurring neurotoxin that irreversibly inhibits succinate dehydrogenase (SDH), the main constituent of the mitochondrial respiratory chain complex II (Alston et al., 1977; Coles et al., 1979) has been extensively documented (Hamilton et al., 2000). Outbreaks of human poisonings have also been reported, and similar to what has been observed in animals, 3-NP ingestion by humans leads to severe clinical features resembling HD, as well as significant neuronal cell death majorly limited to the striatum (Lui et al., 1989, Ludolph et al., 1991; Hamilton et al., 2000; Birkelund et al., 2021).

In animal models, systemic administration of 3-NP leads to extensive neuronal cell death, almost exclusively in the striatum. Chronic or acute administration of 3-NP in rodents and primates has been extensively used to reproduce clinical features of HD, closely recapitulating the motor, biochemical and pathological features of the disorder (Brouillet et al., 1995; Palfi et al., 1996; Brouillet et al., 2005; Bonsi et al., 2006; Túnez et al., 2010), while the first models of MSA that fully recapitulate the disorder, were generated by 3-NP administration in mice transgenic for oligodendrocyte-specific overexpression of alpha-synuclein, underscoring the possible role of complex II dysfunction in the disease (Stefanova et al., 2005; Ubhi et al., 2009; Kuzdas-Wood et al., 2014, Foti et al., 2019).

Despite the extensive body of work in animal and cellular models, the mechanisms leading to 3-NP-induced neuronal cell death are still poorly understood. 3-NP inhibition of SDH leads to impaired mitochondrial bioenergetics, oxidative stress, and loss of ATP (Alston et al., 1977; Coles et al., 1979), triggering a cascade of intracellular events that ultimately

result in cell death (Túnez et al., 2010). However, although 3-NP-induced inhibition of SDH occurs in all brain regions, neurodegeneration occurs primarily in the striatum (Brouillet et al., 1998; Bizat et al., 2003; Bonsi et al., 2006). The underlying basis for preferential striatal vulnerability to 3-NP is currently unknown.

In both rats and mice 3-NP-induced striatal neurodegeneration depends on the strain employed (Alexi et al., 1998; Brouillet et al., 2005; Schauwecker et al., 2005), suggesting that genetic differences between specific strains interact and modify the mechanisms that underlie the toxin-induced neuronal cell death. So far, attempts to identify genetic factors that influence 3-NP-induced neurotoxicity consisted in empirically testing the function of a battery of genes/factors, most of them already known to be involved in either mitochondria function, or neurodegenerative disorders, and in particular in HD. Unfortunately, this approach was not fruitful since inactivation of the examined genes either had no effect (Hanbury et al., 2003; Junyent et al., 2012), or led to moderate increase or decrease in 3-NP toxicity in wild-type mice in a C57BL/6 (B6) genetic background (Mealer et al., 2013; Glat et al., 2016). Similarly, overexpression of genes known to be involved in neuroprotection were also shown to partially protect against 3-NP toxicity (Martínez-Turrillas et al., 2012; Jovicic et al., 2013). Neither of these approaches however is likely to unveil naturally occurring genetic variants that could explain strain-specific resistance or susceptibility, since either inactivation or overexpression of the identified genes is not only out of the normal range of natural variation but also often interfere with unrelated pathways.

Forward genetics using linkage analyses provides an unbiased strategy to screen for relevant susceptibility and resistance genes *in vivo*. Recombinant inbred (RI) strains have been an invaluable resource for genetic mapping of Mendelian quantitative traits in the mouse over the past several decades. Conventional mouse RI strains are developed by crossing two inbred parental strains and sequentially mating the resulting siblings for over 20 generations to ensure that they are at least 99% inbred (Williams et al., 2001; Mulligan et al., 2017). For our study, the RI strains utilized, are derived from a cross (**X**) of the parental C57BL/6J (**B**6) and DBA/2J (**D**2) strains, therefore referred to as BXDs. This panel of strains has been densely genotyped and the genomes of both parental strains have been sequenced at a high level of genomic coverage. Over 6 million sequence variants segregating between B6 and D2 and among the BXD set of strains have now been identified, including nearly 12,000 missense mutations, over 11,000 small insertions and deletions in coding regions, and nearly 16,000 copy number variants spanning one or more exons (Wang et al., 2016; Ashbrook et al., 2021). In addition, gene expression has been profiled in multiple brain regions, including whole brain and striatum for the parental strains and BXD strains using traditional microarray platforms and next generation RNA sequencing. These expression resources allow for the identification of genes whose expression is controlled by a sequence variant within or near the cognate gene — a *cis* expression quantitative trait locus (eQTL) (Schadt et al., 2003; Chesler et al., 2005). The success of using BXDs for high throughput genetic screening is underscored by recent endeavors such as the identification of specific genes and gene variants that confer immunological resistance to Chlamydia (Myiari et al., 2007; Myiari et al., 2012), modulate cognitive aging (Neuner et al., 2016), extend longevity (Merkwirth et al., 2016) or influence cognition in Alzheimer's disease (Heuer et al., 2020).

Using sub-acute 3-NP administration, we have found that while 3-NP treatment induces extensive striatal lesions in the BXD parental B6 strain, the parental D2 strain is completely resistant, with no signs of striatal damage. By analyzing striatal integrity/neuronal cell death in a panel of BXD strains treated with 3-NP, we found that resistance to 3-NP is a highly heritable trait that maps to a 1.2 Mb region in Chromosome 7. Among the possible genes, we identified *Ccnd1*, the gene encoding cyclin D1, as a potential major modulator of 3-NP induced striatal neurodegeneration.

2. Materials and Methods

2.1. Animals

C57BL/6J (B6), DBA/2J (D2) and BXD recombinant inbred strains were bred and maintained in a pathogen-free facility at UTHSC. Mice were maintained on a 12hr light/dark cycle, fed standard chow (Harlan Teklad 7912) and provided with water and food *ad libitum*. All animal experiments were approved by the Institutional Animal Care and Use Committee at University of Tennessee Health Science Center (Memphis, TN) and are in accordance with the National Institutes of Health guide for the care and use of Laboratory animals.

2.2. 3-nitropropionic acid administration

3-nitropropionic acid (Sigma N5636) was prepared fresh weekly in phosphate-buffered saline at a concentration of 5 mg/ml and stored at 4 °C. Mice were injected intraperitoneally (IP) with 50 mg/kg 3-NP twice a day for a period of 3 to 5 days, leading to cumulative doses of 300 to 500 mg of 3-NP.

2.3. Assay for succinate dehydrogenase (SDH) activity

SDH activity was determined as described (Ahmad et al., 2018) with some modifications. Briefly, cerebral cortex, striatum and whole brain from two-month-old untreated and 3-NP treated D2 and B6 female mice were homogenized in ice-cold isolation buffer (10 mM Tris pH 7.4, 1 mM EDTA, 320 mM sucrose). The homogenate was then centrifuged at 1,300 g for 10 min at 4 °C. The post-nuclear supernatant was used for SDH determinations. Protein concentrations were determined using the Bradford method. For SDH activity, each reaction mixture contained 100 μg of protein sample in phosphate buffer containing 3 mM ferricyanide (FeIII) as electron acceptor. The reaction was initiated by addition of 50 mM succinate and SDH activity was determined by calculating the rate of decrease in OD at 420 nm, which corresponds to the rate of potassium ferrocyanide (FeII) formation. As controls, protein extracts were incubated in the same reaction buffer in the absence of succinate or in the presence of 50 mM malonate, an SDH inhibitor.

2.4. Histological analyses

Brains were dissected and fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS) for one week; incubated for 24 hours at 4 °C in PBS containing 0.25 M sucrose, 0.2 M glycine; dehydrated; cleared with toluene; and embedded in paraffin. Paraffin blocks were sectioned at 7 μm, mounted in superfrost slides (Fisher) and stained with haematoxylin and eosin (H&E).

2.5. Immunohistochemistry

Slides were deparaffinized, rehydrated, and incubated with 0.3% H_2O_2 in methanol for 20 min to quench endogenous peroxidase. Sections were then washed with PBS, blocked for 1 hr with 4% BSA, 0.2% Triton X-100 in PBS, and incubated at 4 °C overnight with primary rabbit polyclonal anti-DARPP-32 (AB 1656, Chemicon) or rabbit monoclonal anti-cyclin D1 (MA5–14512, Invitrogen), in 0.4% BSA; 0.2% Triton X-100 in PBS. For the detection of cyclin D1, antigen retrieval was performed by microwaving the slides for 15 min in a microwave safe dish containing antigen-unmasking solution (H-3300, Vector), according to manufacturer's instructions. In all cases, following primary antibody incubation, slides were washed three times with PBS, and primary antibody detection was carried out using the Vector ABC Elite kit according to manufacturer's instructions, followed by incubation with DAB brown substrate (BD Biosciences). Slides immunostained for cyclin D1 were counterstained with hematoxylin QS (H-3404, Vector).

2.6. Counts of Cyclin D1 positive neurons

Cyclin D1 positive neurons were quantified by counting the total number of neurons and number of cyclin D1-stained nuclei in cross sections of the striatum of untreated and 3-NP-treated D2 and B6 mice (n = 3 for each strain and condition). For each case, four images per striatal area of both hemispheres from at least two independently stained forebrain coronal sections were captured using 10X objective and divided into quadrants. Neuronal counts were performed using Image J, as described (Dietrich et al., 2017).

2.7. Quantitative Trait Loci mapping

Quantitative trait locus (QTL) mapping was performed using the GeneNetwork web resource (www.genenetwork.org). Interval mapping was performed by genotype regression against trait values in combination with whole genome permutation to determine the significance threshold for the association between genotype and trait expression. A permutation test establishes genome-wide significance criteria of $p < 0.05$. Three-month old females (n = 2 or 3 per strain) were treated with 3-NP as described above, always paired with at least one sensitive age-matched B6 female as a positive control. Mice were weighed daily during the course of the 3-NP treatment and assessed daily for behavioral changes. Sensitivity or resistance to 3-NP was scored by histological analyses: presence of lesion with overt neuronal cell loss was scored as sensitive (−1) while lack of lesion with no overt signs of neuronal cell loss was scored as resistant (+1).

2.8. Gene expression data

Gene expression data of B6, D2 and their BXD progeny strains were derived from the open access GeneNetwork and GeneNetwork2 databases (gn1.genenetwork.org; gn2.genenetwork.org). Gene expression data for the mouse *Ccnd1* mRNA encompassing the last coding exon/proximal 3'UTR and mid-to distal portions of its 3'UTR in striatum, hippocampus, prefrontal cortex and whole brain were derived from the HBP Rosen Striatum M430v2 PDNN clean, Hippocampus Consortium M430v2 (Jun06) RMA, VCU BXD PFC Sal M430 2.0(Dec06) RMA, and INIA Brain mRNA M430 RMA databases, respectively.

Gene expression data was restricted to probe sets that showed 100% gene specificity, which was verified using the Basic Local Alignment Search Tool (BLAST).

Log2 values were converted to normal scale values prior to ratio determination and graphing.

2.9. Semi-quantitative RT-PCR

Semi-quantitative RT-PCR was performed as described (Dietrich et al., 2011). Briefly, brains were dissected and total RNA was isolated from cortex and striatum of 3 month-old B6 (n=3) and D2 (n=3) female mice using Trizol reagent (GIBCO-BRL), according to the manufacturer's instructions. For reverse transcription, samples were first treated with RQ1 DNAse (to remove DNA contaminants), 1μg total RQ1 DNAse-treated RNA was annealed with random hexamers and first strand cDNA synthesis was carried out using SuperScript IV First Strand Synthesis System (Invitrogen). For each pair of primers, 1.5μl of each RT reaction (equivalent to 75 ng of starting mRNA) was used for semi-quantitative PCR amplification. All PCR reactions were carried out in the same conditions: 45 sec denaturation at 94 °C, 45 sec annealing at 61 °C, and 1 min extension at 72 °C using the pairs of primers specific for Ccnd1: C3 5'-TCCTCAACGACCGGGTGCTG-3' and C4 5'-GGAAGCGGTCCAGGTAGTTCA-3', which amplify a 200 bp product, and MD1 5'-GAGGAAAATTAGGGGACTCCAAA-3' and MD4 5'-GGCATCTGTAAATACACTCTATGA-3', which amplify a 388 bp product.

For internal control, 18S rRNA was PCR amplified as above, using the primers 18Sfor 5'-GGTGGTGGTGCATGGCCGTT-3' and 18Srev 5'-GCAGCCCCGGACATCTAAGG-3' which amplify a 200 bp product.

PCR reactions products were fractionated in 2% agarose gels and stained with ethidium bromide. Images were captured in high definition and band intensities were analyzed by Image J.

2.10. MicroRNA binding sites

To identify the location of putative microRNA (miR) binding sites in the Ccnd1 mRNA 3'UTR, we used miRDB (mirdb.org) an online database for miR target prediction. The whole sequence of the mouse Ccnd1 mRNA 3'UTR (2676bp) was screened for potential miR binding sites, and the locations of sites with target scores above 85 were then annotated.

2.11. Statistics

Data presented are shown as mean ± SD. Data were derived from multiple independent experiments from distinct mice. Animal studies were performed without blinding of the investigator. No statistical method was used to predetermine sample size, but sample size was based on preliminary data and previous publications. In all experiments the differences were considered significant when $p < 0.05$. Open access software was used in most cases. Student's *t*-test was used for comparison of two groups.

3. Results

Although a large fraction of 3-NP studies has been done in rats, several studies have demonstrated that in both, rats and mice, 3-NP striatal neurotoxicity depends on the strain employed (Schauweker, 2005; Brouilllet et al., 2005). Taking this observation into account, we decided to investigate whether the BXD parental strains, B6 and D2, display differences in susceptibility to 3-NP toxicity, which, if so, would justify the continuation of the analyses using the BXD family.

3.1. 3-NP induces striatal neurodegeneration in B6 but not in the D2 strain

Two- to three-month-old D2 (n = 7) and B6 (n = 7) females were injected intraperitoneally (IP) with 50 mg/kg 3-NP twice a day and their behavior and weight monitored daily. After 3 to 4 days of systemic 3-NP administration (total cumulative dose of 300–400 mg/kg), all B6 females became runted, displayed reduced locomotive activity and a head tilt. In contrast, D2 females injected twice daily for a period of 5 consecutive days (total cumulative dose of 500 mg/kg) did not exhibit any abnormal behavior. Females from both strains exhibited a comparable weight loss of about 10% of their initial weight (Fig. S1A), indicating that both strains metabolized the drug similarly. Notably, striatal SDH activity was reduced at a similar rate in both strains, attaining almost complete inhibition of SDH activity after a cumulative 3-NP dose of 200 mg/kg (Fig. S1B), providing direct evidence that differences observed in the two strains are not due to differences in the bioavailability of 3-NP. All mice were sacrificed a few hours after the last injection, and brains were collected and processed for histological analyses. Analyses of unstained and H&E-stained coronal paraffin sections revealed extensive striatal lesions in the brains of all B6 females while no signs of lesions were observed in the brains of D2 females (Fig. 1A-D). Immunohistochemistry for DARPP-32 confirmed extensive medium spiny neuronal cell loss in the striatum of the B6 mice while most neurons were spared in the D2 strain (Fig. 1E, 1F). Importantly, similar results were obtained with age-matched males of each strain (n = 3), suggesting that the mechanism that confers sensitivity in B6 strain and resistance in D2 strain is conserved between males and females.

To ascertain whether this differential response to 3-NP is maintained in adulthood, 12–15-month-old females and males of each strain were subjected to the same experimental procedure. Remarkably, adult B6 females (n = 7) and males (n = 4) exhibited an even more substantial sensitivity to 3-NP, with extensive striatal damage observed with cumulative doses as low as 200 mg/kg, while no lesions were observed in age-matched D2 females (n = 3) or males (n = 3) with cumulative doses as high as 500 mg/kg.

These data indicated that there is a clear phenotype distinction between the two strains, regardless of sex and age, and suggested that the use of BXDs for genetic screen to identify modifiers of 3-NP toxicity would likely lead to the identification of loci that confer resistance to 3-NP-induced striatal neurodegeneration.

3.2.   Forward genetics identifies a 1.2 Mb interval in chromosome 7 that confers resistance to 3-NP neurotoxicity

In order to map potential neuroprotective loci, three-month-old females from 18 randomly selected BXD strains (n = 2 to 3 per strain) were IP injected with 50 mg/kg 3-NP twice a day for 5 consecutive days. For each experimental batch, at least one B6 female was also injected in parallel, as a positive control. Similar to the parental strains, all BXD strains exhibited comparable weight loss during the course of 3-NP administration, but variable behavior at endpoint, ranging from no behavioral abnormalities even with a cumulative dose of 500 mg/kg to severe compromise including runted body, reduced locomotive activity and a head tilt with doses as low as 300 mg/kg. Mice were sacrificed at day 5, and brains processed for paraffin embedding. Histological analyses of coronal brain sections spanning the striatal region revealed that 14 of the 18 strains showed no signs of neuronal loss, recapitulating the resistant phenotype of the parental D2 strain while the other 4 exhibited an identical outcome as the susceptible parental B6 strain, that is, a visible lesion characterized by extensive neuronal cell loss (Fig. 2) and (Fig. S2).

The heritability of the resistance trait allowed us to identify one strong QTL linked to 3-NP resistance in Chromosome 7, with a significant likelihood ratio statistic (LRS) score at 144.1–145.3 Mb interval (Fig. 3). This region contains 12 known genes (Table 1), and literature search pointed to *Ccnd1* (the gene encoding cyclin D1) as the strongest candidate for differential 3-NP sensitivity in parental and BXD strains since aberrant cell cycle re-entry, marked by increased expression of cyclin D1, is a hallmark of neurodegeneration (Park et al., 2000; Akashiba et al., 2008; Liu et al., 2010; Folch et al., 2012; Pelegri et al.,2008; Frade and Ovejero-Benito, 2015).

Significantly, haplotype analyses revealed that all the BXD strains carrying the D2 Ccnd1 allele were resistant to 3-NP-induced striatal neurodegeneration, while the BXD strains sensitive to 3-NP all carried the B6 *Ccnd1* allele.

3.3.   3-NP induces Cyclin D1 expression in striatal neurons of the B6 strain

To evaluate the genetic differences between the two strains we first identified single nucleotide polymorphisms (SNPs) between the B6 and D2 *Ccnd1* alleles (ENSMUSG00000070348) using a bioinformatics approach. This analysis revealed the presence of 39 sequence variants in the *Ccnd1* allele between the two strains, most of them located either in introns or in the regulatory 3'UTR of the *Ccnd1* gene, while the only variant located in the coding region is predicted to be silent. These observations suggested that differences in regulation of *Ccnd1* mRNA expression, stability or translation could be the underlying basis for the differential sensitivity/resistance to 3-NP between the two strains.

It has been shown that *in vitro* and *in vivo* exposure to 3-NP leads to increased cyclin D1 expression in striatal neurons, and this induction precedes neuronal apoptotic cell death (Akashiba et al., 2008; Pelegri et al., 2008). Because most SNPs are located in the 3'UTR regulatory region of *Ccnd1*, we sought to determine if differential regulation of cyclin D1 in response to 3-NP could be the underlying cause of differential resistance/sensitivity between

the two strains. To test this hypothesis, we performed immunohistochemistry for cyclin D1 in untreated and 3-NP treated B6 and D2 brain coronal sections spanning the striatal region, prior to overt neurodegeneration. Our analyses revealed a significant 3.5-fold increase in the number of cyclin D1 positive neuronal nuclei in the B6 striatum compared to the D2 strain in response to 3-NP administration (Fig. 4).

3.4. *Ccnd1* mRNA 3'UTR is alternatively processed in the B6 striatum

To gain further insight into the possible mechanisms underlying the differential cyclin D1 induction, we obtained the data regarding *Ccnd1* mRNA expression in the striatum of B6 and D2 strains from databases at GeneNetwork2 (gn2.genenetwork.org, see materials and methods) to determine whether basal levels of *Ccnd1* expression differ between the two strains. Intriguingly, we found that *Ccnd1* mRNA probes that recognized the last exon, proximal 3'UTR and mid 3'UTR showed similar striatal expression between B6 is and D2. In contrast, *Ccnd1* mRNA probes that recognized the mid-to-distal portion of the 3'UTR showed a dramatic difference in striatal expression between B6 and D2, with this region demonstrating ~70% less abundance in B6 relative to D2 (Fig. 5). This observation prompted us to investigate if this phenomenon occurs in other brain regions as well. For this, we obtained the available data regarding Ccnd1 mRNA last exon and mid-to-distal 3'UTR expression in cerebral cortex, hippocampus, and whole brain of B6 and D2 strains from databases at GeneNetwork (gn2.genenetwork.org, see materials and methods). As shown in Fig. 5, in the cortex and hippocampus the mid-to-distal portion of the 3'UTR is marginally less represented in B6 Ccnd1 transcripts than in D2, and this difference is even lower in other brain regions, raising the possibility that Ccnd1 mRNA transcripts undergo differential post-transcriptional alternative processing preferentially in the striatum. The Affymetrix data was further confirmed by semi-quantitative RT-PCR in cortex and striatum mRNA derived from B6 and D2 mice, using pairs of primers specific for the Ccnd1 coding region and mid-to-distal 3'UTR (Fig. 6).

3.5. The mid-to-distal *Ccnd1* mRNA 3'UTR contains highly conserved negative regulatory elements

The mechanisms involved in the regulation of cyclin D1 expression have mostly been studied and defined in the context of cancer. In human cancer cell lines it is well established that expression of cyclin D1 is negatively regulated by small non-coding microRNAs (miRs) that bind to specific sites located in the mid-to-distal portion of the *CCND1* mRNA 3'UTR (Sander et al., 2005; Jiang et al., 2009), raising the possibility that this regulatory function might be conserved in the mouse *Ccnd1* mid-to-distal 3'UTR and play a role in regulating cyclin D1 expression in response to stress in neuronal cells. For this, we first performed sequence alignment between the mouse *Ccnd1* 3'UTR and human *CCND1* 3'UTR. Sequence alignment between the human and mouse 3'UTR revealed a high degree of homology (78%) between the mouse mid-to-distal portion and the corresponding portion of the human 3'UTR, while flanking sequences share less than 30% homology (Fig. S3). To investigate the distribution of miR binding sites along the 3'UTR of the mouse Ccnd1 gene, we then performed *in silico* analysis using the miRDB-MicroRNA target prediction website (www.mirdb.org). We found that binding sites for miR 503–5p, and miR 202–3p, which have been shown to negatively regulate the expression of human cyclin D1 and decrease

cell proliferation in cancer cell lines (Jiang et al., 2016; Yi et al., 2016; Peng et al., 2019), are conserved in the mouse and are present exclusively in the mid-to-distal portion of the mouse *Ccnd1* 3'UTR (Fig. 6A, Fig. S3). Altogether, these observations suggest that the lack of negative regulatory elements in most of B6 *Ccnd1* transcripts may be responsible for the high levels of 3-NP-induced cyclin D1 protein expression, while retention of negative regulatory elements in D2 *Ccnd1* transcripts is sufficient to blunt the induction of cyclin D1 protein expression in response to 3-NP (Fig. 4).

3.6. Alternative processing of the mid-to-distal 3'UTR in the striatum is dictated by the parental origin of the *Ccnd1* allele

To investigate whether the differential striatal alternative processing of the mid-to-distal 3'UTR is a heritable trait and if it is regulated *in cis* or *in trans*, we obtained the Affymetrix *Ccnd1* expression data of 30 random BXD strains (see materials and methods) and organized the data according to the parental origin of their *Ccnd1* alleles. Strikingly, similar to the B6 parental strain, all the BXD strains that carry the B6 *Ccnd1* allele also display a significant relative reduced expression of the mid-to-distal 3'UTR specifically in the striatum while this region is mostly retained in other brain regions (Fig. 7). Likewise, similar to the parental D2 strain, the mid-to-distal *Ccnd1* 3'UTR is mostly retained in the striatum and other brain regions of all the BXD strains that carry the D2 *Ccnd1* allele (Fig. 7). These data strongly indicate that cis-elements present in the *Ccnd1* alleles are responsible for differential post-transcriptional processing of the mid-to-distal portion of the 3'UTR in the striatum.

In conclusion, our results strongly suggest that the D2 *Ccnd1* variant underlies resistance to 3-NP-induced striatal neurodegeneration while the B6 *Ccnd1* variant confers sensitivity and point to striatal-specific alternative post-transcriptional processing as a potential mechanism underlying strain and brain region selective 3-NP-induced neurotoxicity.

4. Discussion

In humans and animals, 3-NP exposure results in widespread impairment of energy metabolism throughout the brain but only the basal ganglia, and in particular the striatum (caudate and putamen) undergo selective neurodegeneration (Bizat et al., 2003; Brouillet et al., 2005; Bonsi et al., 2006). The mechanisms underlying regional selective neuronal cell loss are still poorly understood. Over the years, several hypotheses have been proposed, but the most widely accepted explanation is that glutamatergic input from the cortex predisposes striatal neurons to excitotoxic and oxidative stress damage, and that their GABAergic nature also contributes to their increased sensitivity (Alexi et al., 1998; Brouillet et al., 2005). Significantly though, *in vitro* studies have shown that Wistar rats' striatal neurons are intrinsically more sensitive than cortical neurons to 3-NP-induced cell death (Akashiba et al., 2008), ruling out that glutamatergic input is required for their increased 3-NP sensitivity and suggesting instead that cell autonomous mechanisms may be important contributing factors. Consistent with this assumption, though 3-NP exposure *in vitro* induces cell death in both striatal and cortical neurons, the pathways leading to cell death differ between the two neuronal cell types. Notably, 3-NP exposure induces up-regulation of cyclin D1 and cell

cycle-re-entry in striatal neurons but not in cortical neurons and pharmacological inhibition of cyclin D-dependent kinases 4 and 6 (CDK4/6) significantly reduces 3-NP-induced cell death in striatal neurons but has little effect in cortical neurons (Park et al., 2000; Akashiba et al., 2008). Though these results point to an important role of cyclin D1 and cell cycle re-entry in 3-NP-induced striatal neuronal cell death *in vitro*, the mechanisms leading to differential 3-NP-induced cyclin D1 upregulation in striatal neurons *in vivo* (Pelegri et al., 2008; Duran-Vilaregut et al., 2011), as well as its role in 3-NP-induced striatal neurodegeneration remain to be elucidated.

In this study we have shown that, contrary to the commonly used B6 mouse strain, the D2 strain is highly resistant to 3-NP-induced striatal neurodegeneration. This trait is highly heritable, and using unbiased forward genetics, we have found that a genetic variant located in a 1.2 Mb region in Chromosome 7 accounts for the differences in sensitivity between the two strains. In view of the literature linking cyclin D1, cell cycle re-entry and 3-NP-induced neurodegeneration, out of the 12 possible genes we identified *Ccnd1* (the gene encoding cyclin D1) as a strong candidate. Our analyses showed that 3-NP induces cyclin D1 in B6 striatal neurons but not in D2 and that cis-elements present in the B6 *Ccnd1* allele lead to striatal-specific post-transcriptional alternative processing of the *Ccnd1* mRNA regulatory 3'UTR.

The mechanisms of regulation of cyclin D1 expression have so far been studied mostly in the context of cancer. *CCND1* represents the second most frequently amplified locus in the human cancer genome (Beroukhim et al., 2010). Interestingly, in most tumors that exhibit elevated cyclin D1 levels, two types of transcripts are present due to alternative post-transcriptional processing and polyadenylation, with the long transcript containing the full-length 3'untranslated region (3'UTR) of the *CCND1* mRNA and the short transcript lacking most of the mid and distal 3'UTR region (Xiong et al., 1991; Mayr and Bartel, 2009). Not only do cancer cells expressing predominantly the short transcript exhibit higher rates of proliferation than those expressing mostly the long transcript (Sander et al., 2005; Slotta-Huspenina et al., 2012), but genetic editing of the 3'UTR favoring preferential expression of the short transcript leads to acceleration of cell cycle re-entry and high rates of cell proliferation (Sander et al., 2005; Wang et al., 2018). Negative regulation of cyclin D1 protein levels is mediated through binding of small non-coding RNAs, miRs, to the mid/distal 3'UTR of the *CCND1* long transcript, thereby reducing mRNA translation (Deshpande et al., 2009). Several miR binding sites have been identified in the mid-to-distal *CCND1* 3' UTR (Deshpande et al., 2009; Jiang et al., 2009), and the essential negative regulatory function of some of them have been confirmed experimentally. For instance, it has been demonstrated that miR 503 and miR 202 bind to the mid-to-distal region of the *CCND1* 3'UTR, and that overexpression of either miR 503 or miR 202 reduce cyclin D1 protein levels in cancer cells and halt cell proliferation, while their downregulation increases cell proliferation (Long et al., 2015; Jiang et al., 2017; Qi et al., 2018; Jiang et al., 2016; Yi et al., 2016; Peng et al., 2019). While the mechanisms leading to reduced retention of the mid-to-distal 3'UTR of *Ccnd1* transcripts in B6 striatal neuronal cells have yet to be established, the high degree of sequence conservation between the mouse and human mid-to-distal portion, including the miR binding sites, suggest that the function of this region is also conserved in the mouse, implying that in B6 *Ccnd1* transcripts are likely to be

more stable in the striatum, which could explain the increased cyclin D1 expression seen in B6 striatum in response to 3-NP.

In dividing cells, the first stage of the cell cycle, the G1 phase, is initiated by increased levels of members of the cyclin D family, followed by activation of CDKs and phosphorylation of the tumor suppressor protein retinoblastoma, which in turn leads to activation of the E2 promoter-binding factor (E2F) family of transcription factors. Active E2F in turn induces transcription of various genes involved in cell cycle, ultimately resulting in mitosis in dividing cells. *In vitro* and *in vivo*, increased cyclin D1 expression in striatal neurons in response to 3-NP leads to activation of cell cycle re-entry pathway (Park et al., 2000; Akashiba et al., 2008; Pelegri et al., 2008). However, in contrast to most cell types, in which cell cycle re-entry leads to cell proliferation, in neuronal cell cycle re-entry instead leads to apoptosis. This has been demonstrated *in vitro,* in several paradigms, including excitotoxicity, oxidative stress and DNA damage (Stefanis et al., 1999; Kruman et al., 2004; Zhang et al., 2020; Park et al., 1997; Park et al., 1998; Akashiba et al., 2008), as well as *in vivo* in mouse models of traumatic brain injury (Hilton et al., 2008; Kabadi et al., 2012a, Kabadi et al., 2012b; Kabadi and Faden, 2014). Notably, inhibition of cell cycle re-entry in all these paradigms exerts significant neuroprotective effect. It is likely therefore that the absence of cyclin D1 induction in the D2 strain prevents cell cycle re-entry, and this appears to be sufficient to prevent 3-NP induced neurodegeneration in this strain.

While the mechanisms leading to cell cycle re-entry and consequent apoptosis following 3-NP exposure are still far from being elucidated, the current knowledge points to 3-NP-induced oxidative stress and oxidative DNA damage as the initial trigger. One of the first and main intracellular effects of 3-NP is the generation of reactive oxygen species (ROS), including hydrogen peroxide (H_2O_2), superoxide anion and hydroxyl radicals, which are known to cause oxidative DNA damage (Liot et al., 2009). Notably, both oxidative damage and neuronal cell loss induced by 3-NP are reduced by antioxidants (Pedraza-Chaverri et al., 2009; Colle et al., 2009; Gao et al., 2015), while mutations in SDH subunits were shown to cause genomic instability (Owens et al., 2012). The mechanisms by which DNA damage elicits cell cycle re-entry in neurons is still not clear. One hypothesis is that post-mitotic neurons re-enter the cell cycle as part of their DNA repair response (Kim and Tsai, 2009; Tomashevski et al., 2010; Zhang et al., 2020). In support of this hypothesis, inhibition of cell cycle re-entry decreases DNA double strand break repair in neurons exposed to DNA damaging agents (Schwartz et al., 2007; Tomashevski et al., 2010). It is currently not known however why in some circumstances neuronal cell cycle re-entry leads to apoptotic cell death. One appealing possibility is that when DNA damage exceeds a certain threshold, due to the decreased baseline levels of DNA repair proteins in neurons, cell-cycle checkpoint responses are hindered and instead of DNA being repaired leading to cell cycle progression, neuronal cells enter the apoptotic pathway (Kim and Tsai, 2009; Schwartz et al., 2007).

Although our analyses indicate that strain-specific *Ccnd1* genetic polymorphisms account for resistance or susceptibility to 3-NP-induced striatal neurodegeneration in mice, in terms of translatability it would be of great importance to determine if similar genetic modifiers of complex II deficiency-induced neurodegeneration also exist in humans. Genetically inherited complex II deficiency is rare, but even within a limited number of patients

the age of onset and range of neurological abnormalities vary extensively despite similar reductions in enzymatic activity, with most patients displaying lesions in the basal ganglia in infancy while others display adult-onset cerebellar atrophy with no involvement of the basal ganglia (Jain-Ghai et al., 2013). Significantly, though the neurological findings vary between individuals, they are strikingly similar between family members (Jain-Ghai et al., 2013), suggesting that epigenetic factors may play an essential role in the age of onset and pathology caused by complex II deficiency. Likewise, the well documented outbreaks of human poisonings with 3-NP also resulted in variable neurological involvement, with bilateral basal ganglia lesions and consequent permanent dystonia observed in only about 50% of the cases (Peraica et al., 1999), further strengthening the likelihood that as in mice genetic factors play an essential role in conferring resistance to 3-NP-induced striatal lesions in humans. Whether polymorphisms in the *CCND*1 gene play a role in these differential outcomes or not remain to be determined. Genetic polymorphisms in *CCND1* exist in the human population, with some polymorphisms linked to increased susceptibility to cancer or increased malignancy (Diehl, 2002; Knudsen et al., 2006; Wang et al., 2014), and others predicted to alter cyclin D1 function (Aftab et al., 2021), however their potential role in neurodegeneration has not been evaluated so far.

Our findings may also have implications to the pathology of Huntington's Disease (HD). HD is an autosomal dominant neurodegenerative disorder caused by expansion of a CAG tract in the amino terminal portion of the protein Huntingtin (Walker, 2007). Although several genetic models of the disease have been generated over the past decades, none of them genetic models recapitulate the extensive striatal neuronal cell death of HD. In contrast, 3-NP models of HD recapitulate not only HD neuropathology but also biochemical and phenotypic manifestations and have been extensively used to investigate mechanisms of HD (Túnez et al., 2010). Importantly, biochemical studies in HD brain tissues have shown a consistent deficit in mitochondria complex II in the caudate and putamen, associated with 50–70% reduction in SDH activity (Gu et al., 1996; Browne et a., 1997). Importantly, restoration of complex II function abolishes cell death in genetic cellular models of HD, indicating that complex II deficits play a significant role in the disease pathology (Benchoua et a., 2006). Interestingly, evidence of cell cycle re-entry has been shown in cellular and animal models of HD, including elevated levels of cyclin D1 (Gines et al., 2003), cdk4 (Fernandez-Fernandez et al., 2011), cyclin B1, and activated cdk5 (Liu et al., 2015; Paoletti et al., 2008). Significantly, evidence of cell cycle re-entry, including elevated levels of cyclin D1, cdk4, E2F-1, and cyclin E (Pelegri et al., 2008; Fernandez-Fernandez et al., 2011) is also seen in HD patients' striata. The possible direct role of cyclin D1 and cell cycle re-entry in HD striatal neuronal cell death has not been investigated so far. However, epigenetic factors are known to modulate the age-of-onset and the progression of striatal neuronal cell death in HD (Reiner et al., 2011; Gusella et al., 2014) and increased expression of cell cycle-related genes is positively associated with the severity of HD in mice (Langfelder et al., 2016), suggesting that genetic polymorphisms in CCND1 or other cell cycle-related genes might modulate HD neuropathology.

In summary, our study suggests that preventing 3-NP-induced cyclin D1 expression might be sufficient to promote resistance to 3-NP-induced striatal neurodegeneration, making cyclin D1 and its downstream pathway possible therapeutic targets for neurodegenerative

Author Manuscript

disorders in which mitochondrial complex II is compromised. These results can potentially be extended to other neurodegenerative disorders as well, since increased cyclin D1 and evidence of cell cycle re-entry is also a hallmark of amyotrophic lateral sclerosis, Alzheimer's disease, and Parkinson's disease (Liu et al., 2010; Folch et al., 2012; Frade and Ovejero-Benito, 2015). Further understanding of the mechanisms underlying regulation of expression of cyclin D1 in response to cellular stress and its role in different neuronal cell types may open new avenues for novel therapeutic strategies for different neurodegenerative disorders.

Highlights

- 3-nitropropionic acid (3-NP) induces striatal lesions in C57BL/6J (B6) but not in DBA/2J (D2) mice

- Forward genetics identified *Ccnd1* (cyclin D1) as a strong candidate for strain-specific 3-NP response

- 3-NP induces cyclin D1 expression in B6 striatum but not in D2

- *Ccnd1* mRNA's 3'UTR is alternatively processed in B6 striatum

- Alternative B6 striatal-specific 3'UTR processing is predicted to increase cyclin D1 levels

Fig. 1.
The D2 strain is resistant to 3-NP-induced striatal neurodegeneration. Dark field images of unstained coronal paraffin sections of B6 (A) and D2 (B) brains. Note that large striatal lesions are seen in B6 but not in D2. H&E-stained coronal paraffin sections spanning the striatum of B6 (C) and D2 (D). Note the extensive neuronal cell loss in B6 striatum. (E-F) Immunohistochemistry for DARPP-32. Extensive medium spiny neuronal cell loss is demonstrated by high magnification (20X) in B6 (E), while neurons are preserved in D2 (F).

Fig. 2.
Resistance to 3-NP-induced striatal neurodegeneration is a heritable trait. (A-J) Representative images of coronal brain sections of sensitive (A,C,E,G,I) and resistant (B,D,F,H,J) BXD strains. (A-B) Dark field images of unstained coronal paraffin sections of the sensitive BXD 102 (A) and resistant BXD 60 (B) strains. (C-J) High magnification of H&E-stained coronal paraffin sections of the striatum from the sensitive BXD strains, BXD 102 (C), BXD 100 (E), BXD 43 (G), BXD 24 (I) and from the resistant BXD strains, BXD 60 (D), BXD 103 (F), BXD 27 (H), BXD 40 (J). Note the extensive cell death in the sensitive BXD strains and the preservation of neuronal integrity in the resistant BXD strains.
Fig. 3.

Recombinant inbred strains identify a 1.2 Mb resistance locus in chromosome 7. Eighteen BXD strains were treated with 3-NP and monitored for the presence or absence of striatal lesions. Results were analyzed by WebQTL software (www.genenetwork.org) and interval mapping are shown as a blue line representing the LRS score across the entire mouse genome. A single significant LRS is present in chromosome 7. All data are accessible through the GeneNetwork web site (www.genenetwork.org; trait identification (ID) BXD 15959).
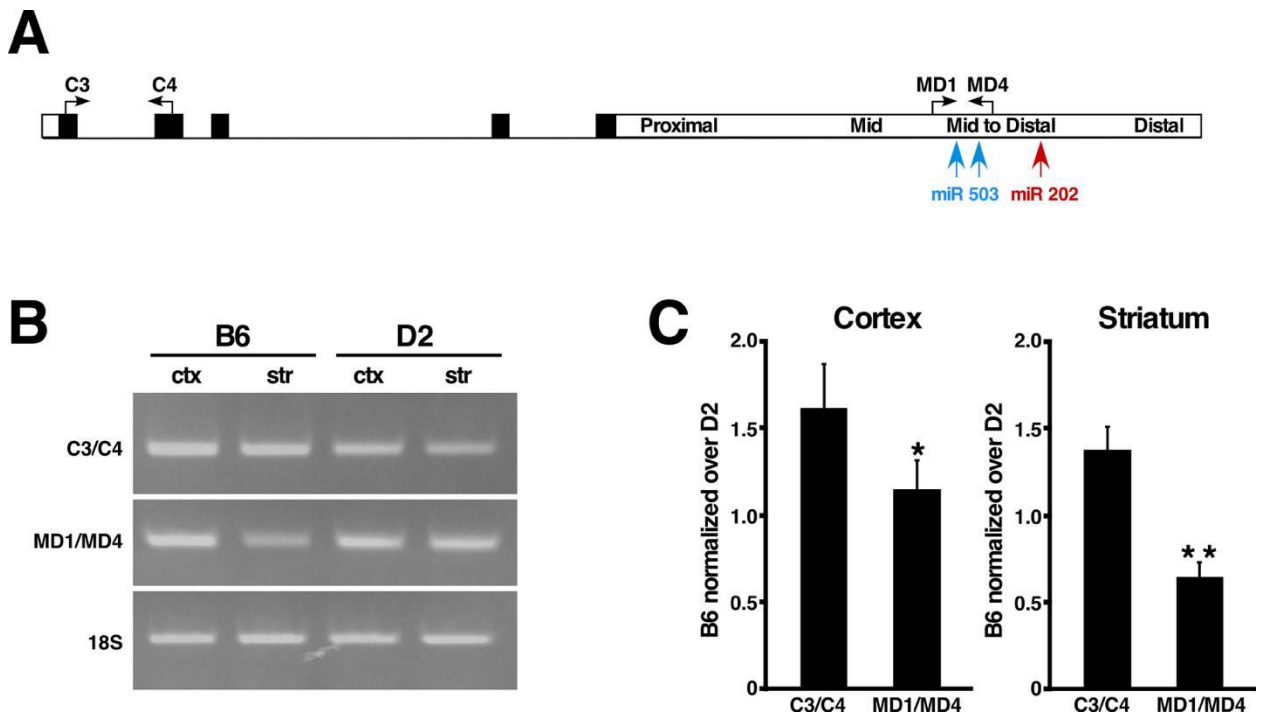

Fig. 4.
3-NP induces cyclin D1 expression in B6 but not in D2 striatal neurons. Representative immunohistochemistry for cyclin D1 in B6 (A) and D2 striatum (B). Positive signal is brown and negative nuclei are stained blue with Hematoxylin QS. (B) Graph representing percentage of cyclin D1 positive neurons in 3-NP-treated B6 (n = 4) and D2 (n = 4) striatum. Data are expressed as mean ± SD. ***p <0.001.

Fig. 5.
The mid-to-distal portion of *Ccnd1* 3'UTR mRNA is alternatively processed in B6 striatum. Affymetrix values of *Ccnd1* expression (last exon, mid and mid-to-distal 3'UTR) in Striatum, Cortex, Hippocampus and whole brain in B6 mice were normalized over the corresponding Affymetrix values of D2. Exon/prox = exon 5 and proximal 3'UTR; mid = mid 3'UTR, mid-to-dis = mid-to-distal 3'UTR.

Fig. 6.
Semi-quantitative RT-PCR confirms preferential alternative processing of the mid-to-distal 3'UTR in B6 striatum. (A) Schematic representation of the *Ccnd1* full length transcript. The positions and orientation of the oligonucleotides used for semi-quantitative RT-PCR are indicated by arrows. Black rectangles represent exons and white rectangle represent the 3'UTR. The positions of miR 503 and miR 202 are indicated in blue and red respectively. (B) Representative image of semi-quantitative RT-PCR of B6 and D2 *Ccnd1* mRNAs from cortex (ctx) and striatum (str). 18S amplification was used as internal control. (C) Band intensities of semi-quantitative RT-PCR from B6 and D2 quantified by Image J and normalized over 18S band intensity. The resulting values of B6 were then normalized over D2 values. Data are expressed as mean ± SD. *p <0.01; **p <0.005.
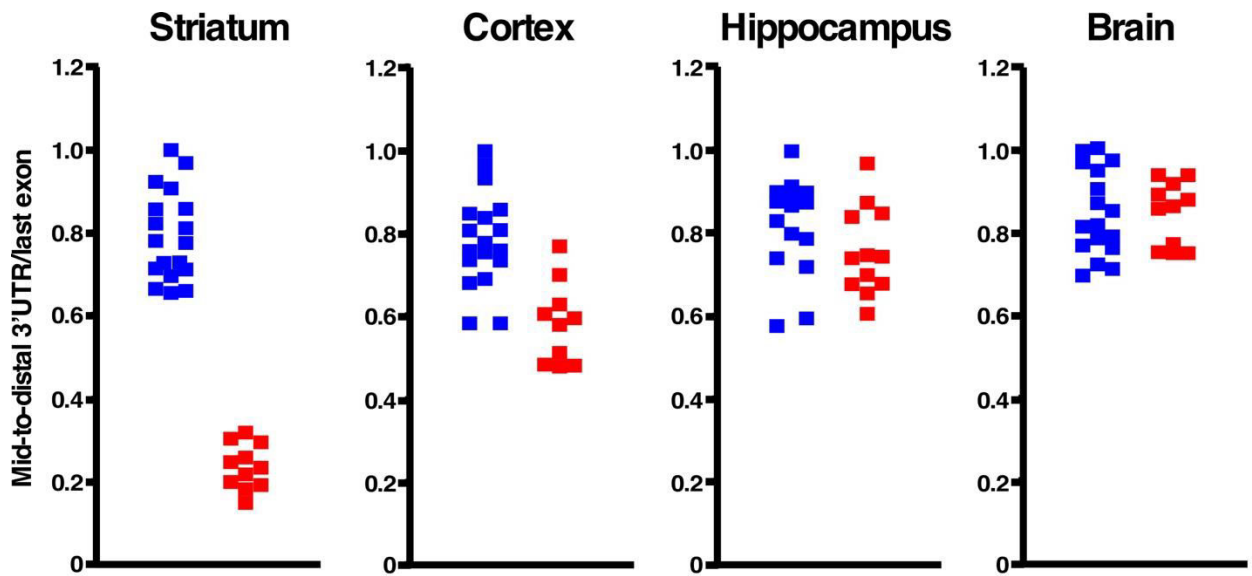

Fig. 7.

Alternative processing of the mid-to-distal 3'UTR in the striatum co-segregates with the parental B6 *Ccnd1* allele in BXDs. The graphs represent Affymetrix probe values of mid-to-distal 3'UTR over the last exon (exon 5) of *Ccnd1* coding region derived from 30 BXDs, 18 carrying the parental D2 Ccnd1 allele (blue) and 12 carrying the parental B6 *Ccnd1* allele (red). The data was organized and graphed according to the parental origin of the *Ccnd1* allele.

Table 1

The 1.2-Mb QTL on chromosome 7 contains 12 known genes

Symbol	Description	Mb Start
Shank2	SH3/ankyrin domain gene 2	144.175519
Cttn	cortactin	144.435723
Fadd	Fas-associated via death domain	144.578322
Tmem16a	transmembrane protein 16A	144.588662
Fgf3	fibroblast growth factor 3	144.838611
Fgf4	fibroblast growth factor 4	144.861385
Fgf15	fibroblast growth factor 15	144.896531
Oraov1	oral cancer overexpressed 1	144.915193
Ccnd1	cyclin D1	144.929930
Tpcn2	two pore segment channel 2	145.253922
Mrgprf	MAS-related GPR, member F	145.300908
Mrgprd	MAS-related GPR, member D	145.314834
