Abstract

Background: Coffee consumption has been associated with a reduced risk of some cancers, but the evidence for renal cell carcinoma (RCC) is inconclusive. We investigated the relationship between coffee and RCC within a large cohort.

Methods: Coffee intake was assessed at baseline in the National Institutes of Health–American Association of Retired Persons Diet and Health Study. Among 420 118 participants eligible for analysis, 2674 incident cases were identified. We fitted Coxregression models to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for coffee consumption vs non-drinkers.

Results: We observed HRs of 0.94 (95% Cl 0.81, 1.09), 0.94 (0.81, 1.09), 0.80 (0.70, 0.92) and 0.77 (0.66, 0.90) for usual coffee intake of <1, 1, 2–3 and \geq 4 cups/day, respectively ($P_{trend} = 0.00003$). This relationship was observed among never-smokers (\geq 4 cups/day: HR 0.62, 95% Cl 0.46, 0.83; $P_{trend} = 0.00003$) but not ever-smokers (HR 0.85, 95% Cl 0.70, 1.05; $P_{trend} = 0.35$; $P_{interaction} = 0.0009$) and remained in analyses restricted to cases diagnosed >10 years after baseline (HR 0.65, 95% Cl 0.51, 0.82; $P_{trend} = 0.0005$). Associations were similar between subgroups who drank predominately caffeinated or decaffeinated coffee ($P_{interaction} = 0.74$).

Conclusion: In this investigation of coffee and RCC, to our knowledge the largest to date, we observed a 20% reduced risk for intake of \geq 2 cups/day vs not drinking. Our findings add RCC to the growing list of cancers for which coffee consumption may be protective.

Key words: Coffee, caffeinated coffee, decaffeinated coffee, renal cell carcinoma, cancer, clear cell tumour, smoking, cohort

Key Messages

- The epidemiologic evidence to date relating coffee consumption to risk of renal cell carcinoma (RCC) has been inconclusive.
- In this prospective analysis of coffee intake and RCC, the largest of its kind to date, we observed a 20% reduced risk for intake of ≥2 cups/day vs not drinking. The relationship was observed among never-smokers only and did not differ between caffeinated- and decaffeinated-coffee drinkers.
- Our findings add RCC to the growing list of cancers for which coffee consumption may be protective.

Introduction

The health effects of coffee, one of the most popular beverages in the world, has been the subject of great debate. Although earlier studies led to concern over cardiovascular-disease risks,^{1,2} recent findings suggest that coffee consumption may be associated with reductions in cardiovascular disease, type 2 diabetes and overall mortality.³⁻⁶ In the case of cancer, the evidence has been similarly controversial. In 1991, the International Agency for Research on Cancer (IARC) classified coffee as a possible human carcinogen (Group 2B).⁷ However, following a 2016 re-evaluation of the scientific literature, IARC downgraded its classification of coffee, concluding that there is inadequate evidence of carcinogenicity (Group 3).⁸ The IARC panel also noted evidence of inverse associations with risk of cancers of the endometrium and liver.⁸ Since that time, additional findings suggesting reduced risks of these and possibly other cancers have been reported.^{9–13}

In the case of renal cell carcinoma (RCC), the epidemiologic evidence to date relating coffee consumption to risk has been inconclusive. A recent meta-analysis¹⁴ was null, although, in an analysis restricted to cohort studies, a weak inverse relationship was observed. To clarify this relationship, we investigated the association between coffee consumption and RCC risk in the National Institutes of Health–American Association of Retired Persons (NIH-AARP) Diet and Health Study—a large prospective cohort.

Methods

Study population

The NIH-AARP Diet and Health Study has been described.¹⁵ Between 1995 and 1996, a comprehensive questionnaire assessing diet and lifestyle was mailed to 3.5 million AARP members who were aged 50–71 years and resided in one of six US states (California, Florida, Louisiana, New Jersey, North Carolina and Pennsylvania) or two US metropolitan areas (Atlanta, Georgia and Detroit, Michigan). Of the 566 398 participants who completed the questionnaire and provided informed consent,

we excluded individuals with questionnaire data that originated from a spouse or other surrogate correspondent (n = 15760), with any self-reported cancer or diagnosed with cancer (except non-melanoma skin cancer) prior to baseline (n = 51346), with only a death record for cancer (n = 4268), with no follow-up time (n = 21), with selfreported end-stage renal disease (n = 970), with missing information on coffee intake (n=2247) and who resided outside the eligible states and metropolitan areas (n=9). We also excluded persons with self-reported history of heart disease (n = 67901) and poor health at baseline (n=3758) to avoid potential bias from changes in coffeedrinking habits arising due to illness.³ The resulting analytic cohort included 420118 participants (240095 men and 180023 women). The NIH-AARP Diet and Health Study was approved by the Special Studies Institutional Review Board of the National Cancer Institute.

Cohort follow-up and case ascertainment

Incident cases of RCC were identified through probabilistic record linkage to the eight original state cancer registries and those of three additional states (Arizona, Texas and Nevada) subsequently added to capture participants who moved to those states during follow-up. Participants were followed from baseline (1995–1996) until the date of first RCC, the date of death, the end of study follow-up (31 December 2011) or the date the participant moved out of the registry area (7.6% of subjects moved out), whichever came first. We defined RCC as a first primary malignancy with the International Classification of Disease for Oncology (ICD-O, 3rd edition) topography code C649 and histology code 8140–8575.

Assessment of coffee intake and other covariates

Participants completed a self-administered 124-item foodfrequency questionnaire (FFQ), as previously described.¹⁵ In an earlier validation of the FFQ, coffee consumption was highly correlated with intake assessed using two nonconsecutive 24-hour dietary-recall questionnaires (Spearman coefficient = 0.80).¹⁶ Usual coffee intake over the last 12 months was assessed using 10 frequency categories, ranging from none to >6 cups/day. Those who reported consuming coffee also provided information on whether they drank caffeinated or decaffeinated coffee more than half the time. We used this information to divide participants into coffee-drinking categories ranging from none to >4 cups/day and further categorized coffee drinkers as predominately caffeinated- or decaffeinatedcoffee drinkers. Information on the use of sweetener or milk/creamer when drinking coffee or tea was also obtained. We also extracted information on demographic, health and lifestyle characteristics from the baseline questionnaire such as age, sex, body mass index (BMI), marriage status, education, smoking, self-reported history of diabetes, total energy intake, alcohol consumed in the past 12 months, self-reported health, healthy eating index (HEI; a measure of diet quality)¹⁷ and state of residence. Self-reported history of hypertension was extracted from a subsequent questionnaire mailed in 1996-1997 and completed by a subset of subjects in our analytic cohort $(n = 259\,847).$

Statistical analysis

We summarized demographic and lifestyle characteristics associated with RCC by coffee intake. We fit Cox proportional-hazards models stratifying by age category at baseline (<55, 55–59, 60–64, 65–69 and \geq 70 years) to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for coffee intake with RCC using attained age as the underlying time metric.

To account for missing data among covariates (0.5% for alcohol consumption, 0.8% for marital status, 1.3% for race/ethnicity, 1.5% for self-reported health, 2.4% for BMI, 2.8% for education, 3.8% for smoking), we conducted multiple imputation using fully conditional specification implemented by the multivariate imputation by chained equations algorithm using R package 'mice'.¹⁸ We obtained 10 imputations from the models including coffee consumption, kidney cancer and aforementioned covariates. HRs were obtained for each of the 10 imputed data sets [function 'with()'] and were averaged over the 10 data sets with the overall variance estimated using the function 'pool()'.

For our analysis, we fit models adjusting only for sex as a covariate as well as full multivariable models additionally adjusting for race/ethnicity (non-Hispanic White, non-Hispanic Black, Hispanic and Asian, Pacific Islander or American Indian/Alaskan Native), BMI (<25, \geq 25 and <30, and \geq 30 kg/m²), marriage status (married or living as married, widowed/divorced/separated, never married),

education (less or completed high school, post-high school or some college, college and postgraduate), smoking (never smoked, quit <20 cigarettes/day, quit >20 cigarettes/day, currently smoking ≤ 20 cigarettes/day, currently smoking >20 cigarettes/day), self-reported history of diabetes (yes/ no), total energy intake (calories), alcohol consumption during the prior 12 months (yes/no) and state of residence. We also ran multivariable models additionally adjusting for self-reported history of hypertension within the subset of participants who completed the follow-up questionnaire capturing this condition. We estimated HRs for RCC with categories of coffee intake (<1, 1, 2–3, \geq 4 cups/day) using no coffee intake as the reference group. We also modelled coffee intake as a continuous variable based on the midpoint of coffee-intake categories (including values of 0.21 and 5 for participants in the categories of <1 and >4 cups/ day, respectively) and calculated a Wald statistic as a test for trend. We tested the proportional-hazards assumption using statistical tests based on the scaled Schoenfeld residuals and observed no indication of a violation after stratifying the baseline hazard by age category.

We conducted stratified analyses and tests of interaction to explore possible modification of the association between coffee intake and RCC by sex and race/ethnicity (e.g. from possible differences in pro- or anti-neoplastic hormonal and biologic pathways affected by coffee, or in behaviours correlated with coffee intake) as well as other risk factors (e.g. by affecting pro- or anti-neoplastic biologic pathways that are also affected by coffee). We tested for interaction by inserting model parameters specifying interaction between coffee intake (modelled as for the trend test) and other variables, including sex, race/ethnicity (non-Hispanic White, other), smoking status (never- or ever-smokers), BMI (<25 and ≥ 25 kg/m²), self-reported history of diabetes, self-reported history of hypertension and alcohol consumption in the multivariable-adjusted model. We further conducted stratified analyses across levels of the aforementioned factors. In addition, we performed subgroup analyses by consumption of predominately caffeinated vs decaffeinated coffee to assess the impact of caffeine on our findings and by RCC subtype (clear cell vs non-clear cell histology) to explore possible effects specific to pathways dysregulated in clear cell RCC. To test for relative-risk heterogeneity across tumour subtypes, we performed a caseonly analysis (clear cell vs non-clear cell) using logistic regression.¹⁹ Lastly, we conducted sensitivity analyses by repeating analyses for different follow-up periods (<5, >5and ≤ 10 , and >10 years after baseline), restricting to coffee drinkers (i.e. using <1 cup/day as the referent category), with additional adjustment for HEI and self-reported health, and stratifying on whether coffee drinkers reported adding any sweetener or milk/creamer. We used RStudio Version 1.3.1093 (http://www.rstudio.com/) for all statistical analyses. All statistical tests were two-sided.

Results

Among 420 118 participants who were cancer-free at baseline, 2674 incident cases of RCC (1981 men and 693 women) were identified. The median age at baseline was 62 years and the majority were male (57%), non-Hispanic White (91%), married (68%) and had attained more than post-high school or some college education (72%) (Table 1). Nearly 90% reported drinking coffee and, of those, 57% reported drinking ≥ 2 cups/day. At baseline, persons with higher coffee intake were more likely to be male, non-Hispanic White, current or former smokers and alcohol drinkers, and they were less likely to have a college education.

We summarized in Table 2 our findings relating coffee intake to RCC risk, both overall and by usual caffeine content. In Cox-regression models, stratifying the baseline hazard by age category and adjusting for sex only, we observed a weak inverse relationship with increasing coffee consumption (HR 0.85, 95% CI 0.73, 0.99 for ≥4 cups/ day of intake vs non-drinkers; $P_{trend} = 0.002$). When we fit the multivariable model, the inverse relationship became stronger (HR 0.77, 95% CI 0.66, 0.90; P_{trend} = 0.00003), mainly due to adjustment for smoking (9% change in HR). Additional adjustment for history of hypertension in the subset with information on this condition led to virtually identical findings (HR 0.75, 95% CI 0.61, 0.91 for \geq 4 cups/day of intake vs non-drinkers; $P_{trend} = 0.0002$). We observed a slightly stronger association with intake for people reporting consumption of caffeinated coffee more than half the time (HR 0.73, 95% CI 0.62, 0.86; $P_{trend} = 0.00003$) compared with usual consumption of decaffeinated coffee (HR 0.85, 95% CI 0.66, 1.09; $P_{trend} = 0.21$), although a test of interaction did not support effect modification by caffeine content $(P_{interaction} = 0.74).$

We also investigated associations across strata of study characteristics. When we stratified analysis by smoking status, we observed an inverse association among neversmokers but not ever-smokers (Figure 1: $P_{interaction} = 0.0009$). The association with coffee was apparent among men but not among women, although a test of interaction did not support effect modification by sex (Supplementary Table 1, available as Supplementary data at IJE online). The association with coffee also did not differ across categories of race/ethnicity, BMI, histories of self-reported diabetes or hypertension, or alcohol consumption (Supplementary Table 1, available as Supplementary data at IJE online). When we repeated our

analysis using <1 cup/day of intake as the reference category, our findings did not materially change (Supplementary Table 2, available as Supplementary data at IJE online). The inverse association was present across different periods of follow-up and was particularly strong for cases diagnosed >10 years after baseline (HR 0.65, 95% CI 0.51, 0.82 for $\geq 4 \text{ cups/day}$ of intake vs nondrinkers; $P_{trend} = 0.0005$; Supplementary Table 3, available as Supplementary data at IJE online). When we conducted separate analyses by tumour subtype, we observed a stronger inverse association for clear cell RCC (n = 926cases; HR 0.64, 95% CI 0.49, 0.82 for $\geq 4 \text{ cups/day}$; $P_{trend} = 0.0002$) compared with non-clear cell RCC (n = 1748 cases; HR 0.87, 95% CI 0.71, 1.06; $P_{trend} = 0.002$), although, in a test of heterogeneity across subtypes, the P-value was 0.13 (Supplementary Table 4, available as Supplementary data at IJE online). Additional adjustment for HEI or self-reported health did not change our findings (Supplementary Table 5, available as Supplementary data at IJE online). When we conducted a sensitivity analysis by stratifying on use of sweetener or the milk/creamer, we observed same results (Supplementary Table 6, available as Supplementary data at IJE online).

Discussion

In this large prospective US cohort, we observed an inverse relationship between coffee intake and RCC after adjustment for important risk factors, with consumption of $\geq 2 \text{ cups/day}$ associated with an $\sim 20\%$ lower risk over 16 years of follow-up. This association was observed among non-smokers but not ever-smokers and remained apparent in sensitivity analyses excluding the first 10 years of follow-up and assessing high vs low intake among coffee drinkers. The association did not materially differ between subgroups who reported drinking caffeinated coffee more than half of the time and those who reported predominantly drinking decaffeinated coffee.

Our findings provide the strongest epidemiologic evidence to date supporting an inverse relationship between coffee consumption and RCC. Past studies of this relationship have been inconsistent; a meta-analysis including 16 case-control and 6 cohort studies did not observe a relationship between coffee consumption and RCC risk.¹⁴ Case-control studies of dietary factors such as coffee are subject to recall bias, since exposures are assessed retrospectively, and to selection bias, if controls are unrepresentative of the source population for cases, the effects of which may substantially and unpredictably bias risk estimates. When the meta-analysis was restricted to cohort studies, a 12% lower relative risk per cup of coffee was **Table 1** Summary of selected characteristics of study participants by coffee consumption (cups/day) in the NIH-AARP Diet and Health Study, 1995–2011 (*n* = 420 118)

 Table 2 HRs and 95% Cls of renal cell carcinoma for daily coffee consumption in the NIH-AARP Diet and Health Study, overall

 and stratified by usual coffee content

HR, hazard ratio; CI, confidence interval; NIH-AARP, National Institutes of Health-American Association of Retired Persons; HR, hazard ratio; CI, confidence interval.

^aAdjusted for sex, race (non-Hispanic White, non-Hispanic Black, Hispanic and Asian, Pacific Islander or American Indian/Alaskan Native), BMI (<25, ≥ 25 and <30, and ≥ 30 kg/m²), marriage status (married or living as married, widowed/divorced/separated, never married), education (less or completed high school, post-high school or some college, college and postgraduate), smoking (never smoked, quit ≤ 20 cigarettes/day, quit >20 cigarettes/day, currently smoking ≥ 20 cigarettes/day), history of diabetes (yes/no), total energy intake (calories, continuous), alcohol consumption in the past 12 months (yes/no), state of residence (CA, FL, GA, LA, MI, NC, NJ, PA).

Figure 1 Association of daily coffee consumption with renal cell carcinoma stratified by smoking status in the NIH-AARP Diet and Health Study. NIH-AARP, National Institutes of Health–American Association of Retired Persons; HR, hazard ratio; CI, confidence interval. Adjusted for sex, race (non-Hispanic White, non-Hispanic Black, Hispanic and Asian, Pacific Islander or American Indian/Alaskan Native), BMI (<25, ≥25 and <30, ≥30 kg/m²), marriage status (married or living as married, widowed/divorced/separated, never married), education (less or completed high school, post-high school or some college, college and postgraduate), self-reported history of diabetes (yes/no), total energy intake (calories, continuous), alcohol consumption in the past 12 months (yes/no), state of residence (CA, FL, GA, LA, MI, NC, NJ, PA).

observed, which is similar in magnitude to the effects that we observed herein. Since the publication of that metaanalysis,¹⁴ three recent cohort investigations have been reported.^{20–22} Weak inverse associations between coffee intake and renal cancer were observed within the Cancer Prevention Study-II (1922 renal-cancer deaths; $\geq 6 \text{ cups/}$ day: HR 0.93, 95% CI 0.77, 1.11) and the Multiethnic Cohort Study (838 incident cases; ≥ 4 cups/day: HR 0.89, 95% CI 0.64, 1.23).^{20,21} An analysis of coffee intake and cancer incidence in the UK Biobank did not observe an association between reported coffee intake and 337 incident renal cancers; however, in a Mendelian-randomization analysis of a genetic instrument for coffee consumption and 1012 renal cancers, a 10% lower risk per predicted

cup of coffee was observed (odds ratio 0.90, 95% CI 0.67, 1.20).²² In summary, the totality of the published cohort evidence is suggestive of an inverse association between coffee intake and RCC, similar to that observed in our study.

In analyses stratified on smoking status, we found an inverse association with coffee intake among never-smokers only. The null effect among smokers may reflect the presence of residual confounding from smoking, which is positively associated with both coffee intake and RCC risk. Past studies of coffee and renal cancer did not observe evidence of an interaction with smoking status,^{20,23,24} although most were limited by case numbers in stratified analyses. We also observed stronger evidence of an inverse association with coffee intake vs non-drinkers among men than among women, although a test of interaction did not support effect modification. Given the absence of supporting evidence at this time, our findings from these subgroup analyses should be interpreted with caution.

There are several potential biologic mechanisms through which coffee intake might lower the risk of RCC. First, coffee contains many antioxidants and anticarcinogenic compounds.^{25,26} In particular, coffee-derived diterpenes, cafestol and kahweol have been shown to induce phase-II enzymes involved in carcinogen detoxification, reduce the expression of phase-I enzymes responsible for carcinogen activation and stimulate intracellular antioxidant defence mechanisms.²⁶ In addition, polyphenolic compounds in coffee have been found experimentally to prevent DNA damage caused by free radicals or carcinogenic agents.²⁷ Second, coffee intake is associated with reduced risk of chronic kidney disease (CKD),²⁸⁻³⁰ a risk factor for RCC, and higher estimated glomerular filtration rate (eGFR).³¹ Similarly, a large Mendelian-randomization analysis found a genetic instrument for coffee intake to be associated with reduced risks of CKD categories 3 to 5 (G3-G5) and albuminuria, and a positive association with eGFR.³² Third, coffee intake has been associated with a lower risk of developing type 2 diabetes,³³ a suspected RCC risk factor, by improving insulin sensitivity.³⁴ Fourth, the diluting effect due to coffee intake may reduce the risk of RCC by increasing urine volume and thereby diluting the concentration of carcinogens in contact with renal epithelial cells.²³ Our finding of a similar inverse association between subgroups of primarily caffeinated and decaffeinated coffee suggests that any protective benefits from coffee are not driven by biologic effects of caffeine itself.

The prospective design is a major strength of our study, which minimized the potential for bias from reverse causation from cancer-induced changes in coffee-drinking habits. The consistency of the observed association across different periods of follow-up and with additional adjustment for self-reported health status at baseline also argue against reverse causation as an explanation for our findings. Also important is its large size; with >2600 incident cases, it is the largest investigation of coffee intake and RCC conducted to date, nearly equalling the total number of cases among cohorts included in the meta-analysis of coffee and renal cancer (n=2736).¹⁴ Importantly, this large size yielded robust statistical power to detect an inverse association of the magnitude observed in our analysis, unlike nearly all previous studies of coffee and RCC. Additional strengths include the availability of data on several risk factors for RCC, most notably BMI, smoking and hypertension, which provided an opportunity to control for potential confounding in the analysis, as well as data on the typical consumption of caffeinated vs decaffeinated coffee, which was not assessed in many prior cohort investigations.

Our study also had limitations. Coffee consumption was self-reported, with participants asked their typical coffee consumption over the last 12 months. Although we were unable to estimate lifetime cumulative coffee consumption, coffee consumption has been shown to be relatively stable over time.³⁵ The limited available information on consumption of caffeinated vs decaffeinated coffee weakened our investigations restricted to these beverage types. In addition, we lacked data on the type of coffee preparation (espresso, boiled or filtered), which is important because constituents of coffee may differ, depending on the method.³⁶ Given that filtered coffee is predominantly consumed in the USA,³⁷ our findings are most likely reflective of the association between filtered coffee and RCC risk. Lastly, our study population was almost entirely non-Hispanic White (91%), precluding analyses of other individual racial/ethnic groups.

Conclusion

In our investigation, to our knowledge the largest of its kind to date, we found an ~20% reduced risk of RCC for coffee intake of \geq 2 cups/day, with evidence for a graded association with lower intake. Our findings add RCC to the growing list of cancers for which coffee consumption may be protective. Additional experimental and epidemiologic research investigating the potential benefits of coffee on risk of RCC and other cancers in diverse populations is warranted.
