Abstract

Background: Statistically significantly increased cancer incidence has been reported from 3 cohorts of World Trade Center (WTC) disaster rescue and recovery workers. We pooled data across these cohorts to address ongoing public concerns regarding cancer risk 14 years after WTC exposure. **Methods:** From a combined deduplicated cohort of 69 102 WTC rescue and recovery workers, a sample of 57 402 workers enrolled before 2009 and followed through 2015 was studied. Invasive cancers diagnosed in 2002-2015 were identified from 13 state cancer registries. Standardized incidence ratios (SIRs) were used to assess cancer incidence. Adjusted hazard ratios (aHRs) were estimated from Cox regression to examine associations between WTC exposures and cancer risk. **Results:** Of the 3611 incident cancers identified, 3236 were reported as first-time primary (FP) cancers, with an accumulated 649 724 and 624 620 person-years of follow-up, respectively. Incidence for combined FP cancers was below expectation (SIR = 0.96, 95% confidence interval [CI] = 0.93 to 0.99). Statistically significantly elevated SIRs were observed for melanoma-skin (SIR = 1.43, 95% CI = 1.24 to 1.64), prostate (SIR = 1.19, 95% CI = 1.11 to 1.26), thyroid (SIR = 1.81, 95% CI = 1.57 to 2.09), and tonsil (SIR = 1.40, 95% CI = 1.00 to 1.91) cancer. Those arriving on September 11 had statistically significantly higher aHRs than those arriving after September 17, 2001, for prostate (aHR = 1.61, 95% CI = 1.33 to 1.95) and thyroid (aHR = 1.77, 95% CI = 1.11 to 2.81) cancers, with a statistically significant exposure-response trend for both. **Conclusions:** In the largest cohort of 9/11 rescue and recovery workers ever studied, overall cancer incidence was lower than expected, and intensity of WTC exposure was associated with increased risk for specific cancer sites, demonstrating the value of long-term follow-up studies after environmental disasters.

The September 11 terrorist attacks (9/11) on the World Trade Center (WTC) in New York City resulted in building collapses and fires that released myriad airborne contaminants including toxic fumes, known or suspected carcinogens (eg, asbestos, silica, benzene, heavy metals), combustion products (eg, polycyclic aromatic hydrocarbons [PAHs]), polychlorinated biphenyls [PCBs]), and many other types of particles (eg, wood, metal) (1-3). The unprecedented months-long rescue and recovery work

exposed thousands of workers to varying intensities and durations of nonradiation-based toxins (4).

For monitoring long-term 9/11 health effects, 3 WTC-exposed cohorts were established: the Fire Department of the City of New York (FDNY) (5), the WTC Health Registry (6), and the General Responder Cohort (GRC) (7). Early assessments of cancer among 9/11 rescue and recovery and clean-up workers (hereafter, rescue and recovery workers) from these 3 cohorts

demonstrated excess incidence of some cancers (eg, prostate, thyroid) compared with the general population (8–10). Studies with additional years of follow-up observed greater-than-expected incidence for melanoma-skin (11) and leukemia (12), in addition to prostate and thyroid cancers. However, these studies examined the 3 WTC-exposed cohorts separately and were limited by low case counts. Further, the intensity of WTC-related exposure varied by study cohort and may affect the precision of estimates in cancer studies (13). After nearly 2 decades, the presence and magnitude of increased cancer risk among rescue and recovery workers remain unclear, necessitating further investigation with a larger sample size and longer follow-up.

To address these limitations, a combined and deduplicated cohort of rescue and recovery workers who were members of any of the 3 WTC-exposed cohorts (combined cohort) was created as a collaborative effort among the cohorts and the New York State (NYS) Cancer Registry (14). This is the first report on the overall cancer incidence and risk associated with WTC exposure in this combined cohort, and the largest sample of WTC rescue and recovery workers studied to date.

Methods

Study Design and Patient Eligibility

In this observational cohort study, the rescue and recovery workers in the 3 WTC cohorts were pooled and deduplicated into a combined cohort of 69 102 workers (14). Briefly, records were pooled from FDNY ($n = 16\ 221$), WTC Health Registry ($n = 29\ 372$), and GRC ($n = 33\ 427$), and 9918 duplicates were removed (14).

We restricted the present study to those aged 18 years or older on September 11 with known race and ethnicity and enrollment before 2009 (see Figure 1). The enrollment cutoff was selected to mitigate selection bias. We also excluded those who died within 6 months of enrollment. For subsequent analyses of first primary cancers, we further excluded persons who had cancer diagnosed prior to start of follow-up. For analyses of WTC exposures, those with missing exposure data and smoking status were excluded.

This study was approved by the institutional review boards of the Albert Einstein College of Medicine, New York City Department of Health and Mental Hygiene, NYS Department of Health, and Icahn School of Medicine at Mount Sinai. Registry linkages were approved by the 12 state health department institutional review boards listed below and the University of Medicine and Dentistry of New Jersey .

Cancer Incidence

Cancer incidence was defined as any primary invasive malignant tumor, including in situ bladder cancers, diagnosed during follow-up (2002–2015). Cancers were identified through linkages with 13 US-based state cancer registries based on names, sex, race, birth date, social security number when available, and/or home addresses. The 13 states were Arizona, California, Connecticut, Florida, Massachusetts, New Jersey, New York, North Carolina, Ohio, Pennsylvania, Texas, Virginia, and Washington, where 93% of the combined cohort members resided based on last known residence (14).

All cancers were classified according to the *International Classification of Diseases for Oncology (ICD-O-3)* (15). The cancer

sites were categorized using the Surveillance, Epidemiology, and End Results (SEER) Site Recode ICD-O-3 and World Health Organization 2008 definitions (16), based on primary site and histology. Cancer stage (localized vs regional or distant) was defined based on SEER summary stage 2000 for cases diagnosed during 2002–2003 and collaborative staging derived SEER summary stage 2000 for cases diagnosed during 2004–2015. If diagnosis month or day was missing, the midpoint (June if month is missing or the 15th if day is missing) was assigned.

WTC Exposure

WTC exposures common to the 3 cohorts were derived from self-reported responses collected at study enrollment: 1) date of first arrival to the WTC site (on September 11, on September 12, between September 13 and 17, or after September 17, 2001); 2) performed tasks on the debris pile from the collapsed towers at the WTC site (yes, no or unknown); and 3) exposed to the dust cloud on September 11 (yes, no or unknown) (14).

Statistical Analyses

External Comparisons. Using standardized incidence ratios (SIRs), we compared the observed cancer incidence in the combined cohort to the expected incidence for all cancer sites combined (hereafter, all-cancers) and by cancer site. Because 81% of cases were identified from the NYS cancer registry, the expected number of cases was calculated based on NYS cancer incidence rates, standardized to age at diagnosis, sex, race and ethnicity (Hispanic and Latino, non-Hispanic White, non-Hispanic Black, American Indian–Alaska Native, and Asian–Pacific Islander), and calendar year (5-year intervals) (17). For members missing ethnicity (14), the North American Association of Central Cancer Registries Hispanic Identification Algorithm was used to assign Hispanic ethnicity (18). SIRs and exact 95% confidence intervals (CI), assuming a Poisson distribution of the observed number of cases, were computed using the SEER*Stat Multiple Primary-SIR session (version 7.0.5; National Cancer Institute, Bethesda, MD).

We estimated SIRs in 2 ways. For both approaches, to exclude individuals who might have enrolled because of preclinical cancer or related symptoms, follow-up started 6 months after September 11 or enrollment date. First, the multiple primaries approach (hereafter, MP-SIR) was used to examine all cancers diagnosed after follow-up began in the entire cohort ($n = 57\ 402$); person-time accrued until date of death or December 31, 2015, whichever occurred first. Second, the first primary cancer approach (hereafter, FP-SIR) was used to assess cancer risk in a cancer-free population, and cohort members with any invasive cancer prior to the start of follow-up were excluded. Among the cancer-free cohort ($n = 56\ 259$), only first primary cancer diagnoses were counted and person-time accrued until the earliest of first invasive cancer diagnosis, death date, or December 31, 2015. For FP-SIR, the NYS reference rate was recalculated removing individuals with prior invasive cancer diagnoses from the denominator. Using the FP-SIR approach, we also estimated SIRs by specific WTC exposures. Surveillance bias was assessed by stratifying SIRs by cancer stage.

Within Cohort Comparisons. Cox regression models were used to estimate hazard ratios (HR) with 95% confidence intervals for FP cancer risk related to WTC exposure (19). Models were run separately for each type of WTC-exposure measurement, estimating the risk of all-cancers and sites with statistically

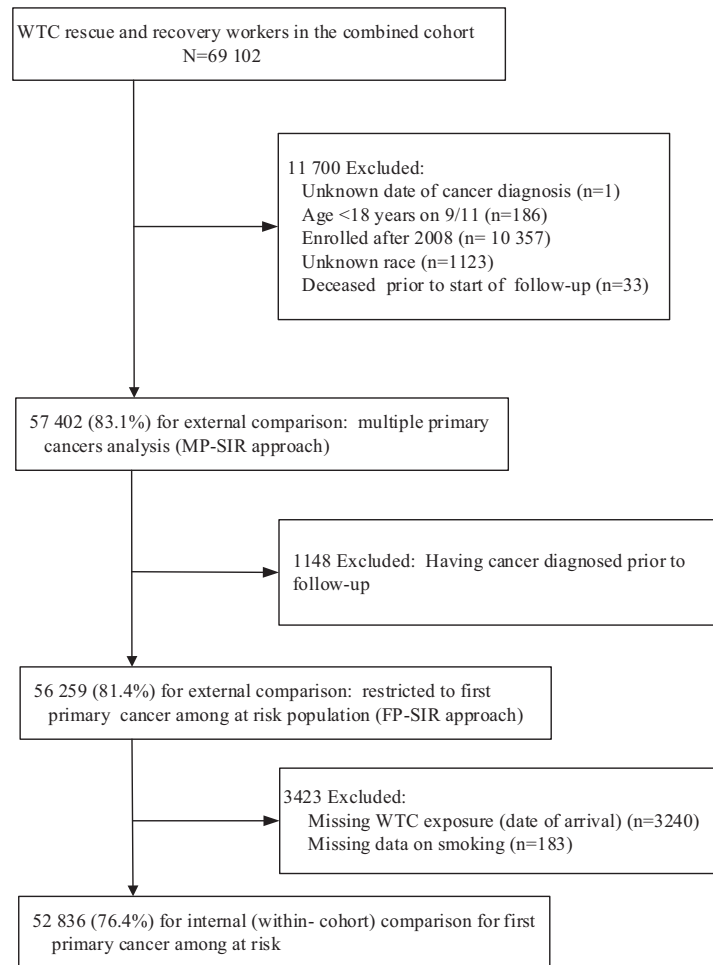

Figure 1. Selection of study sample for data analysis. SIR = standardized incidence ratio; WTC = World Trade Center.

significantly elevated SIRs from external analyses. We limited the within-cohort analysis of tonsil cancer to non-Hispanic White males because 93% (37 of 40) of cases occurred among this demographic.

Follow-up time was calculated as stated above for FP-SIRs. Models were adjusted for age on September 11, sex, race and ethnicity, smoking status (current, former, never, which was defined based on the questions whether someone smoked at least 100 cigarettes in their lifetime and currently smoked cigarettes every day or some days), and year of enrollment (to adjust for potential selection bias from GRC's open cohort design). To test proportionality, we assessed the statistical significance of time-dependent covariates by creating interactions of covariates with survival time and included these in the model. If the coefficient of an interaction term was significant ($P < .05$), proportionality was determined to be violated for that covariate. When age violated the proportional hazard assumption, we controlled for age (5-year intervals) with stratified Cox models (20). To test the exposure-response relationship, we included the date of arrival (from late to early arrival date) as ordinal variable in the multivariable Cox model and examined the statistical significance of the estimate. Analyses were performed using SAS software (v9.4, SAS Institute Inc, Cary, NC). All statistical tests are 2-sided, and statistical significance was indicated if the 95% confidence interval did not contain the null value of 1 or if a P value was less than .05.

Results

Study Sample

The analytic cohort ($n = 57\,402$) was predominantly male (84.1%), non-Hispanic White (71.7%), and mostly (84%) enrolled before 2005 (Table 1). The median age on September 11 was 39 years (interquartile range [IQR] = 13), and nearly 40% had ever smoked (16.2% current smokers) at enrollment.

External Comparisons

During the 649 724 person-year follow-up, 3611 incident cancers were identified (3808.2 expected; SIR = 0.95, 95% CI = 0.92 to 0.98) among 57 402 individuals (MP-SIR) with 3236 reported as first primary cancers (3371.1 expected; SIR = 0.96, 95% CI = 0.93 to 0.99; FP-SIR) (Table 2). The total person-years of follow-up among 56 259 rescue and recovery workers who were at risk for FP at the start of the follow-up was 624 620. For site-specific FP cancers, we observed 3 major sites with elevated SIRs: melanoma-skin (SIR = 1.43, 95% CI = 1.24 to 1.64), prostate (SIR = 1.19, 95% CI = 1.11 to 1.26), thyroid (SIR = 1.81, 95% CI = 1.57 to 2.09), and 1 oral cavity and pharynx subsite: tonsil (SIR = 1.40; 95% CI = 1.00 to 1.91). Eight subsites with statistically significantly lower-than-expected rates were identified. MP-SIR

^aThe combined cohort is deduplicated following a hierarchy of the Fire Department of the City of New York (FDNY), the General Responder Cohort (GRC), and then the World Trade Center Health Registry (WTCHR). This results in FDNY including members of GRC and/or WTCHR, GRC including members from WTCHR but not FDNY, and the remaining from WTCHR.

results were similar to FP-SIR, except the tonsil cancer SIR was not statistically significant.

Workers arriving on September 11 had greater-than-expected incidence (FP approach) of all-cancers, melanoma-

skin, prostate, thyroid, and tonsil (SIR = 1.11, 95% CI = 1.05 to 1.18; SIR = 1.61, 95% CI = 1.29 to 1.99; SIR = 1.45, 95% CI = 1.31 to 1.59; SIR = 2.34, 95% CI = 1.86 to 2.91; SIR = 1.76, 95% CI = 1.08 to 2.72, respectively) (Figure 2). Elevated SIRs were also observed for those arriving on September 12 for melanoma-skin, prostate, and thyroid cancer but not for all-cancers or tonsil. Work on the pile was associated with statistically significantly elevated SIRs for all 4 cancer subsites.

Stage at cancer diagnosis for FP analyses showed SIRs for regional or distant cancers of the tonsil (SIR = 1.47, 95% CI = 1.05 to 1.18), prostate (SIR = 1.33, 95% CI = 1.13 to 1.55), and thyroid (SIR = 1.82, 95% CI = 1.40 to 2.33) were statistically significantly elevated (Table 3). Elevated SIRs were observed for localized melanoma-skin (SIR = 1.51, 95% CI = 1.28 to 1.78) and all-cancers (SIR = 1.14, 95% CI = 1.09 to 1.20) only.

Within Cohort Comparisons

Compared with those arriving after September 17, workers arriving on September 11, 12, or from 13-17 were at increased risk of all-cancers (adjusted hazard ratio [aHR] = 1.47, 95% CI = 1.32 to 1.64; aHR = 1.34, 95% CI = 1.19 to 1.51; aHR = 1.32, 95% CI = 1.17 to 1.48, respectively) and prostate cancer (aHR = 1.61, 95% CI = 1.33 to 1.95; aHR = 1.35, 95% CI = 1.09 to 1.68; aHR = 1.25, 95% CI = 1.01 to 1.54, respectively) (Table 4); the test for trend (late to early arrival at the site) was statistically significant for all-cancers and prostate. Only arrival on September 11 was associated with an increased risk of thyroid cancer (aHR = 1.77, 95% CI = 1.11 to 2.81). Although not statistically significant, the adjusted hazard ratio for tonsil cancer was doubled for those arriving on September 11 (aHR = 2.07, 95% CI = 0.87 to 4.92) or September 12 (aHR = 2.10, 95% CI = 0.80 to 5.50) compared with those arriving after September 12. Direct dust exposure was statistically significantly associated with an increased risk of all-cancers (aHR = 1.21, 95% CI = 1.12 to 1.31) and prostate cancer (aHR = 1.19, 95% CI = 1.14 to 1.49) but not thyroid, melanoma-skin, or tonsil cancer.

After dichotomizing the exposure based on first arrival date to those arriving in 2001 (when fires were still burning) vs those arriving in 2002, we found those arriving in 2001 were at higher risk of prostate cancer (aHR = 2.09, 95% CI = 1.36 to 3.19) and of all-cancers (aHR = 1.76, 95% CI = 1.43 to 2.15) than those arriving in 2002.

Discussion

Using the combined cohort, we observed a lower-than-expected SIR for all-cancers, whereas for the first time, we observed a statistically increased risk for workers arriving on September 11 compared with those arriving later for all-cancers, prostate, and thyroid cancers and an increased risk of all-cancers and prostate cancer for those reporting direct dust exposure. The findings of excess cancer in prostate, melanoma-skin, and thyroid were consistent with previous findings, however, we also observed excess tonsil cancer, a rare cancer that likely would not have been detected among individual cohorts.

In external comparisons, the present study observed excess melanoma-skin, prostate, and thyroid cancers compared with NYS population, consistent with previous findings (8-12). In internal comparisons, early arrival workers who putatively had the greatest intensity of toxic dust exposure were found to be at greater risk of cancer; workers arriving on September 11 were 60% more likely to develop prostate cancer and 77% more likely

to develop thyroid cancer than those arriving a week later. Furthermore, the risk of prostate cancer was double for those arriving in 2001 compared with those arriving in 2002 when the smoldering fires had ended, providing additional support for the potential effect of 9/11 exposure on cancer risk. Although the exact etiologic underpinning for these associations is unknown, both direct and indirect pathways exist. The high concentrations of well-established carcinogenic agents (eg, PAHs, PCBs, dioxins, heavy metals) in the dust, smoke, and debris at the WTC site could cause cancer directly and explain the early arrival-cancer association (2,21). There is an emerging body of literature suggesting thyroid cancer is associated with environmental exposures beyond radiation (22), including PCBs (23) and particulate matter (24-27). Lastly, both chronic inflammation, from inflammatory diseases known to occur more frequently in WTC-exposed populations, and chronic stress, from occupational exposures common in this cohort (eg, firefighting, police, construction, transportation), have been associated with altered immune and inflammatory activities and subsequently increased cancer risk (21,28-36). Although the specific mechanisms may be unknown, the consistent evidence of excess incidence of melanoma-skin, prostate, and thyroid cancer

warrants continued monitoring and treatment availability for this population.

Rescue and recovery workers had lower-than-expected incidence of all-cancers and 8 cancer sites (colon, rectum, liver, pancreas, lung, female breast, corpus and uterus, bladder) over the 14 years following 9/11, counter to previous reports, except for lung cancer (11-13). One possible explanation is that this population may have benefited from early and consistent access to health care and other support systems since exposure. Eligible workers were offered early access to WTC medical monitoring and treatment programs, which continue to offer care to eligible responders (5,7,37). Secondly, cancer development is a result of the interplay of multiple factors, including stochastic effects, environmental-genetic interactions, healthy worker effects, exposures other than 9/11, and latency periods between exposure and incidence that vary across tumor type (38), all of which may or may not be modified by 9/11 exposure. Lastly, using the more diverse NYS general population as reference for study of a worker population may lead to the underestimation of SIR in certain cancers, as the combined cohort is predominantly White, middle-aged, gainfully employed men (39). Similarly, the use of NYS as referent may also contribute to the

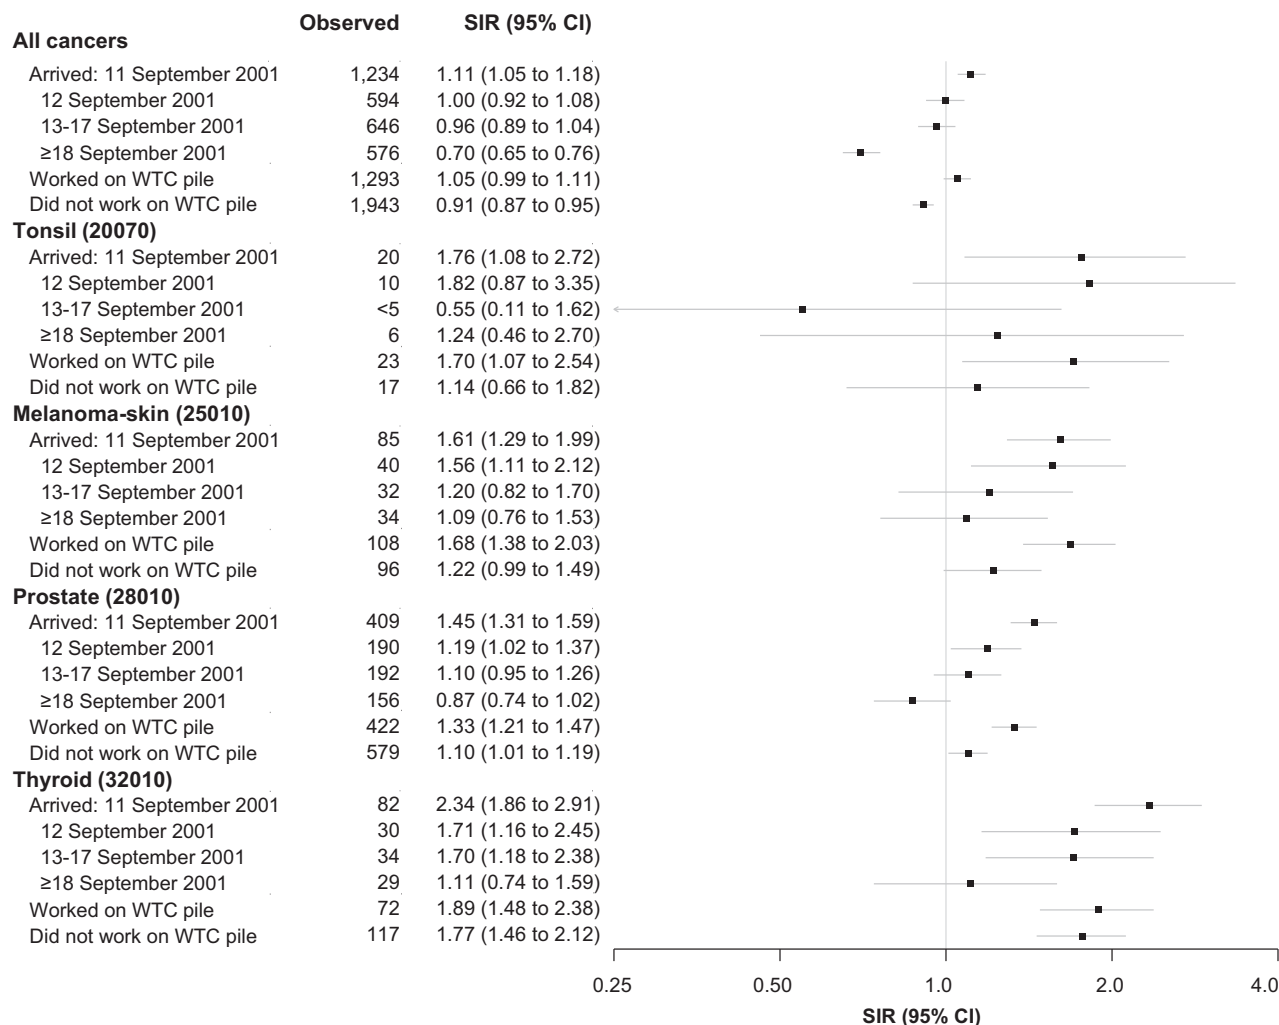

Figure 2. Standardized incidence ratio (SIR) and 95% confidence interval (CI), by World Trade Center (WTC) exposure, among WTC rescue and recovery workers for all-cancers and selected cancer sites with elevated SIR, 2002-2015. The SIR for first primary cancer (FP-SIR approach) was used. Follow-up began 6 months after enrollment, and individuals with non-Hispanic unknown race were excluded. All statistical tests were 2-sided.

Table 3. Standardized incidence ratio (SIR) and 95% confidence interval (CI), by cancer stage, among WTC rescue and recovery workers for first primary cancer in all sites combined and selected cancers with elevated SIR, 2002-2015^a

Cancer site (SEER recode)	Localized		Regional/distant	
	Obs.	SIR (95% CI)	Obs.	SIR (95% CI)
All sites	1838	1.14 (1.09 to 1.20)	1213	0.85 (0.80 to 0.90)
Tonsil (20070)	<5	1.55 (0.42 to 3.96)	36	1.47 (1.03 to 2.04)
Melanoma-skin (25010)	151	1.51 (1.28 to 1.78)	23	1.13 (0.72 to 1.70)
Prostate (28010)	785	1.27 (1.18 to 1.36)	167	1.33 (1.13 to 1.55)
Thyroid (32010)	121	1.84 (1.53 to 2.20)	63	1.82 (1.40 to 2.33)

^aFollow-up began 6 months after enrollment and ended at the earliest of diagnosis date of first primary invasive cancer, date of death, or December 31, 2015. Obs. = Observed; SEER = Surveillance Epidemiology and End Results; WTC = World Trade Center.

underestimation of SIR if the cancer rates in the 12 other states were lower than the NYS rate. The demographic characteristics of the cohort, combined with consistent access to 9/11-related medical monitoring and health care, may mitigate part of the detrimental effects of exposure on cancer incidence. Future

research should leverage other worker populations, such as US firefighters (28) and police officers (40), for comparison to better elucidate overall cancer risk.

To explore the contribution of screening practices to our findings (41,42), we examined SIR in early and later stages

Table 4. Risk of selected first primary cancer as a function of WTC exposure among WTC rescue and recovery workers, 2002-2015 (N = 52 836)

WTC exposures	All sites ^a		Tonsil ^b		Melanoma-skin ^c		Prostate ^a		Thyroid	
	No.	aHR (95% CI) ^d	No.	aHR (95% CI) ^d	No.	aHR (95% CI) ^d	No.	aHR (95% CI) ^d	No.	aHR (95% CI) ^d
Date of arrival at WTC site										
September 11, 2001	1223	1.47 (1.32 to 1.64)	20	2.07 (0.87 to 4.92)	83	1.39 (0.89 to 2.16)	405	1.61 (1.33 to 1.95)	82	1.77 (1.11 to 2.81)
September 12, 2001	589	1.34 (1.19 to 1.51)	9	2.10 (0.80 to 5.50)	40	1.47 (0.91 to 2.38)	189	1.35 (1.09 to 1.68)	30	1.39 (0.81 to 2.37)
September 13-17, 2001	643	1.32 (1.17 to 1.48)	8 ^e	Referent	32	1.14 (0.70 to 1.88)	190	1.25 (1.01 to 1.54)	34	1.49 (0.89 to 2.49)
≥September 18, 2001	572	Referent			34	Referent	155	Referent	28	Referent
Trend (late to early arrival)		1.12 (1.08 to 1.15)		1.23 (0.89 to 1.71)		1.11 (0.97 to 1.28)		1.16 (1.09 to 1.23)		1.17 (1.02 to 1.35)
Worked on pile	1279	1.03 (0.95 to 1.11)	23	1.24 (0.59 to 2.60)	107	1.37 (0.99 to 1.91)	415	1.09 (0.95 to 1.25)	72	0.74 (0.52 to 1.06)
Direct dust exposure on 9/11	1242	1.21 (1.12 to 1.31)	19	1.31 (0.66 to 2.59)	84	1.17 (0.86 to 1.59)	404	1.30 (1.14 to 1.49)	77	1.19 (0.87 to 1.63)

^aAdjusted for age: included strata of age on 9/11 (in 5-year intervals) for all sites combined and prostate cancer because age violated the Cox proportional hazards assumption; otherwise age on 9/11 was included in the model as a fixed effect. aHR = adjusted hazard ratio; CI = confidence interval; WTC = World Trade Center.

^bThe multivariable analysis of tonsil cancer was limited to male and non-Hispanic White workers because 37 of 39 workers with first-time tonsil cancers were male and non-Hispanic and adjusted for age, smoking status, and year of enrollment. Date of arrival on September 13-17, 2001, was combined with ≥ September 18, 2001 group because of small cell counts.

^cRace and ethnicity are categorized into non-Hispanic White vs all others in multivariable analysis for melanoma-skin because 184 of 189 melanoma-skin cases are non-Hispanic White.

^dAdjusted for race and ethnicity, smoking status at enrollment, year of enrollment, age on 9/11, and sex, unless otherwise indicated.

^eIncludes those with dates of arrival at WTC site of September 13-17 and ≥ September 18, 2001.

separately. The results suggest increased screening may play a role with observed excess incidence for all-cancers and melanoma-skin diagnosed at localized stages but not at regional or distant stages. However, the SIRs for prostate and thyroid cancers were similar for both localized and regional/distant stages, suggesting that increased risk is independent of surveillance biases. Among the FDNY cohort, related increases in thyroid cancer diagnoses were reported to be partially due to heightened medical attention and incidental detection (43,44). However, reports on similar clinical characteristics between WTC-exposed and nonexposed hospital-based thyroid cancer cases suggest the potential for more cases than surveillance bias alone would explain (45,46). Studies that better describe the magnitude of difference from the general population because of increased screening and incidental detection on the observed exposure-cancer association are needed.

Certain cancer sites deserve further consideration in future monitoring of this population. Eight persons with w FP mesothelioma were observed, a small, non-statistically significant excess over expected. The consistent finding on deficit of lung cancer (11,12) may be because of lower smoking rate in our study population, as the prevalence of smoking at enrollment (16.2%) was lower than the prevalence in NYS adults (19.9%-23.2%) in a similar time period (47). However, the risk of both cancers remain a major concern in this exposed cohort given their long latency periods (48,49) and numerous known carcinogens well described in WTC dust and fumes (2). Lastly, tonsil and tongue cancers represented more than 70% of cancer in the oral cavity and pharynx site and were examined separately. Forty FP-tonsil cancer cases were identified, which was moderately higher than expected. A recent review described a link between asbestos or PAHs and oral and pharyngeal cancer; it

suggested that direct contact with inhaled chemicals could produce chronic inflammation resulting in malignant transformation (50). However, excess tonsil cancer in this study could also be attributable to temporal trends in human papillomavirus-related cancers or to differential patterns of known risk factors (eg, tobacco, alcohol use) (51,52). These potentially important and emergent cancers should be carefully monitored in future WTC analyses.

Limitations are noted. The 9/11 exposures were self-reported and ambient air measurements immediately following 9/11 were unavailable to objectively quantify exposures or validate self-report. However, there is ample evidence for the presence of a wide range of toxic substances in the aftermath of the WTC collapse and use of arrival date aligns with the qualitatively described sequence of outdoor WTC exposures at Ground Zero (4,53,54). We cannot rule out the role of unmeasured confounding for those risk factors unavailable in this study but known to be associated with the reported cancers (eg, family history of cancer, ultraviolet radiation from the sun, diet) or residual confounding because of imperfectly measured risk factors (eg, pack-years smoking) in the reported estimates. Similarly, a large proportion of our study sample comprises firefighters, police, and construction workers, and increased cancer incidence among these occupation-specific groups has been previously reported (8,31,32,55). Occupational details (eg, years of service) were unavailable in this study, making it difficult to rule out the role of occupation in reported estimates (28,56). Although we restricted study inclusion to entry prior to 2009 and delayed person-time accrual by 6 months after enrollment, selection bias remains a concern because of the various reasons for enrollment into the respective cohorts. Notably, cancer coverage began in 2012 under the James Zadroga 9/11 Health and

Compensation Act, limiting the likelihood of selection into our study sample for cancer-related care (57). Lastly, incomplete case ascertainment is also a concern, because cancer linkages were conducted in 93% of the combined cohort and cases reported by Veterans Affairs hospitals were not included. We posit these missed cases likely bias our findings toward null.

In the largest post-9/11 cohort of rescue and recovery workers ever studied, although the overall cancer incidence was lower than expected compared with the reference population, higher-than-expected SIRs were observed in melanoma-skin, prostate, thyroid, and tonsil cancers. For the first time, we identified a statistically significant association of early arrival with increased cancer risk of all-cancer sites, prostate, and thyroid cancers in internal comparisons. The combined cohort includes a heterogeneous group of rescue and recovery workers with various levels of WTC exposure, allowing for more precise estimations of cancer incidence and risk and the study of rare cancers. Given latency periods between environmental exposure and cancer incidence, future studies will further our understanding of the long-term health effects of 9/11. Finally, our findings demonstrate the value and need for long-term follow-up studies after environmental disasters.
