Received 11 October 1999/Returned for modification 10 December 1999/Accepted 29 February 2000

We recently reported that strain EN1252a, a fluoroquinolone-resistant derivative of *Staphylococcus aureus* NCTC8325 with mutations in *grlA* and *gyrA*, expressed increased levels of fibronectin-binding proteins (FnBPs) and showed a significantly higher attachment to fibronectin-coated polymer surfaces after growth in the presence of subinhibitory concentrations of ciprofloxacin. The present study evaluated the occurrence and frequency of fluoroquinolone-induced FnBP-mediated adhesion in clinical isolates of fluoroquinolone-resistant methicillin-resistant *S. aureus* (MRSA) and methicillin-susceptible *S. aureus* (MSSA). Eight of ten MRSA isolates and four of six MSSA isolates with *grlA* and *gyrA* mutations exhibited significant increases in attachment to fibronectin-coated surfaces after growth in the presence of one-quarter the MIC of ciprofloxacin. Fluoroquinolone-induced FnBP-mediated adhesion of one clinical MRSA strain and the double mutant strain EN1252a also occurred on coverslips removed from the subcutaneous space of guinea pigs. For strain EN1252a, the regulation of *fnb* transcription by sub-MICs of ciprofloxacin was studied on reporter plasmids carrying *fnb-luxAB* fusions. One-quarter of the MIC of ciprofloxacin significantly increased *fnbB*, but not *fnbA*, promoter activity of the fluoroquinolone-resistant mutant but not its fluoroquinolone-susceptible parent ISP794. This response was abolished by pretreatment with rifampin, indicating an effect at the level of transcription. Activation of the *fnbB* promoter was not due to an indirect effect of ciprofloxacin on growth rate and still occurred in an *agr* mutant of strain EN1252a. These data suggest that sub-MIC levels of ciprofloxacin activate the *fnbB* promoter of some laboratory and clinical isolates, thus contributing to increased production of FnBP(s) and leading to higher levels of bacterial attachment to fibronectin-coated or subcutaneously implanted coverslips.

The ability of *Staphylococcus aureus* to recognize several extracellular matrix or plasma proteins that coat indwelling devices promotes bacterial attachment to these artificial surfaces. Clinical and laboratory isolates of *S. aureus* and many other bacterial species express surface proteins called MSCRAMM (microbial surface components recognizing adhesive matrix molecules) that specifically recognize each of the host matrix or plasma components (37). *S. aureus* fibronectin-binding activity is exerted by two closely related fibronectin-binding proteins (FnBPs) encoded by two adjacent genes called *fnbA* and *fnbB* (11, 19). The structural genes coding for FnBPs are partly redundant since both of them need to be inactivated to suppress bacterial interaction with fibronectin (14).

Previous studies indicate that some cell wall-associated proteins, such as protein A and FnBP(s), may be regulated by the interaction of two global regulons called *agr* and *sar* (4, 5, 6, 33). While *agr* is known to downregulate *fnb* genes during the postexponential phase (41, 44), the *sar* locus seems to exert an opposite upregulating effect during the exponential phase, as documented by knockout mutations in each of these regulatory genes (A. L. Cheung and C. Wolz, Abstr. 37th Int. Conf. Antimicrob. Agents Chemother, session 77B, 1997).

Expression of surface proteins may also be affected by exposure to a variety of additional internal and external signals

and regulatory factors. Subinhibitory concentrations of antibiotics may downregulate or upregulate specific adhesins as well as other virulence-associated determinants of *S. aureus* such as FnBPs (39, 40), collagen-binding protein (2), or alpha-toxin (21, 35). On the other hand, the acquisition of single or multiple antibiotic resistance determinants by *S. aureus* may also modulate expression of surface proteins. In a recent study, we found that introduction of the methicillin resistance determinant into the laboratory strains 8325 and Newman of *S. aureus* altered the functional expression of their fibrinogen ClfA adhesin and to some extent FnBPs (56).

Shortly after the introduction of the fluoroquinolones into clinical practice, strains expressing resistance to these compounds were detected, in particular among isolates of methicillin-resistant *S. aureus* (MRSA), which frequently exhibit multiple additional resistance determinants to unrelated antimicrobial agents (51). Fluoroquinolone resistance in *S. aureus* is chromosomally mediated and commonly associated with point mutations in two intracellular targets: (i) site-specific amino acid substitutions in GrlA (topoisomerase IV, A subunit) found at codons 80 (Ser→Phe or Tyr), 84 (Glu→Lys), and 116 (Ala→Glu or Pro) (9, 10, 25, 32, 48, 52, 59) and/or amino acid substitutions in GrlB (B subunit) (12, 45, 46); and (ii) site-specific amino acid substitutions in GyrA (DNA gyrase, A subunit) found at codons 84 (Ser→Leu) and 88 (Glu→Lys) (9, 18, 31, 32, 38, 49, 50) and/or amino acid substitutions in GyrB (B subunit) (18, 46). Combined mutations in *grlA* and *gyrA* confer much higher levels of resistance than single *grlA* mutations (9, 10, 32). Finally, fluoroquinolone resistance may also result from increased *norA*-mediated efflux

of these antimicrobial agents by the *flqB* mutation (20, 30, 32, 36, 49).

We recently reported that an isogenic *grlA gyrA* double mutant of *S. aureus* grown in the presence of subinhibitory concentrations of ciprofloxacin expressed increased levels of FnBPs and showed a significantly higher attachment to fibronectin-coated polymer surfaces (1). This phenomenon was selectively expressed in fluoroquinolone-resistant *grlA gyrA* double mutants, but not in either *grlA* and *gyrA* single mutants or susceptible parental strains. The aims of this report were: (i) to document the occurrence and frequency of increased FnBP-mediated adhesion in a pilot sample of both methicillin-resistant and methicillin-susceptible quinolone-resistant clinical isolates grown in the presence of subinhibitory concentrations of ciprofloxacin, (ii) to evaluate how quinolone-induced over-expression of FnBPs may contribute to increased attachment of *S. aureus* to subcutaneously implanted polymer surfaces, and (iii) to study whether sub-MICs of ciprofloxacin might alter transcription of each *fnb* gene in quinolone-resistant *S. aureus* by using luciferase *fnb-luxAB* reporter plasmids.

## MATERIALS AND METHODS

**Bacterial strains.** The properties of 16 fluoroquinolone-resistant clinical isolates of *S. aureus*, collected from the University Hospital of Geneva, Geneva, Switzerland, the Massachusetts General Hospital, or the Pasteur Institute (Paris, France), are listed in Table 1. Ten isolates were methicillin-resistant (MRSA) and six were methicillin-susceptible *S. aureus* (MSSA). Five MRSA isolates from Geneva, collected in February 1994, and one MRSA from Boston were associated with clinically documented infections. Four MRSA isolates from the Pasteur Institute (kindly provided by N. El Solh) were collected from three separate areas in 1989 and 1990 and characterized by an unusual streptogramin resistance pattern recovered in several patients during a short period of time. The presence of this characteristic antibiotic resistance pattern suggested an epidemiological mode of transmission for each of these four MRSA isolates. All six quinolone-resistant MSSA isolates were collected in Boston in 1993 and 1994 and were not epidemiologically linked, and five of them were associated with infections.

The properties of isogenic strains and plasmids used in this study are listed in Table 2. Single *grlA* and *gyrA* quinolone-resistant mutant strains MT5224c4 and SS1, respectively, and the double *grlA gyrA* mutant strain EN1252a of *S. aureus* have been previously described (1).

Plasmids pFNBA6 and pFNBB6 carrying the promoter of *fnbA* and *fnbB*, respectively, fused with a *luxAB* reporter gene (coding for bacterial luciferase) were transduced from strain DU5883 (14) with phage 85 into strains ISP794 and EN1252a. Control experiments verified that the susceptibility to ciprofloxacin of

strains ISP794 and EN1252a was unaffected by the presence of plasmids pFNBA6 and pFNBB6 (data not shown).

To obtain a derivative of strain EN1252a, in which the *agr* locus has been replaced with *tetM*, as originally developed in strain RN6911 ( $\Delta$ *agr::tetM*) (34), phage 85 was used to transduce this *agr* mutation from strain ALC 355 (58) to strain EN1252a, with selection for tetracycline resistance. The presence of the  $\Delta$ *agr::tetM* mutation in strain CB3, which is a derivative of strain EN1252a, was assessed by Southern blot hybridization, and the Agr<sup>-</sup> phenotype was confirmed by defective hemolysin production on sheep blood agar plates.

**Susceptibility to antimicrobial agents.** Antimicrobial susceptibilities of the clinical isolates were determined by the disk diffusion method (29). The following antibiotics were tested: oxacillin, gentamicin, fosfomycin, rifampin, fusidic acid, and ciprofloxacin and, when indicated, streptogramin A and B.

The MICs of ciprofloxacin for fluoroquinolone-resistant strains were determined by a macrodilution method using Mueller-Hinton broth (MHB) (Difco, Detroit, Mich.) and a standard inoculum of 10<sup>6</sup> CFU/ml (28).

**Characterization of *grlA* and *gyrA* point mutations by DNA sequencing.** Point mutations determining fluoroquinolone resistance in MRSA and MSSA clinical isolates were recorded by sequencing the quinolone-resistance determining regions (QRDR) of *grlA* and *gyrA* as previously described (12). Chromosomal DNA was purified from bacterial cells lysed with lysostaphin and lysozyme using a previously described phenol-chloroform procedure (24, 43). QRDR of *grlA* and *gyrA* were amplified by a standard PCR protocol (Qiagen, Basel, Switzerland), using oligonucleotide primers identical to those described by Schmitz et al. (46) and Fournier and Hooper (12). PCR products were purified with a PCR purification kit (Qiagen), sequenced by a fluorescent-dye terminator method (Abi Prism; Perkin-Elmer), and resolved and automatically analyzed with a 373A Stretch Sequencer (Perkin-Elmer).

**In vitro bacterial adhesion assay to fibronectin.** The attachment properties of the different clinical and laboratory strains of *S. aureus* were measured using a previously described adhesion assay with polymethylmethacrylate coverslips coated in vitro with three different concentrations of purified fibronectin as previously described (1, 14, 15, 55). Adhesion of *S. aureus* was evaluated by incubating for 1 h at 37°C the fibronectin-coated coverslips with 10<sup>7</sup> CFU of washed cultures of late-logarithmic-phase cells, metabolically radiolabeled with [<sup>3</sup>H]thymidine during growth for 5 h at 37°C, as previously described (1, 14, 55). At the end of the attachment period, the fluids containing unbound bacteria were removed, the coverslips were rinsed, and radioactivity on the coverslips was determined. Each of the clinical isolates was tested after continuous incubation of the 5-h cultures with a single subinhibitory concentration equivalent to one-quarter the MIC of ciprofloxacin which was run in parallel with a culture in control quinolone-free MHB.

For the laboratory isolates ISP794 and EN1252a, 5-h cultures of either strain were also continuously incubated with either 1/4, 1/8, or 1/16 the MIC of ciprofloxacin or control MHB, respectively.

Each adhesion experiment was performed at least three times, and the results were expressed as the mean  $\pm$  standard error of the mean. For each clinical isolate, the significance of differences between exposure and no exposure to ciprofloxacin during growth was evaluated by the nonparametric Wilcoxon signed-rank test as previously described (1). The adhesion profiles of ciprofloxacin-exposed and unexposed cells were considered significantly different from each other when all increases or decreases accumulated for the three coating concentrations of fibronectin yielded *P* values of <0.05 with a two-tailed significance level (1).

To evaluate the significance of differences in the attachment of strain EN1252a grown under control conditions or in the presence of three different subinhibitory concentrations of ciprofloxacin, we used the Kruskal-Wallis test followed by the Dunn procedure for comparison of specific groups (42).

**Bacterial adhesion to explanted coverslips.** We used a previously described animal model of foreign body infection, in which four perforated cylinders termed tissue cages, each containing three polymethylmethacrylate coverslips, were implanted subcutaneously into guinea pigs (54, 60). After an infection-free period of 4 weeks, guinea-pigs were sacrificed and the subcutaneously implanted tissue cages with enclosed coverslips were removed (54). After extensive rinsing in phosphate-buffered saline, each explanted coverslip coated in vivo with extracellular matrix components was tested in the in vitro bacterial adhesion assay as described above. The most highly adhesion-promoted clinical fluoroquinolone-resistant isolate was tested with explanted coverslips and compared to isogenic quinolone-resistant and -susceptible laboratory isolates of *S. aureus*. For each strain, the significance of cumulated differences between exposure and no exposure to ciprofloxacin during growth was evaluated by the nonparametric Mann-Whitney test (42), using *P* values of <0.05 with a two-tailed significance level.

**SDS-PAGE and Western ligand affinity blotting.** Bacterial protein extracts were prepared from whole cells grown and lysed with lysostaphin as previously described (1). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western ligand affinity blotting were performed on lysostaphin extracts of the different strains to identify and quantify the amount of FnBPs by densitometric analysis as previously described (1).

**Luciferase assay.** To analyze the expression of each *fnb* promoter in the presence or absence of subinhibitory concentrations of ciprofloxacin, the pFNBA6 or pFNBB6 plasmid-containing strains EN1252a or ISP794 were first grown overnight at 35°C in MHB supplemented with chloramphenicol (5  $\mu$ g/ml).

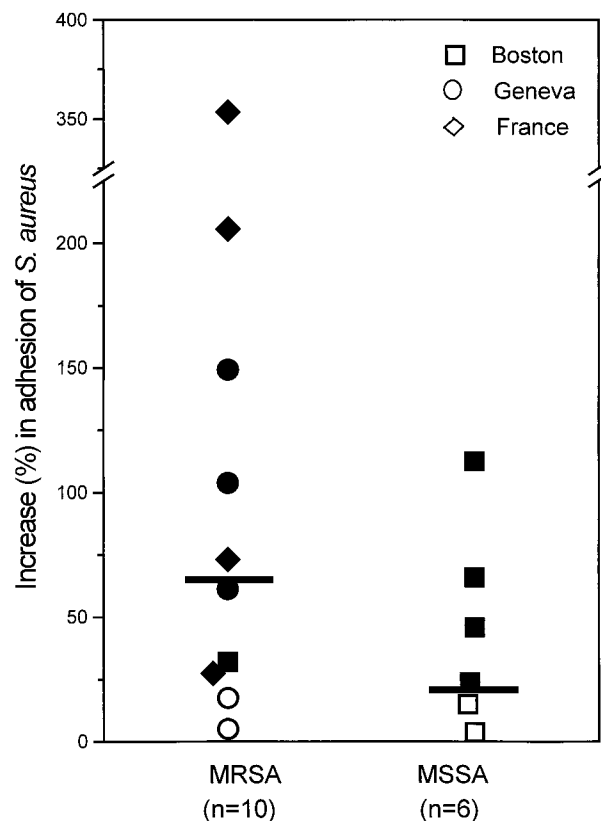

FIG. 1. Percentage increases in the adhesion to fibronectin-coated coverslips of 10 MRSA or 6 MSSA fluoroquinolone-resistant clinical isolates from either Boston, Mass. (□, ■), Geneva, Switzerland (○, ●), or France (◇, ◆), promoted by growth in the presence of one-quarter the MIC of ciprofloxacin for each strain. Solid symbols represent strains whose adhesion is significantly promoted by ciprofloxacin-containing growth medium; open symbols represent strains whose adhesion is not significantly promoted.

Then, 600- $\mu$ l aliquots of washed overnight cultures were diluted into 30-ml aliquots of MHB in conical flasks and grown at 35°C for a maximal period of 5 h, in the absence or presence of one-quarter the MIC of ciprofloxacin. At regular intervals, duplicate 1-ml samples were removed, one being assayed for luminescence and the other being for monitoring growth of the culture by the absorbance at 540 nm. Luciferase activity was assayed after adding to a 1-ml portion 10  $\mu$ l of 1% (vol/vol) dodecanal in ethanol using a LKB Wallac 1250 Luminometer. The specific light units (SLU) were determined by dividing the relative light units by absorbance at 540 nm (14). Each experiment was performed at least three times, and the results were expressed as the means  $\pm$  standard errors. For each strain and each time point, the significance of differences in SLU expressed by ciprofloxacin-exposed compared to unexposed cultures was evaluated by the paired *t* test, using *P* values of <0.05 with a two-tailed significance level.

To evaluate the lag time of *fnb* promoter responses to subinhibitory concentrations of ciprofloxacin, 38- $\mu$ l portions of washed overnight cultures of either strain, EN1252a(pFNBB6) or ISP794(pFNBB6), were inoculated into flasks containing 30 ml of antibiotic-free MHB. After 4 h of growth at 35°C, each bacterial culture was split into four subcultures, each growing in a different medium: (i) plain MHB, (ii) MHB containing rifampin (2  $\mu$ g/ml), (iii) MHB supplemented with either one-quarter or one-eighth the MIC of ciprofloxacin, or (iv) MHB first treated with rifampin (2  $\mu$ g/ml) for 5 min at 35°C before addition of one-quarter the MIC of ciprofloxacin. The RNA synthesis inhibitor rifampin was used to determine that the ciprofloxacin-promoted increase of luciferase activity occurred at the level of transcription of the *fnb* genes. At 20 min, samples were processed for SLU measurements as described above. Each experiment was performed at least three times, and the results were expressed as the mean percent changes  $\pm$  standard errors over the 20-min period. For each strain, the significance of percent changes in SLU expressed by each ciprofloxacin- or/and rifampin-treated group was compared to that of unexposed cultures by one-way variance analysis followed by paired *t* test for comparison of specific groups, using *P* values of <0.05 with a two-tailed significance level.

**Evaluation of plasmid copy number.** Assays of chloramphenicol acetyltransferase (CAT) activity were used as a control for the copy number of the fusion plasmids in strains EN1252a and ISP794. Lysostaphin extracts of either strain

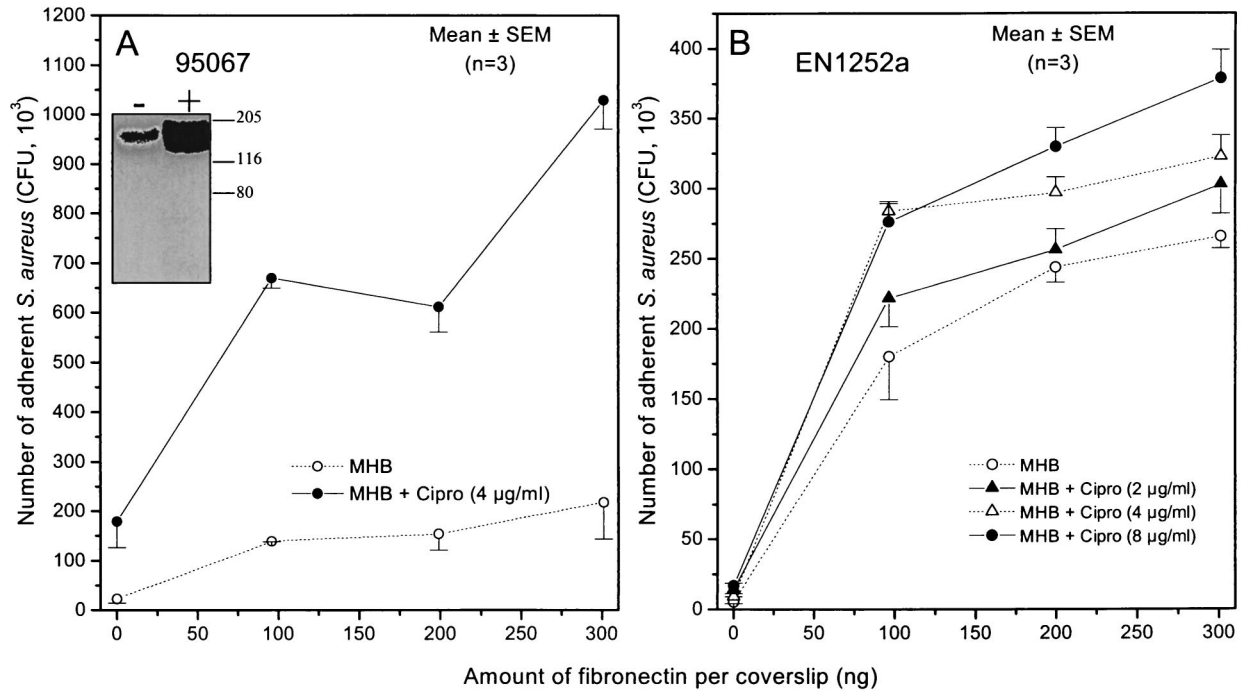

FIG. 2. Adhesion to fibronectin-coated coverslips of the fluoroquinolone-resistant strains 95067 (A) and EN1252a (B) of *S. aureus* grown in the absence or presence of the indicated concentrations of ciprofloxacin. The insert in panel A shows expression of FnBPs by Western ligand affinity blots in a bacterial lysate of strain 95067 grown in the absence (-) or presence (+) of one-quarter the MIC of ciprofloxacin.

grown in the presence or absence of one-quarter the MIC of ciprofloxacin were prepared as described above. Protein concentrations were determined by the Pierce method. CAT activity was assayed with a commercial kit (CAT-ELISA; Roche, Basel, Switzerland).

## RESULTS

**Ciprofloxacin-containing growth medium can alter adhesion of clinical quinolone-resistant isolates of *S. aureus*.** None of the 16 quinolone-resistant clinical isolates showed any reduction in bacterial adhesion after growth in the presence of one-quarter the MIC of ciprofloxacin (Fig. 1). Average adhesion values of the 10 MRSA and 6 MSSA isolates grown in control ciprofloxacin-free medium ranged from  $86 \times 10^3$  to  $394 \times 10^3$  CFU/coverslip and  $113 \times 10^3$  to  $297 \times 10^3$  CFU/coverslip, respectively. After growth in the presence of one-quarter the MIC of ciprofloxacin, average adhesion values of MRSA and MSSA isolates ranged from  $101 \times 10^3$  to  $769 \times 10^3$  CFU/coverslip and  $239 \times 10^3$  to  $360 \times 10^3$  CFU/coverslip, respectively. Only four isolates, two MRSA and two MSSA isolates, showed nonsignificant marginal increases in adhesion. All other isolates exhibited significant average increases in attachment to fibronectin-coated surfaces, ranging from 27 to 353% for 8 of 10 MRSA isolates and 22 to 112% for 4 of 6 MSSA isolates (Table 1).

An important property of the randomly collected clinical MRSA isolates was the wide diversity of amino acid changes in the QRDR of their *gylA* and *gylB* loci (Table 1). This provided indirect evidence that we were not dealing with a single clone in particular for the Geneva subgroup, of which four of five isolates were collected in the Orthopedic Clinic within a 1-month interval.

The most remarkable changes in adhesion were found in the subgroup of multidrug-resistant strains collected from the Pasteur Institute, which showed some evidence of epidemic transmission. Among them, strains BM10762 and 95067 exhibited

206 and 353% average increases in attachment, respectively, following growth in the presence of one-quarter the MIC of ciprofloxacin. The adhesion profiles of strain 95067 grown either in the absence or presence of one-quarter the MIC of ciprofloxacin are shown in Fig. 2A. Western fibronectin affinity blots confirmed that increased adhesion of strain 95067 was associated with an 3.5-fold increase in the amount of FnBPs promoted by growth in the ciprofloxacin-containing medium (Fig. 2A, inset). Calibration curves performed with three different amounts of protein extract of strain 95067 loaded on SDS-PAGE and tested by Western affinity blots verified that the ciprofloxacin-promoted increase in FnBPs was within the linear range of the densitometric analysis, as shown previously (1). Further experiments also demonstrated increased amounts of FnBPs, reaching 152 and 90% in clinical strains BM10762 and 95057 grown in the presence of one-quarter the MIC of ciprofloxacin, respectively. Such increases in FnBPs were consistent with the increased adhesion of strains BM10762 and 95057 of 206 and 73%, respectively (Table 1).

Figure 2B shows the adhesion profiles of strain EN1252a, a well defined quinolone-resistant *gylA gylB* double mutant of *S. aureus* 8325, grown in the absence or presence of increasing subinhibitory concentrations of ciprofloxacin. Attachment of this fluoroquinolone-resistant mutant was previously shown to be significantly promoted by one-quarter the MIC of ciprofloxacin (1). Growth in the presence of 1/16 the MIC of ciprofloxacin (2 µg/ml) led to a marginal, nonsignificant increase in bacterial adhesion compared to growth in ciprofloxacin-free medium. In contrast, growth in the presence of higher subinhibitory concentrations of ciprofloxacin, namely, one-eighth the MIC (4 µg/ml) and one-quarter the MIC (8 µg/ml), led to significant increases in adhesion. Interestingly, the dose responses of strain EN1252a adhesion promoted by growth in the presence of one-eighth MIC and one-quarter the MIC of ciprofloxacin were almost equivalent, representing a plateau of

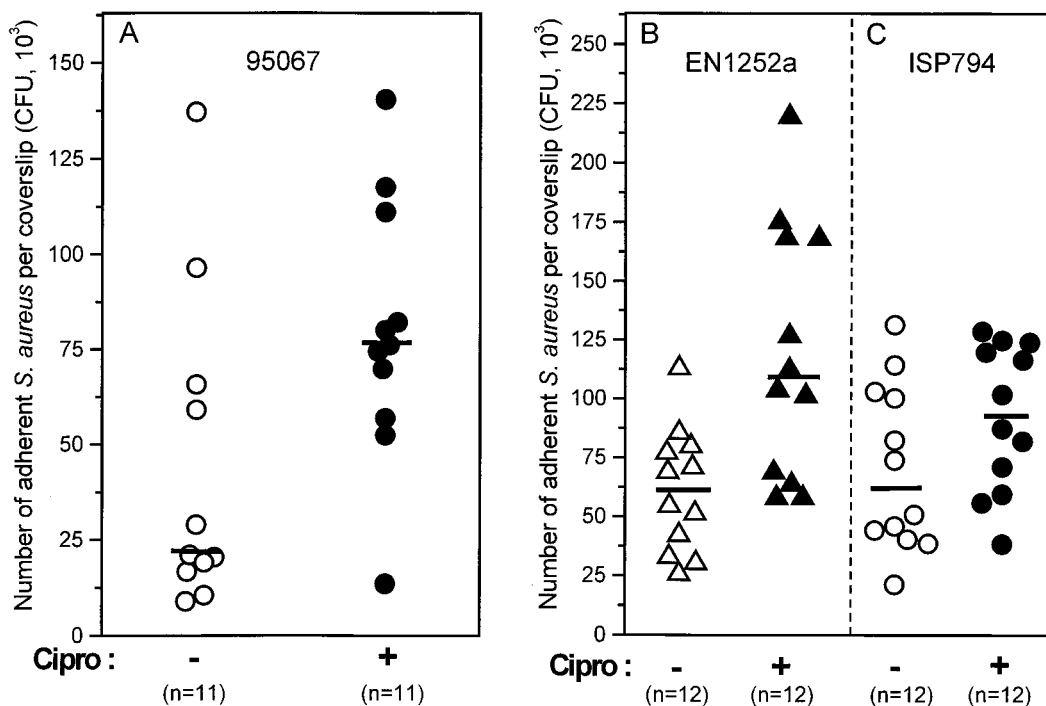

FIG. 3. Adhesion to coverslips explanted from guinea pigs of the clinical MRSA strain 95067 (A), the double *glaA gyrA* mutant strain EN1252a (B), and its parent ISP794 (C) grown in the absence (open symbols) or presence (solid symbols) of one-quarter the MIC of ciprofloxacin for each strain, namely 4  $\mu\text{g/ml}$  for 95067, 8  $\mu\text{g/ml}$  for EN1252a, and 0.06  $\mu\text{g/ml}$  for ISP794.

response at these subinhibitory concentrations. Western fibronectin affinity blotting assessed that strain EN1252a grown in the presence of 1/4 and 1/8 the MIC but not 1/16 the MIC of ciprofloxacin exhibited an increased production of FnBPs (data not shown), thus confirming previously reported data recorded with 1/4 the MIC of this fluoroquinolone and further correlating increased FnBP expression and increased adhesion (1). Of note, growth in the presence of one-eighth the MIC of ciprofloxacin did not alter the growth rate of strain EN1252a, which grew at a rate identical to that in control antibiotic-free MHB.

Taken together, the dose response of FnBP production and increased adhesion of strain EN1252a were closely related to each other. Optimal promotion of FnBP-mediated adhesion was obtained by growing fluoroquinolone-resistant organisms in the presence of ciprofloxacin concentrations that are still clinically relevant.

**Adhesion of fluoroquinolone-resistant *S. aureus* to explanted coverslips.** The attachment of clinical strain 95067 to coverslips explanted from guinea pigs increased from  $21 \times 10^3$  to  $76 \times 10^3$  CFU/coverslip for organisms grown in ciprofloxacin-containing medium (one-quarter the MIC) compared to those grown in control medium (Fig. 3A). Similarly, attachment of EN1252a *glaA gyrA* was increased significantly in the presence of one-quarter the MIC of ciprofloxacin (from  $62 \times 10^3$  to  $108 \times 10^3$  CFU/coverslip [Fig. 3B]). In contrast, the median attachment increase of the fluoroquinolone-susceptible parental strain ISP794 (from  $62 \times 10^3$  to  $94 \times 10^3$  CFU/coverslip [Fig. 3C]) did not reach statistical significance. Finally, neither strains EN1252a nor ISP794 showed increased attachment when grown in the presence of one-eighth the MIC of ciprofloxacin (data not shown). Thus, as was the case for adhesion to fibronectin-coated coverslips, adhesion to explanted coverslips was promoted by ciprofloxacin in a dose-dependent manner.

**Activation of *fnbA* and *fnbB* promoter by subinhibitory concentrations of ciprofloxacin.** To study whether expression of the *fnbA* and *fnbB* promoters was modified by subinhibitory concentrations of ciprofloxacin in fluoroquinolone-resistant or fluoroquinolone-susceptible *S. aureus*, we used the previously described *fnbA-luxAB* and *fnbB-luxAB* reporter plasmids pFNBA6 and pFNBB6 (14) transferred into the double mutant strain EN1252a or its susceptible parent ISP794.

In the first set of experiments, expression of *fnbA* or *fnbB* promoters was recorded on EN1252a or ISP794 cells that were continuously exposed to one-quarter the MIC of ciprofloxacin for 5 h. In contrast to the *fnbA* promoter, which exhibited no specific response to ciprofloxacin (data not shown) and was not further studied, the *fnbB* promoter of strain EN1252a was significantly more active from 2 to 5 h in the presence of ciprofloxacin than in its absence (Fig. 4A). Of note, the quinolone-induced response of the *fnbB-lux* fusion observed in the fluoroquinolone-resistant strain EN1252a was not seen with its quinolone-susceptible parent ISP794 (Fig. 4A). The presence of one-quarter the MIC of ciprofloxacin in the medium slightly dampened the growth rate of strain EN1252a but had no effect on strain ISP794 (Fig. 4B).

To verify that the increased luciferase activity was not due to differences in plasmid copy number, CAT activity of the *fnbB-lux* fusion plasmid, which is not under control of the *fnbB* promoter, was determined for strains ISP794 and EN1252a. No difference was observed between strains grown in the presence or absence of ciprofloxacin (data not shown).

Further experiments with the parent and *glaA gyrA* double mutant (strain EN1252a) were carried out to study the initial phase of *fnbB* activation by one-quarter the MIC of ciprofloxacin. At 20 min after the addition of ciprofloxacin, strain EN1252a(pFNBB6) (Fig. 5A) showed a significant increase in SLU of  $39\% \pm 4\%$  compared to a slight nonsignificant decrease ( $-2\% \pm 3\%$ ) of cells grown in quinolone-free MHB

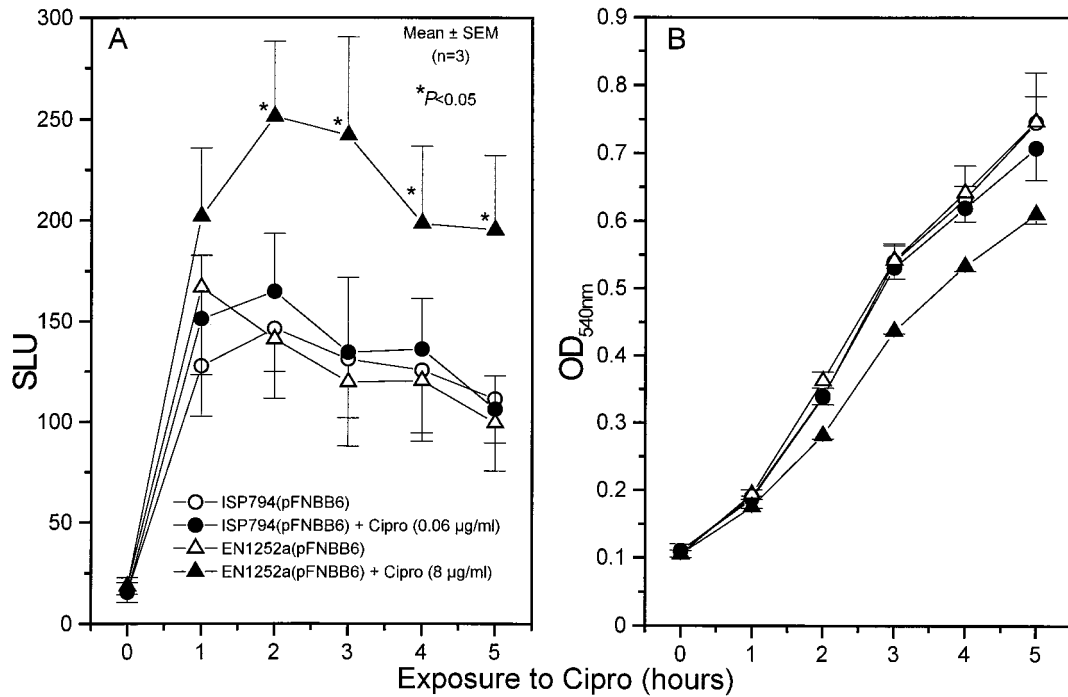

FIG. 4. Luciferase activity of the *fnbB-luxAB* reporter plasmid in strains EN1252a(pFNBB6) and ISP794(pFNBB6) either unexposed or continuously exposed for 5 h to one-quarter the MIC of ciprofloxacin (A) and bacterial growth monitored by measuring the optical density at 540 nm (B). \*,  $P < 0.05$  for culture grown with ciprofloxacin compared to that without ciprofloxacin.

(Fig. 5A). Control experiments verified that the growth rate of fluoroquinolone-exposed or unexposed strain EN1252a (pFNBB6) monitored by optical density was equivalent to that monitored by CFU counts (data not shown).

Pretreatment of the ciprofloxacin-exposed organisms with

rifampin (2 µg/ml) abolished the fluoroquinolone-promoted increase in SLU of strain EN1252a, indicating that this increase was due to increased transcription of the *fnbB-lux* fusion and not to some other unrelated mechanism. Since the average SLU of rifampin-pretreated organisms decreased at 20 min by

FIG. 5. Increase in SLU by the *fnbB-luxAB* reporter plasmid in strain EN1252a(pFNBB6) or ISP794(pFNBB6) exposed for 20 min to either control MHB or MHB supplemented with rifampin (2 µg/ml), with one-quarter the MIC (8 µg/ml) of ciprofloxacin, or with rifampin (2 µg/ml) followed by ciprofloxacin (8 µg/ml).

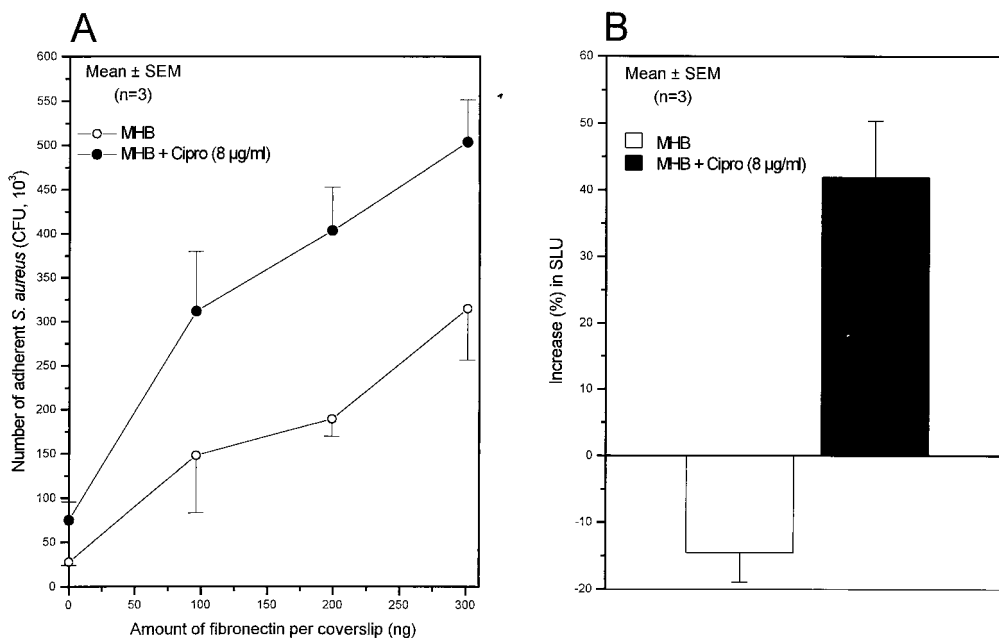

FIG. 6. (A) Adhesion to fibronectin-coated coverslips of the *agr*-defective fluoroquinolone-resistant strain CB3 of *S. aureus* grown in the absence or presence of the indicated concentrations of ciprofloxacin. (B) Increase in SLU by the *fnbB-luxAB* reporter plasmid in strain CB3(pFNBB6) exposed for 20 min to either control MHB or MHB supplemented with one-quarter the MIC (8 µg/ml) of ciprofloxacin.

9% ± 4% and 16% ± 2% for cultures incubated without and with ciprofloxacin, respectively (Fig. 5A), this finding indicated that the turnover of the *fnbB-lux* fusion protein was marginal in these experimental conditions. In contrast to strain EN1252a, the fluoroquinolone-susceptible parental strain ISP794 showed no significant change in SLU at 20 min after the addition of ciprofloxacin (13% ± 8%), rifampin (4% ± 4%), or rifampin plus ciprofloxacin (6% ± 4%). These values were similar to those of control cells whose SLU marginally increased by 7% ± 1% (Fig. 5B). Thus one-quarter the MIC of ciprofloxacin could selectively activate the *fnbB* promoter of the fluoroquinolone-resistant strain EN1252a but not the fluoroquinolone-susceptible strain ISP794.

To further confirm that the ciprofloxacin-promoted increase in *fnbB* expression was not an indirect effect of decreased growth rate, we also compared the rates of activation of *fnbB-lux* in strain EN1252a by either one-eighth or one-quarter the MIC of ciprofloxacin in the growth medium. At 20 min after the addition of ciprofloxacin, strain EN1252a(pFNBB6) showed significant increases in SLU of 45% ± 7% and 29% ± 7% when exposed to one-eighth and one-quarter the MIC of ciprofloxacin, respectively, while exhibiting a slight nonsignificant decrease of -4% ± 2% in quinolone-free MHB. During this 20-min period, the increase in optical density of strain EN1252a (30% ± 2%) was not affected by one-eighth the MIC of ciprofloxacin in MHB, being at least equivalent to that in quinolone-free MHB (26% ± 2%) and slightly superior to that in MHB containing one-quarter the MIC of the fluoroquinolone (21% ± 2%). These data ruled out the notion that decreased growth rate is an absolute requirement for the effect of a sub-MIC of ciprofloxacin on *fnbB* gene expression in the quinolone-resistant strain EN1252a.

**Activation of the *agr* locus is not required for ciprofloxacin-promoted *fnbB* gene expression.** The contribution of *agr* activation to the ciprofloxacin-mediated *fnbB* gene activation was tested by comparing strain EN1252a with its *agr*-defective mutant strain CB3, which showed equivalent ciprofloxacin MICs.

Adhesion rates of strains CB3 (Fig. 6A) and EN1252a (not shown) were similarly promoted by growth in the presence of one-quarter the MIC of ciprofloxacin in MHB. Furthermore, activation of *fnbB-lux* by one-quarter the MIC of ciprofloxacin recorded in the *agr*-defective strain CB3(pFNBB6) (Fig. 6B) was equivalent to that recorded in strain EN1252a(pFNBB6) (data not shown). Thus, the *agr* locus was not required for activation of the *fnbB* promoter by one-quarter the MIC of ciprofloxacin.

## DISCUSSION

A few recent studies indicate that exposure of *S. aureus* to subinhibitory concentrations of some antibiotics may trigger in this pathogen a paradoxical increase in some of its virulence factors (1, 21, 35). Sub-MIC levels of  $\beta$ -lactams, in particular nafcillin, were shown to induce *hla* gene expression and increase alpha-toxin production in *S. aureus* (21, 35). We recently reported that an isogenic fluoroquinolone-resistant *grlA grxA* double mutant of *S. aureus* NCTC8325 grown in the presence of subinhibitory concentrations of ciprofloxacin expressed increased levels of FnBPs and showed a significantly higher attachment to fibronectin-coated polymer surfaces (1).

In this study, adhesion of a majority (12 of 16) of fluoroquinolone-resistant clinical isolates, including 10 MRSA isolates and 6 MSSA isolates which were not epidemiologically linked, was significantly promoted by growth in the presence of one-quarter the MIC of ciprofloxacin for each strain. These results, which mimic the findings of our previous study with isogenic fluoroquinolone-resistant mutants of NCTC8325, may indicate a common ciprofloxacin-induced upregulation of fibronectin adhesins in both clinical and laboratory strains which may be of epidemiological relevance. The most impressive responses in ciprofloxacin-promoted adhesion were found in two epidemic though geographically distinct multidrug-resistant strains of MRSA. Much larger representative samples of epidemic and nonepidemic strains will have to be tested to

document a possible correlation between intensive use of fluoroquinolones and selection of particularly invasive *S. aureus* isolates with a high potential of epidemic transmission. Interestingly, one recent study evaluating the relationship between the incidence of MRSA and the use of different classes of antimicrobials in Belgian hospitals found a correlation with increasing use of quinolones in a multivariate analysis (7). In another prospective randomized study, outbreaks of MRSA superinfections causing late-onset pneumonia were clearly associated with ciprofloxacin use in intensive care units (23).

Adhesion rates of the most highly promoted clinical strain, 95067, and that of the isogenic fluoroquinolone-resistant mutant EN1252a were also significantly increased on coverslips explanted from guinea pigs after growth in the presence of one-quarter the MIC of ciprofloxacin. This finding indicated that fibronectin, which is associated with several other extracellular matrix components, including collagen, laminin, and glycosaminoglycans (53, 54), was indeed playing a leading role in promoting the attachment of both clinical and laboratory isolates to such subcutaneously implanted biomaterials. Since coverslips explanted from guinea pigs promoted less regular attachment than fibronectin-coated surfaces, this might be due to variable amounts of fibronectin adsorbed on the subcutaneously implanted surfaces and to the potential contribution or antagonistic effects of other extracellular matrix components to *S. aureus* adhesion. The large variability in quantitative adhesion data recorded on explanted coverslips probably explained why only one-quarter the MIC, but not lower sub-MICs of ciprofloxacin, was able to significantly promote *S. aureus* attachment to in vivo-coated biomaterials.

To evaluate the potential activation of *fnbA* and/or *fnbB* gene by sub-MIC levels of ciprofloxacin, we used luciferase *fnb-luxAB* reporter plasmids transformed into fluoroquinolone-resistant or -susceptible isogenic strains EN1252a and ISP794, respectively. As previously described in other strains (14), the luciferase activity mediated by the *fnbB* promoter was two to three times higher than that of the *fnbA* promoter in both strain EN1252a and ISP794 grown in control antibiotic-free MHB. In this study, continuous incubation of strains EN1252a and ISP794 with one-quarter the MIC of ciprofloxacin demonstrated at 2 to 5 h a specific activation of the *fnbB*, as opposed to *fnbA*, promoter which occurred only in the fluoroquinolone-resistant double *glaA gyrA* mutant but not its fluoroquinolone-susceptible parent. This difference was not attributable to a change in plasmid copy number. In short-term experiments evaluating the activation of the *fnbB* promoter by sub-MICs of ciprofloxacin, the fluoroquinolone-resistant strain EN1252a but not its fluoroquinolone-susceptible parent ISP794 already expressed increased luciferase activity at 20 min compared to expression in control antibiotic-free MHB. Since pretreatment with the RNA transcription inhibitor rifampin abolished the ciprofloxacin-induced response, this indicated that the increased luciferase activity indeed reflected increased transcription of the *fnbB-luxAB* reporter plasmid in the fluoroquinolone-resistant strain EN1252a. In addition, the rifampin pretreatment experiments showed a marginal turnover of luciferase under these experimental conditions. This observation, which validated the use of the *luxAB* reporter plasmid at 35°C, was in contrast to other observations reporting a high instability of luciferase at 37°C (16). Taken together, these observations suggest that ciprofloxacin at sub-MICs can activate by undefined mechanisms the *fnbB* promoter in fluoroquinolone-resistant *glaA gyrA* laboratory isolates as well as in a substantial proportion of the clinical isolates of *S. aureus* that were tested. Our data suggest that this *fnbB* promoter activation is responsible for increased production of FnBP(s), lead-

ing to a higher level of bacterial attachment to fibronectin-coated or subcutaneously implanted coverslips.

Different bacterial response mechanisms may contribute to the ciprofloxacin-activated increase in FnBP-mediated adhesion in fluoroquinolone-resistant mutants of *S. aureus*. Fluoroquinolones are known to induce the SOS response in gram-negative bacteria stemming from DNA damage thought to be generated by collisions of the DNA replication fork with ternary complexes of drug, DNA, and either topoisomerase IV or DNA gyrase (3, 13, 17, 22, 57). Other studies indicate that fluoroquinolones can also induce heat shock proteins DnaK and GroEL in *Escherichia coli*, mediated by the sigma 32 transcription factor (26, 27). It is also possible that fluoroquinolones have either direct or indirect effects on some global regulator(s) of *S. aureus* known to affect the expression of FnBP and other cell surface proteins (41) such as *agr* (33) or *sar* (44); Chung and Wolz, 37th ICAAC). A recent report also indicates that *agr*- or *sar*-defective mutants express a somewhat lower level of methicillin resistance, which is associated with a reduction in levels of PBP1 and PBP3 but not PBP2' (8). While the present study, which was carried out with an *agr* knockout mutant, indicates that this global regulator is not required for the ciprofloxacin-induced response in *fnbB* transcription, further studies are in progress to evaluate the potential role of other global regulators, such as the *sar* locus or the more complex heat shock and SOS response systems.

In conclusion, sub-MIC levels of ciprofloxacin and potentially other fluoroquinolones may upregulate adhesin expression in *S. aureus* strains resistant to these antimicrobial agents. Further in vitro and in vivo studies are needed to evaluate the molecular mechanisms of this bacterial response and its clinical and epidemiological relevance.

#### ACKNOWLEDGMENTS

This work was supported by the Swiss National Foundation (grant 3200-045810.95/2 [to P.V.]) and the National Institute of Health (grant AI23988 [to D.C.H.]).

We thank Xiamei Zhang for performing the DNA sequencing of the Boston strains, T. J. Foster for providing the reporter plasmids and A. L. Cheung strain ALC 355, Manuela Bento for technical assistance, and William Kelley for helpful discussion.
