Abstract: Primary care clinicians have a vital role to play in the diagnosis and management of patients with major depressive disorder (MDD). This includes screening for MDD as well as identifying other possible psychiatric disorders including bipolar disorder and/or other comorbidities. Once MDD is confirmed, partnering with patients in the shared decision-making process while considering different treatment options and best management of MDD over the course of their illness is recommended. Vortioxetine has been approved for the treatment of adults with MDD since 2013, and subsequent US label updates indicate that vortioxetine may be particularly beneficial for specific populations of patients with MDD, including those with treatment-emergent sexual dysfunction and patients experiencing certain cognitive symptoms. Given these recent label updates, this prescribing guide for vortioxetine aims to provide clear and practical guidance for primary care clinicians on the safe and effective use of vortioxetine for the treatment of MDD, including how to identify appropriate patients for treatment.

Keywords: antidepressant, measurement-guided care, shared decision-making

Plain Language Summary

Diagnosis and management of major depressive disorder (MDD) in a primary care setting

- Primary care clinicians need practical guidance for the diagnosis and management of MDD, which is a major health concern in the United States.
- A variety of tools suitable for clinical practice can support primary care clinicians in screening depressive symptoms and suicide risk, distinguishing MDD from other mood disorders (eg, bipolar disorder) and monitoring for disease outcomes over time.
- Shared decision-making between the primary care clinician and patient can help improve patient education and comfort, providing an opportunity for the clinician to address any stigma associated with MDD in a nonjudgmental way.

Distinguishing characteristics of vortioxetine

- Vortioxetine is a serotonin modulator and stimulator approved for the treatment of MDD in adult patients aged 18 years or older.
- In addition, vortioxetine has demonstrated efficacy as maintenance therapy for the prevention of MDD relapse and/or recurrence. New data have recently demonstrated that long-term continuation of treatment with vortioxetine delays recurrence of depressive episodes compared with placebo.
- Subsequent updates to the vortioxetine US label support its use in patients with treatment-emergent sexual dysfunction and those experiencing certain cognitive symptoms.

- Importantly, vortioxetine has demonstrated good tolerability, with no dose adjustments required for patients with renal or hepatic impairment.

Introduction

With major depressive disorder (MDD) recognized as a major mental health concern in the US population,^{1,2} screening for depression is now recommended as part of routine primary care. A vast number of reports in the literature have documented the devastating impact of MDD and associated suicide on the individual, family, and society as a whole. Primary care clinicians (PCCs) are at the front lines of diagnosing and managing patients who suffer from depression. For this reason, education and practical guidance for PCCs on the screening and management of individuals at risk for MDD and suicide are needed.

Screening for MDD, Suicide Risk, and Measurement-Guided Care

The United States Preventive Services Task Force (USPSTF) 2016 recommendations for screening for MDD include, but are not limited to, a comprehensive list of high-risk individuals: women, young and middle-aged adults, non-White persons, persons who are undereducated or who have lower socioeconomic status, previously married, or unemployed, or those who have chronic illnesses or other mental health disorders, or a family history of psychiatric disorders.³ Assessment of drug and alcohol abuse may also provide insight into individuals at risk for depression and suicide, given the rates of suicide by overdose and unintentional overdose with associated deaths.⁴ Alcohol and/or drug abuse or dependency may also contribute to poor response to treatment of MDD.⁵

Use of validated self-administered screening tools, such as the 9-item Patient Health Questionnaire (PHQ-9), is an important standard of care that not only helps in the diagnosis of individuals with MDD but also guides management and monitoring of symptoms.^{6,7} Measurement-guided care refers to a systematic approach to treatment for clinical practice that includes routine use of validated symptom scales and side effect measurements. These tools should be brief, either self-administered or easy to administer as measurement instruments. Guidance can then be provided for clinicians on when and how to modify medication doses at critical decision points.^{8,9} Table 1 provides an overview of some of the key screening and monitoring tools for MDD, suicide risk, and differential diagnosis. Examples of screening instruments for MDD recommended by the USPSTF include the PHQ in various forms and the Hospital Anxiety and Depression Scale in adults, the Geriatric Depression Scale in older adults, and the Edinburgh Postnatal Depression Scale in postpartum and pregnant women.³ The PHQ-9 and the Columbia-Suicide Severity Rating Scale may be particularly useful in primary care settings.^{10,11} In addition, the US National Strategy for Suicide Prevention recommends the use of suicide-prediction tools, and the European Psychiatric Association endorses using these tools as adjuncts to an individual psychiatric assessment.¹²

MDD is truly a diagnosis of exclusion. It is imperative to rule out bipolar disorder (BPD) to make a diagnosis of MDD.¹³ It has been estimated that as many as 1 in every 4 to 5 patients presenting with a major depressive episode may eventually transition to BPD.¹⁴ This may be in part because patients with BPD who present for treatment are more likely to present with depressive symptoms than with symptoms of mania. Two screening tools in particular, the Rapid Mood Screener (RMS) and Mood Disorders Questionnaire (MDQ) are suitable for screening BPD in primary care settings.¹⁵ Patients who screen positive on the RMS or MDQ should undergo a full clinical evaluation for BPD.¹⁶

Suicidal ideation and behavior is implicated in several neuropsychiatric disorders, including borderline personality disorder, schizophrenia, and BPD.^{17,18} Suicide risk is an important consideration for patients with MDD who initiate treatment with antidepressants, as antidepressants as a class have been associated with an increased risk of suicidal thoughts and behaviors in certain age groups.¹⁹ As an example, when given to individuals with BPD as monotherapy, antidepressants can precipitate an unintended response, such as no response, poor response, or antidepressant misadventure, which can precipitate hypomania and mania, subsequently leading to worsening of disease and heightened suicide risk.^{20,21} Treatments including anti-anxiety medications and opioid-based analgesics have been associated with an increased suicide risk in certain patients, although caution should be exercised when examining associations and drawing conclusions about causality from observational data.²² Thus, suicide screening is important for all patients receiving treatment with antidepressant therapy, and assessment of suicidal ideation and behaviors should be a routine part of treatment monitoring.^{4,18} Of note, denial of suicidal ideation would appear to be more common than previously acknowledged, thus presenting a formidable challenge for

clinicians, since denial, by itself, is an inadequate indicator of suicide risk.¹⁸ The USPSTF is currently updating its recommendations on screening patients for suicide.²³ In terms of timing and frequency of assessment, it is considered ideal for PCCs to have 3 contacts with the patient within 12 weeks after the initial identification of a depressed patient, though visit frequency must be optimized based on individual patient needs. The PHQ-9 should be administered during follow-up visits to monitor patient progress and to assess treatment response, keeping in mind that item 9 on the PHQ-9 asks about suicidality.²⁴

Of relevance to clinical practice for the monitoring of side effects related to treatment is the Frequency, Intensity, and Burden of Side Effects Rating (FIBSER) Scale, which is a brief self-report scale developed to document these domains of side effects from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) prospective clinical trial. In that clinical program, which enrolled over 4000 patients, the FIBSER was demonstrated to be a reliable and valid measure of the 3 domains of side effects in a depressed population and is brief enough to be well-suited to clinical practice.²⁵ Another simple self-report measure, the Antidepressant Side-Effect Checklist, is a reliable scale for the assessment of side effects related to antidepressant therapy. It measures 21 adverse reactions, including dry mouth, drowsiness, and difficulty sleeping.²⁶

While these screening and monitoring tools can provide a helpful standardized way to evaluate patients for depression and depressive symptoms in clinical practice, consideration of individual patient characteristics, including comorbidities and the use of concomitant medications, can help guide treatment selection and improve the chance of positive treatment outcomes.²⁷

Shared Decision-Making in Primary Care Settings: Collaboration Between the Clinician and Patient

In primary care settings, shared decision-making between the clinician and patient can improve patient education and comfort; this should include educating the patient about treatment options and taking into consideration any concerns the

patient may have about treatment.²⁸ Key concerns expressed by patients receiving long-term (3–15 years) treatment for MDD included weight gain, withdrawal effects, and sexual dysfunction.²⁹ In addition to providing the patient with an opportunity to address treatment issues and concerns, the PCC has an opportunity to address any associated stigma and discrimination via psychoeducation in a validating, nonjudgmental manner. Legitimizing depression as a chronic illness has been shown to increase the patient's willingness to receive appropriate care.³⁰ Patient resources from established mental health associations and foundations may also help newly diagnosed patients with MDD feel supported, improve their education on the condition, and minimize their isolation. These support groups allow patients to discuss their conditions and foster the shared decision-making process by offering a platform for provider-patient discussions. Table 2 provides a list of selected patient support resources and groups from various mental health foundations.

Beyond the patient-provider relationship, seeking permission to involve family members and friends in psychoeducation and treatment can be important for fostering a positive therapeutic relationship.³⁰ Information from family members, friends, and other supporters may help confirm the differential diagnosis of MDD, BPD, and suicidality; however, caution should be advised, as input from certain family members or friends may be unhelpful, and must always be engaged with the consent and endorsement of the patient.^{30,31}

Current treatment options for patients with MDD include psychotherapy and pharmacotherapy, alone or in combination. Involvement of patients in the shared decision-making process while considering these treatment options is critical for long-term adherence and improvement of MDD. Common pharmacological options include selective serotonin reuptake inhibitors (SSRIs), serotonin (5-HT) transporter (SERT) inhibitors, tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs).³⁰ Among these options is vortioxetine, a second-generation multimodal serotonergic agent, approved in the US for the treatment of MDD in adult patients since 2013 (Table 3).¹⁹ The mechanism of antidepressant effect of vortioxetine is not well understood, but it is thought to act via serotonin reuptake inhibition and serotonin receptor modulation.^{19,32}

Vortioxetine Clinical Profile

Recent label updates for vortioxetine include new relapse-prevention data and improvements in patients with treatment-emergent sexual dysfunction (TESD) and those experiencing symptoms related to cognitive processing speed. Here, we provide practical guidance for the implementation of vortioxetine in the management of MDD in primary care settings, with case vignettes (hypothetical examples) highlighting patients who may be particularly suitable for treatment with vortioxetine. In addition, the management of potential adverse events (AEs) with vortioxetine and the need for a shared

decision-making process to evaluate benefit-risk ratio is also addressed. [Figure 1](#) provides an overview of how patients with MDD may be screened, diagnosed, and monitored in primary care settings, and includes considerations for selecting vortioxetine to treat MDD.

Six 6- to 8-Week Studies Supported the Approval of Vortioxetine for the Treatment of MDD

Vortioxetine was approved for the treatment of MDD in adult patients based on six 6- to 8-week randomized, double-blind, placebo-controlled, fixed-dose studies including 1 study in the elderly ([Figure 2](#)); and 1 maintenance study in adult inpatients and outpatients who met the *Diagnostic and Statistical Manual of Mental Disorders IV Text Revision* criteria for MDD.^{19,33–37} In the placebo-controlled studies, patients were randomized to receive vortioxetine 5 mg, 10 mg, 15 mg,

In Study 1, the analysis was performed at week 6, and in others at week 8. The primary efficacy measure was based on MADRS score, except for Studies 2 and 6 (HAM-D-24 scores). 20 mg, or placebo once daily. The primary efficacy measures were the Hamilton Depression Scale-24 or the Montgomery-Åsberg Depression Rating Scale (MADRS) total score (Table 4).^{19,33–37} In each of these studies, at least 1 dose group of vortioxetine was superior to placebo in improvement of depressive symptoms as measured by mean change from baseline to endpoint visit on the primary efficacy measurement used in each study.^{19,33–37} The initial antidepressant effect of vortioxetine was generally observed starting at week 2 and increased in subsequent weeks, with the full antidepressant effect of vortioxetine not observed until week 4 or later.^{19,37}

Vortioxetine Has Demonstrated Efficacy as a Maintenance Therapy for the Prevention of MDD Relapse

Vortioxetine is effective as a maintenance therapy for MDD over the long term and may be suitable for patients who are at risk of relapse of MDD.^{19,38} This was evaluated in a double-blind, randomized, placebo-controlled study, with an open-label, fixed-dose period of 12 weeks followed by a double-blind, fixed-dose, placebo-controlled period of 24–64 weeks. Participants in remission at weeks 10 and 12 (as defined by MADRS total score ≤ 10) who received vortioxetine during the double-blind period had significantly longer time to relapse (defined as MADRS total score ≥ 22 or an insufficient therapeutic response) compared with participants who received placebo during the double-blind period.^{19,38}

In a US-based relapse prevention study of 580 patients in stabilized remission after open-label treatment with 10 mg vortioxetine, randomization to 5, 10, or 20 mg vortioxetine led to a statistically significant longer time to recurrence of depressive episodes compared with placebo.^{19,39} Importantly, patients achieving remission on the 10 mg/day dose of vortioxetine in the acute phase maintained remission and treatment tolerability during the double-blind phase across the approved dose range.³⁹ These data were part of a subsequent label update for vortioxetine.

Vortioxetine is a Suitable Treatment for MDD in Older Patients Aged 64 to 88 Years

Vortioxetine may be a suitable treatment for older patients with depression, with a lifetime prevalence of 14.4% in individuals aged ≥ 65 years, based on a recent large-scale study conducted in the US.⁴⁰ In a randomized, double-blind, placebo-controlled, fixed-dose study of vortioxetine in patients aged 64 to 88 years with MDD, vortioxetine was superior to placebo on the Clinical Global Impression of Improvement scale, which is a clinician's assessment of the patient's global functioning prior to and after treatment initiation (Figure 2, Table 4).^{19,41,42}

Use of Vortioxetine in Patients with TESD

TESD is a key concern of patients with MDD and frequently a reason for early self-discontinuation of antidepressant therapy.^{29,43} As many as 73% of patients receiving treatment for depression express concern about sexual problems as a side effect of treatment.^{29,43} Therefore, it is important to routinely inquire about possible sexual side effects of antidepressant treatment. Based on results from 2 clinical studies, vortioxetine may be a treatment of choice in managing depressive disorders when sexual functioning is a concern.^{19,44} The effect of vortioxetine on TESD induced by prior SSRI treatment in MDD patients whose depressive symptoms were adequately treated was evaluated in an 8-week, randomized, double-blind, active-controlled (escitalopram), flexible-dose study.^{19,45} The allowed prior monotherapy treatments (before switch to vortioxetine) included citalopram, paroxetine, or sertraline, and participants were required to have been on a stable dosage for at least 8 weeks.⁴⁵ Improvement in TESD (induced by prior SSRI treatment) in participants who switched to vortioxetine was superior to the improvement observed in participants who switched to escitalopram after 8 weeks of treatment, while both drugs maintained the patients' prior antidepressant response (Figure 3).^{19,45}

Of note, vortioxetine 10 mg (but not 20 mg) showed statistically significantly less TESD in healthy individuals compared with paroxetine 20 mg and placebo, highlighting the benefit of vortioxetine without the confounding effects of MDD.⁴⁴ Lower doses of vortioxetine produced an incidence of TESD comparable with placebo. Thus, vortioxetine is a suitable antidepressant therapy for patients experiencing TESD, and the dose of vortioxetine may be lowered if patients experience side effects of a sexual nature or any other side effects. (Box 1).

Box 1 Case Vignette 1

Switching from SSRI to Vortioxetine Because of TESD

A 28-year-old woman with a 12-month history of MDD who has been effectively treated with an SSRI begins to experience diminished sexual functioning. Specifically, she reports loss of interest in sex and reduced ability to have an orgasm. She has a long-term partner and no other health concerns of note. Her PCC discusses the extent of the patient's sexual dysfunction with her and decides to switch her from her current SSRI to vortioxetine 10 mg for 1 week, followed by an increase to 20 mg. On initial follow-up 1 month later, the patient reports a mild improvement in symptoms of TESD and good tolerability of vortioxetine. At another follow-up 1 month later, the patient reports a good response to treatment, with increased interest in sex and improvement in ability to have an orgasm. This is consistent with her responses on the Changes in Sexual Functioning Short-Form, which the PCC asks her to complete during her follow-up. The patient reports mild nausea and dizziness at this visit, but otherwise reports good tolerability. Her PCC asks to see her again in 3 months.

Use of Vortioxetine in Individuals with MDD and Symptoms Related to Cognitive Processing Speed

Treating cognitive symptoms such as slowed processing speed, impaired learning and memory, as well as worsened executive function, decision-making, and response control can improve both functioning and performance in patients with MDD.⁴⁶ Patients treated with vortioxetine have shown improvements in processing speed, which is an aspect of cognitive function that can be impaired in MDD. Subjective complaints of cognitive deficits are prevalent in MDD, with deficits in processing speed being one of the most replicated cognitive symptoms reported.⁴⁶ Cognitive processing speed may affect a person's ability to perceive, recognize, and appropriately interpret emotions, and deficits in these aspects of cognition have the potential to impair coping abilities and interfere with a patient's normal functioning and outcomes.⁴⁷ Data from 2 clinical studies suggest that vortioxetine may be a suitable treatment for patients with MDD who experience symptoms related to processing speed. Two 8-week randomized, double-blind, placebo-controlled studies were conducted to evaluate the effect of vortioxetine as measured by the Digit Symbol Substitution Test (DSST) during the treatment of acute MDD. The DSST is a neuropsychological test that specifically measures processing speed.^{19,36} In both studies, patients in the vortioxetine group had a statistically significant greater improvement in the number of correct responses on the DSST; depressed mood as assessed by change from baseline in MADRS total score also improved in both studies.^{19,36,48} (Box 2).

Vortioxetine Has a Favorable Benefit-Risk Profile, with Good Tolerability and No Dose Adjustments Required for Patients with Renal or Hepatic Impairment

Vortioxetine was well tolerated in clinical trials; nausea, constipation, and vomiting were the most common AEs associated with vortioxetine.¹⁹ Frequency of nausea with vortioxetine was dose-dependent, and usually considered mild or moderate in intensity, with a median duration of 2 weeks.^{19,49}

No clinically significant differences in the exposure of vortioxetine were observed based on age, sex, ethnicity, or renal or hepatic function, and thus, no dose adjustments are required for patients with hepatic or renal impairment (Table 3); however, other dose adjustments may be required as reviewed in the next section.^{19,50}

Vortioxetine is not approved for the treatment of children and adolescents aged <18 years.¹⁹ However, like other antidepressants, vortioxetine carries a boxed warning for suicide risk because of an observed increase in suicidal thoughts and behaviors in pediatric and young adult patients taking antidepressants.¹⁹ Of note, vortioxetine was not included in the original meta-analysis that led to the requirement for the boxed warning for antidepressants by the US Food and Drug Administration Advisory Committee; however, this labeling requirement was mandated for all antidepressants.^{51,52} In fact, a recent post hoc, pooled analysis of short- and long-term clinical trials for vortioxetine did not find an increased risk of suicidality in adults with MDD.⁵¹ As a general rule, however, all patients should be monitored closely for worsening and emergence of suicidal thoughts and behaviors.¹⁹

Dosing and Initiation of Vortioxetine Treatment, Drug Interactions, and Timing Considerations for Discontinuation

The recommended starting dose of vortioxetine is 10 mg administered orally once daily without regard to meals. Dosage should then be increased to 20 mg per day, as tolerated, or decreased to 5 mg once daily for improved tolerability in

Vortioxetine for Elderly Patient with Cognitive Issues

A 74-year-old man recently diagnosed with MDD complains of having difficulty concentrating. Comorbidities include high blood pressure and a history of asthma; concurrent medications are lisinopril and a bronchodilator. As part of the clinical workup, Alzheimer's disease was ruled out, and a Mini-Mental State Exam was performed, with a resulting score of 29/30. After a discussion with the patient about his treatment options, the patient was prescribed vortioxetine at the full dose, as dose reductions are not required based on age. However, due to the age of the patient, his PCC monitored for signs and symptoms of hyponatremia, such as nausea, confusion, and headache, as elderly patients on antidepressants are at increased risk for this. At a follow-up visit 1 month later, the patient was tolerating vortioxetine well and did not report any signs or symptoms of hyponatremia but did report feeling nauseous at times and having dry mouth. At a 3-month follow-up visit, the patient reported improvement in symptoms of depression and ability to concentrate.

patients at risk of AEs.¹⁹ Drugs such as monoamine oxidase inhibitors, other serotonergic drugs, strong inhibitors of CYP2D6, strong CYP inducers, drugs that interfere with hemostasis, and drugs that are strongly bound to plasma protein may have clinically important interactions with vortioxetine (Table 3).^{19,50}

Unlike other antidepressant therapies that require tapering, vortioxetine can be discontinued abruptly. However, abrupt discontinuation of the 15 mg/day and 20 mg/day dosages of vortioxetine is associated with adverse reactions such as headache and muscle tension; therefore, it is recommended that dosages of 15 mg/day or 20 mg/day be reduced to 10 mg/day for 1 week prior to full discontinuation if possible.¹⁹

Conclusions

Primary care clinicians have a vital role to play in the proper diagnosis and management of patients with MDD. Shared decision-making, as well as early and repeated follow-up visits with appropriate monitoring for AEs and suicidality, symptom improvement, and treatment adherence is recommended.^{4,7-9,27,28,30} This includes screening for MDD, ensuring the accuracy of the MDD diagnosis by excluding BPD as well as partnering with patients to provide them with the appropriate treatment options.¹⁵ Understanding each patient's symptoms and treatment goals are important for the practitioner to determine the suitability of the antidepressant treatment. Involvement of patients in the decision-making process while evaluating different treatment options is critical for long-term adherence and remission of MDD.^{7,28,30,39} Discussion about treatment options, duration of treatment, likelihood of recurrent depression (after expected remission of MDD), as well as recommendation of mental health resources and support groups for newly diagnosed patients with MDD may also help patients feel more supported as they begin their treatment.^{7,29,53-55}

One of the most troubling AEs for patients on antidepressant therapy is TESD.^{29,43} Thus, having a focused conversation with patients while discussing sexual effects of different treatment options is very important. Vortioxetine is a suitable acute and long-term treatment for adult patients with MDD and may be especially useful for patients experiencing sexual dysfunction associated with their current antidepressants. In addition, vortioxetine can also be a preferred treatment for patients with MDD who experience symptoms related to impaired cognition. Increasing the speed of cognitive processing has recently been established as another beneficial attribute for vortioxetine and is now expressed as such in the package label. Patients who are treated with vortioxetine for MDD should be monitored for response to treatment and for resolution of suicidality, with the goal of achieving and maintaining remission.^{7,24,38,39} Many AEs associated with antidepressants can be evaluated with approved screening tools (eg, FIBSER), and patients should be monitored and involved in the decision-making process to improve medication adherence and plan for any dose adjustments, if needed.^{4,7,24,27} There should be a discussion about the duration of successful antidepressant therapy and referral to a mental health specialist, as psychotherapy may help patients better understand stressors that may trigger or exacerbate their depressive symptoms. These considerations often increase the chance of successful treatment outcomes for patients with MDD.

Neuropsychiatric Disease and Treatment is an international, peer-reviewed journal of clinical therapeutics and pharmacology focusing on concise rapid reporting of clinical or pre-clinical studies on a range of neuropsychiatric and neurological disorders. This journal is indexed on PubMed Central, the 'PsycINFO' database and CAS, and is the official journal of The International Neuropsychiatric Association (INA). The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
