Abstract

Introduction: Patients undergoing weight loss surgery do not improve their aerobic capacity or peak oxygen uptake (VO₂peak) after bariatric surgery and some still complain about asthenia and/or breathlessness. We investigated the hypothesis that a post-surgery muscular limitation could impact the ventilatory response to exercise by evaluating the post-surgery changes in muscle mass, strength, and muscular aerobic capacity, measured by the first ventilatory threshold (VT). **Methods:** Thirteen patients with obesity were referred to our university exercise laboratory before and 6 months after bariatric surgery and were matched by sex, age, and height to healthy subjects with normal weight. All subjects underwent a clinical examination, blood sampling, and body composition assessment by dual-energy X-ray absorptiometry, respiratory and limb muscle strength assessments, and cardiopulmonary exercise testing on a cyclo-ergometer. **Results:** Bariatric surgery resulted in a loss of 34% fat mass, 43% visceral adipose tissue, and 12% lean mass (LM) ($p <$

0.001). Absolute handgrip, quadriceps, or respiratory muscle strength remained unaffected, while quadriceps/handgrip strength relative to LM increased ($p < 0.05$). Absolute VO₂peak or VO₂peak/LM did not improve and the first VT was decreased after surgery (1.4 ± 0.3 vs. 1.1 ± 0.4 L min⁻¹, $p < 0.05$) and correlated to the exercising LM (LM legs) ($R = 0.84$, $p < 0.001$). **Conclusions:** Although bariatric surgery has numerous beneficial effects, absolute VO₂peak does not improve and the weight loss-induced LM reduction is associated to an altered muscular aerobic capacity, as reflected by an early VT triggering early exercise hyperventilation.

Introduction

Bariatric surgery is considered as a long-term effective therapy reducing morbidity and mortality [1], while associated with a rapid and significant weight loss, especially in the first 6 months [2]. Previous studies reported beneficial effects of bariatric surgery on physical functioning and mobility: reduced disability, joint pain, arthritis and enhanced musculoskeletal function, walking capacity, exercise economy, endurance test duration, etc.

[3–5]. Fat mass loss after bariatric surgery also leads to an increased peak oxygen uptake ($\text{VO}_{2\text{peak}}$) relative to body weight (expressed in $\text{mL kg}^{-1} \text{min}^{-1}$), which presents a great advantage for body weight-bearing efforts [6]. However, no study reported an increase in absolute $\text{VO}_{2\text{peak}}$ (L/min), reflecting the intrinsic aerobic capacity [6]. Previous studies performed 6 months after surgery reported either a significant absolute $\text{VO}_{2\text{peak}}$ drop [3, 7–10] or a tendency to decrease [11]. Thus, even when surgery is successful, absolute $\text{VO}_{2\text{peak}}$ is not improved and some patients still complain about asthenia or/and breathlessness [6]. The underlying mechanisms of those physical deconditioning symptomatology remain unclear. It has previously been suggested but not conclusively demonstrated that the muscle mass loss accompanying post-surgery weight loss may interfere with aerobic exercise performance after bariatric surgery [6, 12]. Indeed, the large-scale weight loss after bariatric surgery results not only in a substantial loss of fat mass (FM) but is also associated with significant lean mass (LM) loss, with muscle proteins serving as a source of amino acids for the functioning of other cells. Previous studies underlined the deleterious effects of excessive LM loss during weight loss programs on metabolism, thermoregulation, and functional capacity [13]. However, the link between post-bariatric surgery LM loss and the respiratory and cardiovascular response to maximal and submaximal aerobic exercise have been understudied until now. We, therefore, hypothesized that combining accurate body composition assessment (including leg LM), limbs, and respiratory muscle strength measurements, together with a cyclo-ergometer cardio-pulmonary exercise test (CPET), would allow us to describe the physiological influence of a muscle mass limitation on respiratory, cardiovascular, or metabolic response to exercise before and after bariatric surgery. We also believed that comparison with a control group of healthy subjects with normal weight matched for age, sex, and height would highlight the impact of overweight before bariatric surgery and enable to assess whether differences persist 6 months after weight loss surgery.

Methods

Study Population

Thirteen patients with obesity (6 men/7 women, 49 ± 14 years old, 168 ± 7 cm, 112 ± 17 kg, body mass index [BMI]: 39.5 ± 3.5 kg m^{-2}) recruited from the local University Hospital, Department of Gastric Surgery performed identical experimental protocol on two occasions: before and 6 months after bariatric surgery. Each pa-

tient with obesity included in the present study was individually paired to a healthy subject with normal weight matched by race, sex, age, and height recruited in his social environment. The characteristics of all 26 participants are shown in Table 1.

All participants gave their informed written consent to the study, approved by the local Ethical Committee (reference: P2016/448). Patients suffering from heavy musculoskeletal, cardiovascular, or pulmonary disease or under beta blockers were excluded. However, 5 patients with obesity suffered from mild arterial hypertension, 5 from sleep-apnea, 3 from impaired glucose tolerance, and 7 dyslipidemia. All patients with obesity underwent bariatric surgery without complications: sleeve gastrectomy ($n = 12$) or laparoscopic Roux-en-Y gastric bypass ($n = 1$). After bariatric surgery, all patients benefited from a nutritional follow-up with appointments every 2 months with the same dietitian. All patients were counseled about the principles of healthy eating, with 3 small meals per day, at least 5 daily servings of fresh fruits and vegetables and vitamin supplements. Protein intake recommendations were individualized regarding sex, age, and weight. A minimal protein intake of 60 g/day and up to 1.5 g/kg ideal weight per day was targeted.

The patients were advised to increase their daily physical activities and to walk as much as possible. However, no controlled or structured exercise training was imposed or proposed.

Healthy subjects with normal weight declared themselves as healthy and free from any proven pathology. All participants had a normal electrocardiogram (ECG) at rest.

Experimental Protocol

All subjects were invited to the laboratory to perform the following test sequence: clinical examination and fasting blood sampling, body composition assessment, respiratory and skeletal muscle strength assessment followed by a CPET. Patients with obesity repeated the protocol 6 months after bariatric surgery.

Clinical Assessment

Clinical assessment included a medical history, clinical examination with measurements of resting blood pressure (sphygmomanometry), ECG, pulsed oximetry (Nelcor Puritan Bennett Inc., Pleasanton, CA, USA), and fasting blood sampling. Fasting blood tests were analyzed for metabolic syndrome assessment by the same hospital laboratory with measurements of fasting glycemia, triglyceride, and high-density lipoprotein cholesterol. The hemoglobin level was also evaluated, being a determinant of O_2 transport and a potential limiting factor of the $\text{VO}_{2\text{peak}}$.

The Global Physical Activity Questionnaire (GPAQ) was used to assess self-estimated moderate and vigorous intensity activities amount and self-estimated sedentary behavior [14]. The questionnaires were completed by the investigator during an interview with each of the participants.

Anthropometry

All the measurements were performed in the morning after an overnight fast. Stature was measured to the nearest 0.5 cm with a wall-mounted stadiometer. Weight was measured to the nearest 0.1 kg on a standing weighting scale (BC-418; TANITA, Tokyo, Japan) wearing no shoes and light clothing. BMI was expressed in kg/m^2 where kg is the person's weight in kilograms and m^2 is the height in meters squared. The percentage of excess of BMI loss after surgery was calculated based on an ideal BMI of 25 kg/m^2 . Waist circumference was assessed with a standard flexible nonelas-

tic metric tape over the midpoint between the last rib and the iliac crest with the patient standing and exhaling. Total and regional FM and LM were acquired using dual energy X-ray absorptiometry (Lunar Prodigy; GE Healthcare, Madison, WI, USA) and analyzed using enCORE software (version 15.0). The regions of interest (ROI) for regional body composition (left and right arm, left and right leg, trunk) were first defined automatically by the software. Then the arm and leg ROI were manually corrected by the investigator to make them cut proximally across the coracoid process and the line along the lower ramus and the opening of the acetabulum, respectively [15]. Visceral adipose tissue analysis was performed using fully automated software (CoreScan; GE Healthcare). The software segments the abdominal fat measured by dual energy X-ray absorptiometry into subcutaneous fat and visceral fat within the android region of the abdomen. VAT is then estimated by subtracting subcutaneous fat from the total android fat. The method has previously been validated against computed tomography in patients with a wide range of BMI [16, 17].

Muscle Strength Measurements

Isometric quadriceps strength was measured during knee extension using a digital force gauge (Sauter FK 1K, Balingen, Germany) in a sitting position, knee angle at 90°. Relative quadriceps strength was expressed as the ratio of absolute quadriceps strength divided by the lower limb LM.

During handgrip muscle strength evaluation, subjects were asked to squeeze a dynamometer as hard as possible (Idass Fitness, Cornwall, UK) in a standardized standing position, with a 90° shoulder flexion and complete elbow extension. Relative handgrip strength was expressed as the ratio of absolute handgrip strength divided by the upper limb LM.

A respiratory pressure meter (Micro RPM; CareFusion, Wokingham, UK) was used to assess the respiratory muscle strength. This unit measured the maximum inspiratory pressure (MIP) and expiratory pressure (MEP). The device was connected to a PC running PUMA (MicroRPM) allowing real-time display of respiratory pressure. Measurements were performed according to ATS/ERS statements for respiratory muscle testing at rest, in the seated position with a nasal clip [18]. MIP was determined as the maximal pressure recorded during an inspiration maneuver starting from residual lung volume. MEP was determined as the maximal pressure recorded during an expiration maneuver starting from total lung capacity. Muscle strength measurements were repeated at least five times, with minimum three reproducible maneuvers (variation equal or less than 10%) and the highest value was considered for analyses.

CPET

Aerobic capacity was assessed using a classical incremental CPET on an electrically braked cyclo-ergometer (Ergoselect II

1200; Ergoline, Bitz, Germany). VO_2 , CO_2 production (VCO_2), and ventilation (VE) were collected breath by breath through a facial mask and analyzed every 8 s using a metabolic system (Exp'Air[®]; Medisoft, Dinant, Belgium) calibrated with room air and standardized gas. Expiratory volume in 1 s was measured at rest before the exercise test to calculate the maximum ventilatory ventilation.

The CPET was performed in agreement with ERS guidelines [19]. The initial power started at 30 W for warm up with increments of 15–30 W/min, estimated from previous CPET performance and for an optimal test duration between 10 and 12 min until volitional exhaustion. Identical incremental CPET workload protocol was repeated before and after bariatric surgery and imposed to the matched control subject. Heart rate (HR), ECG, and pulsed oximetry were continuously monitored during the test. Effort was considered maximal when two of the following criteria were met: VO_2 increase less than 100 mL/min while workload further increases, respiratory exchange ratio (RER) >1.10, achievement of age predicted maximal HR, and incapacity to maintain the pedal rate ≥ 50 rpm. $\text{VO}_{2\text{peak}}$ was expressed in absolute value, relative to body weight or relative to LM. The VT, used as a surrogate of muscle aerobic exercise capacity, was determined by the V-slope method by two blinded independent experienced exercise physiologists. Chemosensitivity and ventilatory efficiency were assessed using the VE/ VCO_2 slope measured during the entire exercise test. The VE/ VO_2 ratio was reported to evaluate the ventilatory cost for a given O_2 metabolism. The HR/ VO_2 slope measured throughout the test was used to quantify the chronotropic response to exercise. The metabolic efficiency during exercise was evaluated by calculation of the VO_2 /workload (W) slope measured from rest to the respiratory compensation point. O_2 pulse and VT were corrected by the LM of the lower limbs (LM legs) as it reflects the main muscle mass consuming O_2 during a cycloergometer exercise. This correction was used to dissociate the convective (stroke volume [SV] or cardiac output [Q]) and the muscular O_2 extraction (Ca-vO_2) component of O_2 pulse and VT, respectively.

Statistical Analysis

Data are presented as a mean \pm SD. Normal distribution of the data was tested using the Shapiro-Wilk test. Normally distributed data were compared using unpaired *t* test for the comparison of the pre-surgery condition versus control group, and post-surgery condition versus control group, and paired *t* test was used for the pre- versus post-surgery conditions comparisons. Pearson's correlation coefficient was used for the analysis of associations between VT and LM in the different groups. Data analysis was conducted using GraphPad Prism 8 (GraphPad Software, San Diego, CA, USA) and significance threshold was set at a *p* value lower than 0.05.

Results

Body Composition

Six months after bariatric surgery, all these parameters were significantly decreased (Table 1) with a mean total body weight loss of 22% (-25 ± 8 kg), which repre-

Fig. 1. Regional changes in FM and LM 6 months after bariatric surgery. All the reported changes pre- versus post-surgery were statistically significant ($p < 0.001$). VAT reduction exhibited the most important change compared to any other regional fat mass loss ($p < 0.001$). Arms FM loss was lower than legs and trunk FM loss ($p < 0.05$) which were not different ($p > 0.05$). LM loss was homogeneously reduced over the different body regions ($p > 0.05$). VAT, visceral adipose tissue.

sents a change in BMI of -8.8 ± 2.8 kg/m² and an excess of BMI loss of $-23 \pm 7\%$. The FM loss induced by bariatric surgery ($-34 \pm 11\%$) was associated to a decrease in LM ($-12 \pm 3\%$). Regional post-surgery changes in FM and LM are shown in Figure 1. For FM, the greatest change was observed for VAT ($-43 \pm 16\%$), while LM was homogeneously reduced in all body regions after surgery and was no more significantly different from healthy subjects with normal weight. Six months after surgery, VAT, total FM, and relative FM (%) remained significantly higher in patients as compared to healthy subjects with normal weight.

Metabolic Characteristics

Bariatric surgery improved metabolic parameters (mean blood pressure, high-density lipoprotein cholesterol, triglyceride, fasting glycemia) which were no more different from healthy subjects with normal weight. Hb levels remained unaffected by surgery (Table 1).

Daily Physical Activity Level

The results of the GPAQ questionnaire are exposed in Table 1. After bariatric surgery, self-estimated sedentary, and vigorous physical activity time remained unchanged and moderate activity time was slightly improved. No difference in daily sedentary time and weekly moderate activity time were observable when comparing post-surgery patients with obesity versus healthy subjects with normal weight but vigorous physical activity time remained lower in patients.

Limbs and Respiratory Muscle Strength

After bariatric surgery, the relative handgrip and quadriceps force was improved and no more different from healthy controls (Table 2). Neither obesity nor bariatric surgery affected inspiratory or expiratory muscle strength (Table 2).

Aerobic Capacity

CPET results are displayed in Table 3. Bariatric surgery increased maximal workload, RER, VE/VO₂, VO₂ relative to body weight, and HR/VO₂ slope (beat/L) but absolute VO₂ at the VT was reduced. The latest is illus-

trates in Figure 2 as well as the different ways of expressing VO₂peak before and after bariatric surgery. No change in VO₂ relative to body weight, relative to LM or relative to LM legs at the VT was observed (Table 3; Fig. 2).

After bariatric surgery, the maximal VO₂ (absolute, relative to body weight or relative to LM) and the VT level were lower than in control subjects. Absolute VT measured during cycling CPET was positively correlated to the LM of the legs, 6 months after bariatric surgery and in control subjects, but not in the pre-surgery condition (Fig. 3).

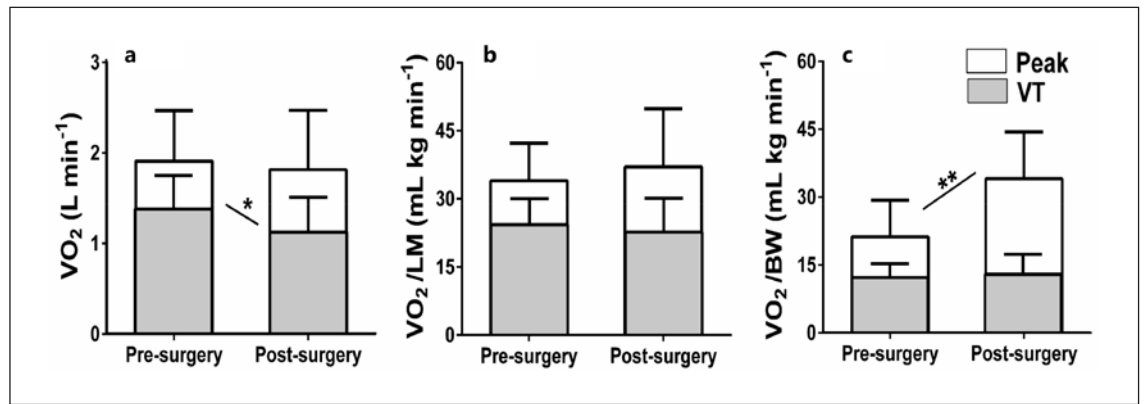

Fig. 2. Comparisons of pre- versus post-surgery VO_2 at the VT (gray) and at peak exercise (white). VO_2 is expressed in absolute value (a), adjusted for LM (b), and adjusted for body weight (BW) (c). Six months after bariatric surgery, $\text{VO}_{2\text{peak}}$ relative to BW increased due to weight loss, absolute $\text{VO}_{2\text{peak}}$, and VO_2 relative to LM remained unchanged and the absolute VT was reduced. * $p < 0.05$, ** $p < 0.01$.

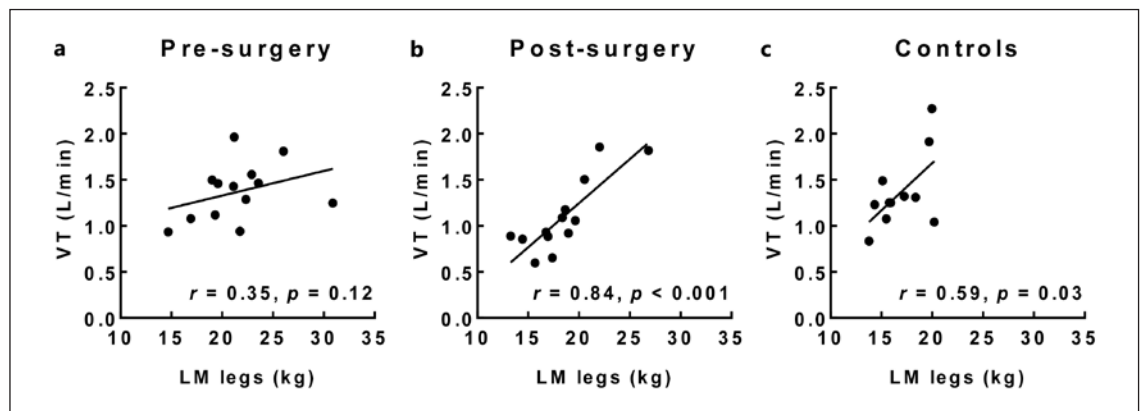

Fig. 3. Absolute VO_2 at the first VT as a function of the lower limbs LM (LM legs) in obese patients before bariatric surgery (a), 6 months after bariatric surgery (b) and in healthy control subjects (c). VT was significantly correlated to LM legs after bariatric surgery and in healthy controls.

Discussion

The present results confirm the positive effects of bariatric surgery on metabolic prognostic factors and the muscle strength/LM ratio. However, 6 months after bariatric surgery, absolute $\text{VO}_{2\text{peak}}$ did not improve, and the VT was reduced. This appeared in a context of a 12% decrease in lean body mass. The presently observed positive correlation between the cycling LM and the VT measured during a cyclo-ergometer CPET after bariatric surgery gives credit to the tested hypothesis of a post-surgery muscular aerobic capacity limitation impacting the ventilatory response to exercise, characterized by early an-

aerobic metabolism and early hyperventilation stimulations.

While patients with obesity are known to have impaired skeletal muscle aerobic function, previous studies reported that bariatric surgery may have beneficial qualitative muscular effects on oxidative capacity but associated to a quantitative muscular alteration [20, 21]. Indeed, during the heavy weight loss phase, proteolysis provides a source of amino acids needed for metabolic cell functions causing muscle mass reduction [13]. The present study reported a 12% LM loss 6 months after surgery with the legs LM after weight loss positively correlated to the VO_2 at the VT (Fig. 3b). This suggests that even if weight loss

may have beneficial effects on aerobic muscle function, a lower muscle mass after surgery overrides the positive qualitative effects and is associated to an overall lower muscular aerobic capacity, as reflected by lower VT. This is of importance as VT represents the energy requirement level above which anaerobic metabolism is activated and is associated with a consequent hyperventilation response [22, 23]. Interestingly, a low VT associated to a high maximal RER is typically observed in muscular deconditioning conditions with early triggering of the anaerobic metabolism activation and early hyperventilation response [24]. As the VE-breathlessness relationship during exercise has been shown to remain unaffected after bariatric surgery, one can suspect that this early exercise induced hyperventilation may cause respiratory discomfort at lower submaximal exercise intensities [25].

Cardiovascular Response to Exercise

In the present study, weight loss surgery stimulated the chronotropic response as reflected by the increase of the HR versus absolute VO_2 slope. Neunhaeuser et al. [3] suggested that since cardiovascular and pulmonary function are not supposed to be negatively affected by bariatric surgery, an increased chronotropic response rather reflects a cardiac compensatory effect of a decreased muscular aerobic capacity.

Maximal O_2 pulse, the product of maximal stroke volume (SV_{max}) and peak arteriovenous oxygen content difference ($\text{Ca-vO}_2\text{peak}$), was previously found to be unchanged or declined after surgery, in relation to an altered muscular oxygen extraction ($\text{Ca-vO}_2\text{peak}$) [6]. Maximal O_2 pulse corrected for the exercising muscle mass (LM legs) better reflects SV_{max} when comparing situations of quantitative muscle mass changes (cfr post-surgery reduction of LM). This indirect index of SV_{max} remained unaffected after surgery in the present study, suggesting little or no influence of weight loss on SV_{max} . Therefore, according to Fick's Principle, it might be speculated that identical absolute VO_2peak after surgery was related to an unchanged SV_{max} and a compensatory chronotropic stimulation in response to a lower Ca-vO_2 induced by lower limb muscle mass loss.

Respiratory Response to Exercise

Previous studies reported that VAT and subcutaneous trunk fat loss after bariatric surgery improves overall pulmonary function with reduced work of breathing an enhanced ventilatory response to exercise resulting in improved gas exchange [26, 27]. In the present study, subjects suffering from obesity showed no ventilatory efficiency or chemosensibility alteration with no ventila-

tory limitation or exercise induced hypoxemia. However, post-bariatric surgery increase in maximal VE/VO_2 might reflect a muscular deconditioning state with high hyperventilatory response to exercise.

Muscle Strength

The present results show no difference in MIP and MEP between the pre- and post-surgery conditions and compared to healthy subjects with normal weight. Previous studies showed conflicting results with either unchanged [28], increased [29], or reduced [30] respiratory muscle strength 6 months after bariatric surgery. Type II errors, male/female equilibrium, initial BMI, FM distribution, and loss may account for discrepancies between studies.

The increase in relative (but not absolute) limb muscle strength after the bariatric surgery, among others mechanisms, could be related to an improvement in both muscle activation (triggered by the increased moderate physical activity time) and/or alleviation of central obesity (VAT loss), known to affect muscular metabolism pathways and inflammation [31].

Limitations

The number of patients evaluated before and after bariatric surgery was small and thus type II but also type I errors could have occurred in spite of a paired sample design or a careful matching. Moreover, physical activity levels were assessed using a physical activity questionnaire which presents a lower reliability as compared to objective methods [32]. While GPAQ validity may be criticized, a recent systematic review by Keating et al. [32] showed a good to very good reliability for quantifying time spent in moderate and vigorous activities. To improve GPAQ validity, we used the interviewer-administered version of the questionnaire since it presents a higher correlation with accelerometer measurements for moderate-to-vigorous physical activity than the self-administrated version [33]. It should also be emphasized that both nutritional status and physical activity levels highly influence the post-bariatric surgery LM loss and may therefore have influenced the present results. The adherence to the protein intake recommendations may interfere with LM loss but was not measured in the present study.

Conclusion

Bariatric surgery reduced total FM and VAT with considerable positive metabolic benefits associated with a preserved cardiovascular response to exercise resulting in

unchanged aerobic capacity. However, bariatric surgery results in a substantial LM loss which is associated with a decreased VT. Indeed, LM is correlated to the VT suggesting that a lower LM alters the muscular aerobic capacity after bariatric surgery. Consequently, a slightly increased chronotropic response to exercise and an early triggering of exercise hyperventilation response are observed. The present results support the idea that a muscular aerobic capacity limitation should be taken into consideration during bariatric surgery follow-up in particular when LM loss, low VT, or exercise breathlessness complaints are observed.

Acknowledgments

We would like to thank all the participants of the study. We express our gratitude to the Department of Surgery of Erasmus Hospital for their sincere cooperation. We offer special thanks to Michel Lamotte (PhD, Physiotherapist), Godefroid Chantal (Physiotherapist), Marie Barea (Nutritionist), and Alain Carpentier for their help and encouragement.

Statement of Ethics

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Hel-

sinki Declaration and its later amendments or comparable ethical standards. Written informed consent was obtained from all individual participants included in the study, approved by the local Ethical Committee (reference: P2016/448).

Conflict of Interest Statement

The authors have no conflicts of interest to declare.
