

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

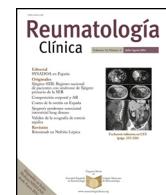

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

COVID-19 reactive arthritis

Post COVID-19 arthritis

Post COVID-19 ReA

ABSTRACT

Background: Rheumatological manifestations following COVID-19 are various, including Reactive Arthritis (ReA), which is a form of asymmetric oligoarthritis mainly involving the lower limbs, with or without extra-articular features. The current case series describes the clinical profile and treatment outcome of 23 patients with post-COVID-19 ReA.

Methods: A retrospective, observational study of patients with post-COVID-19 arthritis over one year was conducted at a tertiary care centre in India. Patients ($n=23$) with either a positive polymerase chain reaction test for SARS-CoV2 or an anti-COVID-19 antibody test were included. Available demographic details, musculoskeletal symptoms, inflammatory markers, and treatment given were documented.

Results: Sixteen out of 23 patients were female. The mean age of the patients was 42.8 years. Nineteen patients had had symptomatic COVID-19 infection in the past. The duration between onset of COVID-19 symptoms and arthritis ranged from 5 to 52 days with a mean of 25.9 days. The knee was the most involved joint (16 out of 23 cases). Seven patients had inflammatory lower back pain and nine had enthesitis. Most patients were treated with non-steroidal anti-inflammatory drugs (NSAIDs) and steroids – either depot injection or a short oral course. Three patients required treatment with hydroxychloroquine and methotrexate which were eventually stopped. No relapse was reported in any of the patients.

Conclusion: On combining our data with 21 other case reports of ReA, a lower limb predominant, oligoarticular, asymmetric pattern of arthritis was seen with a female preponderance. The mean number of joints involved was 2.8. Axial symptoms and enthesitis were often coexistent. Treatment with NSAIDs and intra-articular steroids was effective. However, whether COVID-19 was the definitive aetiology of the arthritis is yet to be proven.

¿Existe la artritis reactiva post-COVID?: experiencia de un centro de tercer nivel de atención con revisión de la literatura

RESUMEN

Palabras clave:

Artritis reactiva por COVID-19

Artritis post-COVID-19

Artritis reactiva post-COVID-19

Antecedentes: Las manifestaciones reumatólogicas posteriores al COVID-19 son diversas, entre ellas, la artritis reactiva, que es una forma de oligoartritis asimétrica que afecta principalmente a los miembros inferiores, con o sin características extraarticulares. La serie de casos actual describe el perfil clínico y el resultado del tratamiento de 23 pacientes con artritis reactiva posterior a COVID-19.

* Corresponding author.

E-mail address: dr.a.chattopadhyay@gmail.com (A. Chattopadhyay).

¹ Dr. Atanu Pal and Dr. Rashmi Roongta contributed equally to this paper.

Métodos: Se realizó un estudio observacional retrospectivo de pacientes con artritis post-COVID-19 durante un año en un centro de atención terciaria en India. Se incluyeron pacientes ($n=23$) con una prueba de reacción en cadena de la polimerasa positiva para SARS-CoV-2 o una prueba de anticuerpos anti-COVID-19. Se documentaron los detalles demográficos disponibles, los síntomas musculoesqueléticos, los marcadores inflamatorios y el tratamiento administrado.

Resultados: Diecisésis de los 23 pacientes eran mujeres. La edad media de los pacientes fue de 42,8 años. Diecinueve pacientes habían tenido infección sintomática por COVID-19 en el pasado. La duración entre el inicio de los síntomas de COVID-19 y la artritis osciló entre 5 y 52 días, con una media de 25,9 días. La rodilla fue la articulación más comúnmente involucrada (16 de 23 casos). Siete pacientes tenían dolor lumbar inflamatorio y 9 tenían entesitis. La mayoría de los pacientes fueron tratados con medicamentos antiinflamatorios no esteroideos y esteroides, ya fuera una inyección de depósito o un ciclo oral corto. Tres pacientes requirieron tratamiento con hidroxicloroquina y metotrexato, que finalmente se suspendieron. No se reportaron recaídas en ninguno de los pacientes.

Conclusión: Al combinar nuestros datos con otros 21 informes de casos de artritis reactiva, se observó un patrón de artritis oligoarticular asimétrico predominante en las extremidades inferiores con predominio femenino. El número medio de articulaciones afectadas fue de 2,8. A menudo coexistían síntomas axiales y entesitis. El tratamiento con antiinflamatorios no esteroideos y esteroides intraarticulares fue eficaz. Sin embargo, aún no se ha demostrado si el COVID-19 fue la etiología definitiva de la artritis.

Introduction

Immune-mediated manifestations of Corona Virus Disease-19 (COVID-19) have been reported, among which vasculitis, antiphospholipid antibody syndrome, myositis, lupus, and arthritis are the major rheumatological ones.¹ Mechanisms underlying the development of immune-mediated inflammatory diseases like reactive arthritis (ReA) after COVID-19 infection are yet to be elucidated properly. Transient virus-mediated immunosuppression along with high cytokine levels, especially interleukin-17, which is elevated in ReA, may be responsible for the development of ReA.^{2,3} Humoral response to viral particles acting as antigens and deposition of these immune complexes within the joints might be responsible for the development of arthritis.⁴ Molecular mimicry is also another mechanism proposed in the pathogenesis of viral arthritis and COVID-19 related immunological consequences (but not arthritis specifically).⁵ However, further studies on pathomechanisms of arthrogenicity of coronavirus are required.

ReA is a form of asymmetric oligoarthritis mostly involving the lower limbs, with or without extra-articular features, usually preceded by an infection of the gastrointestinal or urogenital tract. Symptoms develop 1–3 weeks after the infection and apart from arthritis, conjunctivitis, dactylitis, enthesitis, and inflammatory lower back pain may occur. Classically, ReA is known to occur after bacterial infections like Chlamydia,⁶ ReA can rarely be associated with streptococcal, staphylococcal, and even chlamydial respiratory infections.^{7,8} To the best of our knowledge, ReA triggered by respiratory viral infections have not been reported in the pre-coronavirus era. Viral infections can be associated with musculoskeletal symptoms in the acute phase, but the development of ReA is rare. Since the emergence of coronavirus in late 2019, a few case reports of ReA after COVID-19 infection have been reported.^{4,9–27} Amongst inflammatory arthritis, other reported conditions after COVID-19 infection is rheumatoid arthritis and seronegative spondyloarthropathy.²⁸

Here, we present a case series of ReA after a definitive COVID-19 infection.

Methods

A retrospective study of patients presenting with oligo or polyarthritis to the Rheumatology outpatient department of a tertiary care centre from June 2020 to February 2021 was conducted. As there are no definitive criteria for diagnosing reactive

arthritis, it was diagnosed based on the clinical presentation of arthritis following a documented COVID-19 infection. Cases were collected based on author recall and review of the database. Patients diagnosed with rheumatoid arthritis, spondyloarthropathy, psoriatic arthritis, gout, Systemic lupus erythematosus (SLE), osteoarthritis was excluded. Patients with prior history of arthritis were excluded. Patients who tested positive for Antinuclear Antibody, Rheumatoid Factor, anti-Cyclic Citrullinated Peptide were excluded. Only patients with a documented history of COVID-19 illness [by Polymerase Chain Reaction (PCR) testing] 1–8 weeks before symptoms or those with positive COVID-19 antibody test (done at the discretion of the treating physician) were included. The COVID-19 antibody test comprised of antibody Immunoglobulin (Ig) G measured by chemiluminescent microparticle assay and total antibodies (IgG and IgM) using electrochemiluminescence immunoassay. The cut off indices for these tests were 1.4 and 1 respectively. None of the patients had been previously vaccinated against COVID-19. Patients with a history suggestive of reactive arthritis but without documented evidence of COVID-19 (both PCR and antibody-negative) were excluded. Available demographic details and information on the number and pattern of joints (with clinical synovitis) involved, inflammatory markers and treatment were collected. For patients where a doubt regarding synovitis in a particular joint existed, an ultrasound examination was performed to confirm the same. Patients were questioned about a relapse of symptoms on follow up visits. Ethical clearance has been obtained for the study from the Institutional ethical committee (IPGME&R Research Oversight Committee; IPGME&R/IEC/2021/558; dated 28th September 2021).

Results

A total of 23 patients fulfilled the inclusion criteria. The available demographic details, details of COVID-19 serology, and musculoskeletal symptoms are given in Table 1.

Sixteen out of 23 patients were female. The age of the patients ranged from 19 to 69 years (mean 42.8 ± 14.1 years). Nineteen patients had a past history of symptoms suggestive of COVID-19, with fever being the commonest symptom, present in all patients. Only 2 patients required hospitalisation for the management of COVID-19 (patients 2, and 3). Four patients had no definitive symptom of COVID-19 but antibody tests were ordered by the treating physician because of similarity of symptoms with patients with documented preceding COVID-19 infection. In patients with prior

CRP, C-reactive protein; DIP, distal interphalangeal; F, female; IACS, intra-articular corticosteroids; M, male; MCP, metacarpophalangeal; MTP, metatarsophalangeal; NSAIDs, non-steroidal anti-inflammatory drugs; PCR, polymerase chain reaction; PIP, proximal interphalangeal.

symptoms, the duration between onset of fever and arthritis ranged from 5 to 52 ($n=19$) days with a mean of $25.9 (\pm 12.8)$ days. Knee was the most commonly involved joint. Knee joint involvement was seen in 16 out of 23 patients, and bilateral knee joint was affected in 9 out of those 16 cases. Ankles were involved in 15 and wrists in 7 out of 23 patients. Seven patients had inflammatory low back pain fulfilling the Assessment of SpondyloArthritis international Society criteria²⁹ and 9 had enthesitis. The Achilles tendon was the most common site of enthesitis followed by chest wall enthesitis. Amongst other features of reactive arthritis, only bilateral conjunctivitis was present in one patient. Most patients were treated with Non-Steroidal Anti-Inflammatory Drugs (NSAIDs) and steroids (either depot injection or a short oral course). Three patients required prolonged treatment – two with hydroxychloroquine (HCQ) 5 mg/kg/day and one with methotrexate 15 mg/week because of persistent joint pain after steroid tapering. HCQ was discontinued after 4 months and methotrexate after 5 months of treatment. There was no relapse of symptoms in any of the above-mentioned patients.

Discussion

COVID-19 associated rheumatological complaints include myalgia, arthralgia and fatigue which can occur either during or after the infection.^{28,30} Arthritis occurring a few days after recovery has been reported in the form of ReA, acute arthritis or post-viral arthritis. However, apart from the serologic evidence of past COVID-19 infection, the attribution of the arthritis to COVID-19 is partly

speculative and cannot be done beyond doubt. It is also possible that the arthritis is a part of a prolonged COVID infection-called as post-acute COVID-19 syndrome. In our series, 23 patients presented with arthritis after a documented COVID-19 infection. Twenty-one cases of arthritis after COVID-19 are reported in the literature^{4,9–27} (Table 2).

Out of these 21 cases, 12 were male and 9 were female. However, in our cohort, a majority of the patients (16 out of 23) were women. The age group of previously reported 21 patients varied from 16 to 73 years which was similar to what was reported by us. The duration between onset of COVID-19 symptoms and arthritis symptoms varied from 3 to 37 days. Although the patient who developed symptoms in 3 days was concurrently positive for COVID-19, the authors state that he might have been tested later in the course of his disease as evidenced by the high Cycle threshold value in RT-PCR.¹⁵

From the pooled data available from 44 patients (23 from our cohort and 21 from previous reports), 25 were female and 19 were male. The mean age of the population was 45 ± 14.24 years. The mean number of days from the onset of COVID-19 symptoms to the onset of arthritis was ($n=39$) was 23.4 ± 11.16 days.

The pattern of joint involvement in the 21 reported cases^{4,9–27} showed arthritis affecting knees and ankles in 9 and 8 patients respectively (shown in Fig. 1).

Small joints of the hands were involved in 7 of the 21 reported cases. Few cases were limited to arthritis of the small joints of the hands or feet^{12,15–17} which is unusual in reactive arthritis. Our series showed a lower limb predominant arthritis with only three

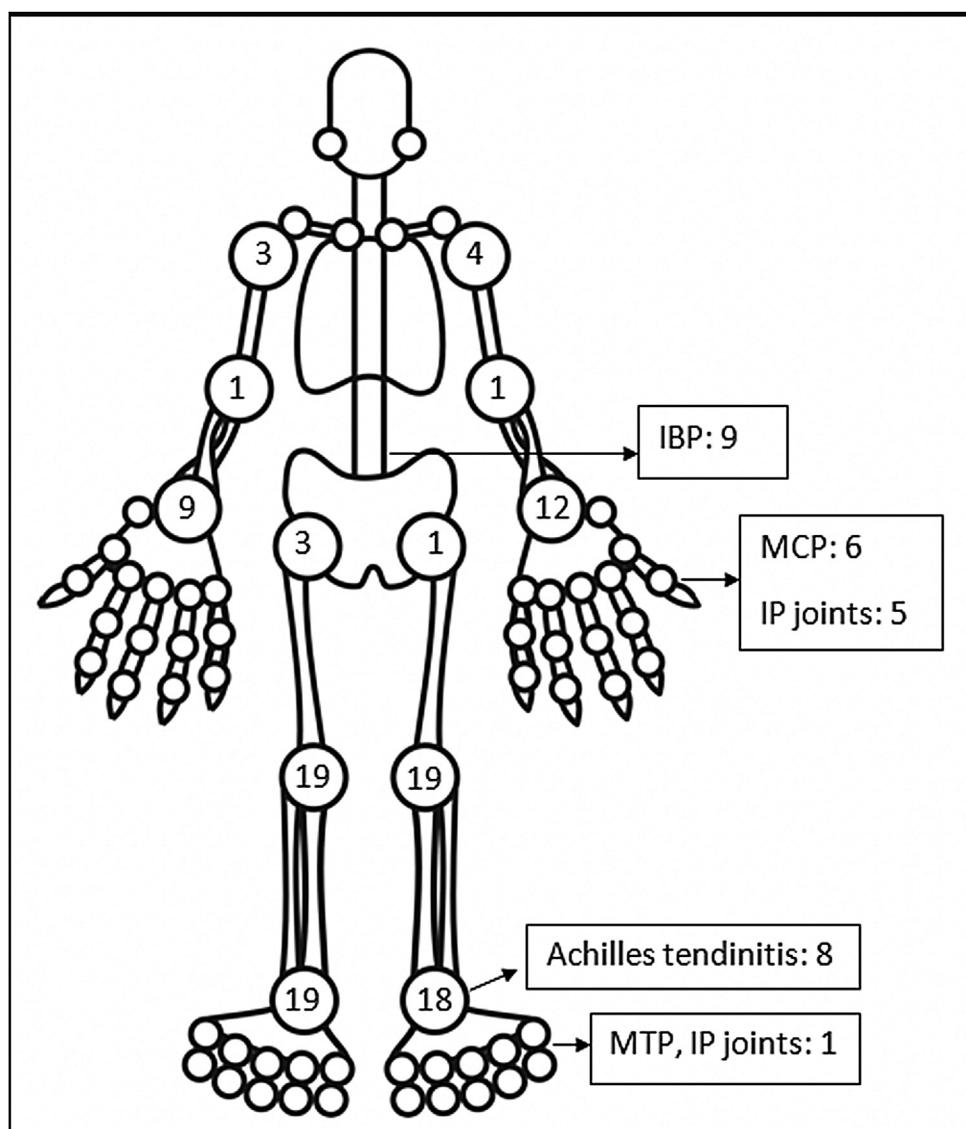

Fig. 1. Frequency of joint involvement in post-COVID ReA patients.

patients having arthritis of the small joints of the hand. Out of the total 42 cases of ReA with peripheral arthritis following COVID-19 patients, 29 (69.05%) had oligoarthritis with involvement of fewer than 5 joints, and 13 (30.2%) had polyarthritis. One case had only inflammatory low back pain (IBP) with no articular involvement¹³ and another had right-hand tenosynovitis.¹⁶ Eleven patients had monoarthritis. On reviewing the pooled data, the exact number of joints involved were available for 36 patients. The mean number of joints involved was 2.8 ± 1.7 . An asymmetric pattern of joint involvement is typical of ReA, and we found that out of 40 patients with information about symmetry of joint peripheral joint involvement, 27 had asymmetric arthritis and 34 had symmetric arthritis.

IBP was present in 7 of our patients and two in the rest of the reported cases (who were also Human Leucocyte Antigen-B27 (HLA-B27) positive).^{13,23} Of the reported cases in which HLA-B27 was tested, 4 patients tested positive.^{13,21,23} A Magnetic Resonance Imaging (MRI) of the sacroiliac joints and an HLA-B27 test could have added an informative aspect to the management and follow up of these patients. Enthesitis involving the chest wall and Achilles' tendons was present in 11 out of 44 patients. Enthesitis and IBP were coexistent in 5 patients. This leads us to believe

that these patients might be a group susceptible to developing spondyloarthropathy. These patients will be kept under surveillance. The low incidence of back pain and enthesitis reported in the case reports might be due to the prompt response to NSAIDs given for arthritis or due to steroids which the patient might have received for COVID-19.

The level of C-Reactive Protein (CRP) was normal in some and elevated in some patients. Most of the patients were treated with NSAIDs and/or either intra-articular corticosteroid (IACS) injection or systemic steroids. One of our patients (Patient No. 13) had a diffuse erythematous, maculopapular, non-pruritic rash during the presentation which resolved subsequently ([Supplementary Fig. S1](#)) and another had bilateral conjunctivitis. Other symptoms associated with ReA like balanitis, and urethritis were absent in our patients but one case report had balanitis.¹⁵

Certain limitations of our study need to be addressed. The small sample size of 23 patients was due to the inability to test for COVID-19 antibodies in some patients with suspected post-COVID-19 ReA. The patients were recruited by the author recall posing the issue of recall bias. Testing for HLA-B-27 and MRI of sacroiliac joints for patients with inflammatory back pain was not done. Infections causing ReA like Yersinia, Salmonella, Shigella could not be

definitively ruled out, although the patients were questioned for a preceding history of a urinary tract infection or gastroenteritis. The possibility of the symptoms being an initial manifestation of other inflammatory arthritides cannot be conclusively ruled out without long term follow up of these patients. Synovial fluid analysis was not done for any of the patients, hence it was not possible to completely rule out crystal arthropathy. To conclude definitively that COVID-19 is responsible for the arthritis in these patients is difficult and is a hypothesis pending to be proven. Despite these limitations, this is probably the largest case series describing ReA following COVID-19 infection to date. Further studies are required to gather more knowledge regarding post-COVID-19 reactive arthritis.

Conclusion

Herein, we report 23 cases of reactive arthritis after COVID-19 infection. On combining this data with other 21 reported cases of ReA we found that it occurred more commonly in females. A lower limb predominant, oligoarticular, asymmetrical pattern was common, although involvement of the small joints has also been adequately reported. The mean number of joints involved in all patients was 3. Axial symptoms and enthesitis were present and often coexistent. Treatment with NSAIDs and intra-articular steroids lead to successful resolution in most cases.
