
INTRODUCTION TO THIS ISSUE

Dealing with TB in wildlife

Introduction

Tuberculosis (TB) is a disease caused in humans and animals by infection with members of the *Mycobacterium tuberculosis* complex (MTC). In wild mammals, TB is mostly due to *M. bovis* and closely related mycobacteria such as *M. caprae*. These infections are shared between wildlife, domestic animals and humans, causing zoonotic disease mainly in developing countries, huge economic losses to the livestock industry, as well as conservation concerns worldwide. This Special Issue on TB in wildlife comprises original papers on a diversity of epidemiological situations at the wildlife–domestic animal–human interface over a broad geographical range. This introduction to the Special Issue includes a global perspective and an overview of TB in wildlife and its control, using New Zealand as a case study, with an outlook on forthcoming research.

Global perspective of TB in wildlife

M. bovis is a multi-host pathogen that thrives in complex systems at the wildlife–livestock interface. This makes eradication unlikely if the role of all wildlife hosts is not clear enough for relevant reservoirs to be targeted at the same time. The best known wildlife TB reservoirs occur in the British Isles (Eurasian badger, *Meles meles*), the Iberian Peninsula (Eurasian wild boar, *Sus scrofa*, red deer, *Cervus elaphus*, fallow deer, *Dama dama*), southern Africa (African buffalo, *Syncerus caffir*, among other hosts), North America (white-tailed deer, *Odocoileus virginianus*, in Michigan), and New Zealand (introduced Australian brushtail possum, *Trichosurus vulpecula*). Several recent reviews have addressed wildlife TB, underlining the need to understand epidemiological complexity, and to use integrated approaches for TB control at the interface [1, 2].

However, wildlife TB often occurs outside these better known hotspots. For instance, badger, deer and wild boar TB is increasingly recorded in continental Europe outside the Iberian Peninsula [1]; wild boar and feral pig TB is increasingly recorded in America (e.g. [3, 4]); white-tailed deer TB probably occurs in northern Mexico [5]; and large parts of Africa and Asia still lack a proper assessment of the distribution of wildlife TB. Moreover, some non-bovine domestic and semi-domestic hosts, particularly pigs, goats, camelids or elephants, deserve much more attention regarding their growing role in infection maintenance (e.g. [3, 6, 7]).

In those regions where wildlife MTC infection is regarded as a significant barrier to TB eradication in cattle, research on TB control at the wildlife–livestock interface is making significant progress [4]. For TB eradication in cattle strategies that reduce pathogen transmission between wildlife and domestic animals and between non-bovine livestock and cattle must be developed [8]. This can be achieved by preventative actions, such as host population control through random or selective culling, or through habitat management, and by vaccination. The alternative options of zoning or no-action should also be considered, particularly in view of a cost–benefit assessment. Ideally, tools from several fields should be combined in an integrated control strategy. TB control in New Zealand is an example of such an approach.

Dealing successfully with wildlife TB: the New Zealand case study

After its first confirmed detection in wildlife in New Zealand in 1967, bovine TB spread to wildlife populations over about 35% of New Zealand's land area [9]. Through the combined management of infection in livestock and wildlife, only 0·2% of herds were infected in New Zealand at the end of 2011, the first of

the 3 years required to meet the OIE standard for TB-free country status.

That success was largely due to increasingly effective TB vector control operations across some eight million hectares [10]. Improvements in the diagnosis and eradication of TB in cattle and deer herds [11] and stringent movement control and animal identification of livestock also played a significant role [12]. Subsequently, the number of infected herds dropped below 60, a 96.5% decrease from 1714 in 1994. With the number of cattle and deer herd infections at low levels throughout New Zealand, strategic objectives have changed to address the long-term need of total eradication of TB from wildlife. [13].

The 15-year time-frame of the current strategy sets the platform for eradicating TB from New Zealand. The programme's extensive wild animal control and surveillance schemes initially aim to achieve this across 2.5 million hectares, about one quarter of the 10 million hectares that infected wildlife inhabit. Success with this goal will demonstrate the feasibility of eradicating TB successfully from wild animals throughout the country in the long term and across difficult terrain. New Zealand's prospect of successfully eradicating TB is enhanced by the fact that none of the key wildlife hosts of TB are native animals, and all of them are also controlled to greater or lesser extent as pests of native biodiversity.

The eradication of TB from the complex of wildlife hosts in New Zealand (possums, deer, pigs, ferrets) was long considered impossible. However, theoretical models [14, 15] give a better understanding of the roles of the various wildlife vectors of TB [16–18], and improved possum control in extensive forest areas [19] have shown that maintaining very low possum densities across sufficiently large areas for several years will lead to the eradication of TB. Very low possum densities means that the few remaining infected possums will probably die before transmitting the disease to others, leading to a collapse in the disease cycle within their populations and in spillover hosts.

Effective lethal control of possums (the main wildlife maintenance host) remains the cornerstone of TB eradication in New Zealand. Over the last 10 years, progressive improvements in the methodology for large-scale toxin deployment have enabled more efficacious and cost-effective possum control [19, 20], backed by the development of new surveillance methods to detect wildlife at low population densities [21, 22].

Wildlife surveying will play an increasingly prominent role in a strategy based on detecting and eradicating TB in wildlife. Information derived from wild animal surveys includes the location of detection devices, traps and animals caught, together with the post mortem and laboratory findings. These data are being used to analyse whether or not TB has truly been eradicated from a given wild animal population and area, an approach referred to as Proof of Freedom [23, 24]. This involves a novel spatial model of wildlife disease-surveillance data using parameters governing home-range size, probability of capture, probability of disease transmission and spatial variation in the probability of infection of reservoir hosts and spillover sentinel wildlife to make inference on the probability of eradication. Such an approach is likely to have broader application in the management of wildlife TB in other countries.

Conclusions and outlook

We need to understand complexity: the growing evidence on the role of apparently minor or lesser known hosts in TB maintenance shows that an excessive focus on the best known wildlife reservoir hosts can be a risk, due to spill-back from unexpected sources. This is well illustrated in this Special Issue in the paper by Walter *et al.* regarding Virginia possums (*Didelphis virginiana*) in Michigan, USA [25]. Targeted research is needed to assess the spill-back risks from less relevant hosts [17]. It would also be prudent to investigate the prevalence of wildlife TB outside the best known hotspots listed above, particularly where the available information is limited or host populations are changing, so that further disease spread can be prevented.

Based on this understanding, there is an urgent need to monitor TB both in livestock and in wildlife. Only an organized monitoring scheme combining disease indicators with population indicators will enable the outcome of any interventions to be assessed [26]. Finally there is a need for more detailed in-depth research on (integrated) TB control at the wildlife–livestock interface.

Two decades ago, O'Reilly & Daborn [8] stated in their review on *M. bovis* that:

In countries where there is transmission of infection from endemically infected wildlife populations to cattle or other farmed animals, eradication is not feasible and control measures must be applied indefinitely.

The example from New Zealand shows that, in fact, eradication of TB in cattle is a realistic goal if TB control in the wildlife reservoir is successfully addressed. Hopefully, other wildlife TB hotspots will follow this example and succeed in this endeavour. This will need strong scientific support, to which the knowledge contained in this Special Issue is a significant contribution.
