ABSTRACT

Background

Venous access is an essential part of caring for the sick neonate. However, problems such as contamination of fluids with bacteria, endotoxins and particulates have been associated with intravenous infusion therapy. Intravenous in-line filters claim to be an effective strategy for the removal of bacteria, endotoxins and particulates associated with intravenous therapy in adults and are increasingly being recommended for use in neonates.

Objectives

To determine the effect of intravenous in-line filters on morbidity and mortality in neonates.

Search methods

We used the standard search strategy of the Cochrane Neonatal Review Group. We searched the electronic databases MEDLINE (from 1966 to May, 2015), EMBASE (from 1980 to May, 2015), CINAHL (from 1982 to May 2015) and the Cochrane Central Register of Controlled Trials (CENTRAL; 2015, Issue 5). We did not impose any language restrictions. Further searching included cross references, abstracts, conferences, symposia proceedings, expert informants and journal handsearching.

Selection criteria

We included randomised controlled trials (RCTs) or quasi-RCTs that compared the use of intravenous in-line filters with placebo or nothing in neonates.

Data collection and analysis

We followed the procedures of the Cochrane Neonatal Review Group throughout. We checked titles and abstracts identified from the search. We obtained the full text of all studies of possible relevance. We independently assessed the trials for their methodological quality and subsequent inclusion in the review. We contacted authors for further information as needed. Statistical analysis followed the procedures of the Cochrane Neonatal Review Group.

Main results

There were four eligible studies that recruited a total of 704 neonates. This review of low to very low quality evidence found that the use of in-line filters compared with unfiltered fluids for intravenous infusion had no statistically significant difference in effectiveness on overall mortality (typical RR 0.87, 95% CI 0.52 to 1.47; typical RD -0.01, 95% CI -0.06 to 0.04; two studies, 530 infants), proven and suspect

Intravenous in-line filters for preventing morbidity and mortality in neonates (Review)

septicaemia (typical RR 0.86, 95% CI 0.59 to 1.27; typical RD -0.02, 95% CI -0.09 to 0.04; two studies, 530 infants), or other secondary outcomes (including local phlebitis and thrombus, necrotising enterocolitis, duration of cannula patency, length of stay in hospital, number of catheters inserted and financial costs).

Authors' conclusions

There is insufficient evidence to recommend the use of intravenous in-line filters to prevent morbidity and mortality in neonates.

PLAIN LANGUAGE SUMMARY

Intravenous in-line filters for preventing morbidity and mortality in neonates

Review question: Does the use of in-line filters on intravenous lines reduce morbidity and mortality in neonates?

Background: Preterm or sick newborn infants are often fed with nutrients and fluids that are delivered directly into a vein. This intravenous delivery can be associated with infection, toxins released by bacteria, and tiny particles that may be in the fluids, such as rubber and plastic, going into the blood. In adults, placing a filter in the intravenous line has been reported to be effective in reducing such risks, and filters are increasingly being recommended for use in newborn infants.

Study characteristics: The review authors searched the medical literature and identified four eligible studies that recruited a total of 704 newborns.

Key findings: Septicaemia and illness, deaths or problems with the intravenous lines were no different with or without a filter.

Conclusions: There is insufficient evidence to recommend the use of intravenous in-line filters to prevent morbidity and mortality in newborn infants.

SUMMARY OF FINDINGS

Summary of findings for the main comparison. Intravenous in-line filter for preventing morbidity and mortality in neonates

Intravenous in-line filter for preventing morbidity and mortality in neonates

Patient or population: patients with preventing morbidity and mortality in neonates

Settings:

Intervention: Intravenous in-line filter

Outcomes	Illustrative comparative risks* (95% CI)		Relative effect (95% CI)	No of Participants (studies)	Quality of the evidence (GRADE)	Comments

*The basis for the **assumed risk** (e.g. the median control group risk across studies) is provided in footnotes. The **corresponding risk** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

CI: Confidence interval; **RR:** Risk ratio;

GRADE Working Group grades of evidence

High quality: Further research is very unlikely to change our confidence in the estimate of effect.

Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.

Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.

Very low quality: We are very uncertain about the estimate.

- 1 All studies were at high risk of bias
- 2 Large difference in relative risk estimates between studies
- 3 Unable to assess publication bias as <10 studies were included in the meta-analysis
- 4 Single study
- 5 Low event rates

BACKGROUND

Description of the condition

Venous access is an essential part of caring for the sick neonate; however, problems associated with intravenous infusion therapy include contamination of fluids with bacteria, endotoxins and particulates (Bethune 2001; Evans 2006).

Infusion therapy carries a risk for catheter-associated septicaemia (Evans 2006; Geiss 1992). Infection can originate from the catheter tubing, the ports, at the cannula site or from contaminated infusion fluid. Factors cited as increasing the risk for catheter-related infection include type of intravenous fluid, for example total parenteral nutrition solutions or solutions with high concentrations of dextrose (Pearson 1996). While not all infections lead to septicaemia, immunocompromised patients such as neonates, are at greater risk, and infection becomes a major problem (Ng 1989). In adult patients, use of the bacterial retention filter lead to fewer clinically significant bacteremias (Quercia 1986).

Contamination of intravenous administration sets with gram-negative bacteria has been reported to lead to rapid proliferation of endotoxins (Bethune 2001). In adults, endotoxins have been implicated in several serious disease processes, including respiratory distress syndrome (Parsons 1989), septic shock (Glauser 1991), multiple organ failure, endotoxic shock, and systemic inflammatory response syndrome (Casale 1990; Glauser 1991; Suffredini 1989a). Cardiovascular changes such as increased heart rate, decreased vascular resistance and depressed left ventricular function (Suffredini 1989b), and increased intestinal permeability (O'Dwyer 1988) have also been reported. Periventricular leukomalacia is an ischaemic lesion of the periventricular white matter that is primarily seen in premature neonates (Hill 1992; Volpe 2001). Animal studies have demonstrated the development of periventricular leukomalacia in the brains of newborn kittens following injection of endotoxins (Gilles 1977) and it has been postulated that endotoxins may be involved in the pathogenesis of a proportion of cases of periventricular leukomalacia in the human neonate (Volpe 2001).

Particulate matter may cause localised phlebitis (Marshall 1987). The duration of cannulation has been found to contribute to the development of infusion-related phlebitis (Maki 1991), and this may require the cannula to be replaced. Frequent cannula change is an added cost to treatment and may cause the patient pain and distress (Chee 2002).

Adverse systemic effects of particulate matter including granulomata formation in the lung (Marshall 1987) and ischaemic necrosis, are a common finding in necrotising enterocolitis (Ballance 1990). Garvan examined intravenous fluids available in Australia, England, Europe and the United States of America for the presence of particulates. Microscopic analysis found rubber particles, crystals, cellulose fibres, fungal spores, starch granules, and a crustacean claw (Garvan 1964). More recent studies found glass fragments from the opening of glass ampoules (Shaw 1985), and particles from rubber stoppers and intravenous equipment (Kirkpatrick 1988). Inorganic elements such as calcium, silicon, aluminium, lead and iron, that may have originated from the manufacture and packaging processes (Backhouse 1987), have also been found. Positively-charged in-line filters are reported to be effective in the retention of endotoxins (Barnett 1996).

Description of the intervention

There are two main intravenous filter pore sizes; the 0.22 micron filter is used for aqueous solutions, and the 1.2 micron filter is recommended for larger molecule solutions such as lipids. The 0.22 micron filter has also been reported to remove air, micro-organisms and particulate matter. In addition, endotoxin retention is reportedly achieved by using a positively charged filter membrane; toxic macro-molecules are released by gram-negative bacteria and are claimed to be effective for up to 96 hours (Bethune 2001).

How the intervention might work

Intravenous in-line filters were conceived and first utilised in the 1960s for the retention of particulate contamination. Since then, filter systems have been further refined. Intravenous in-line filters are currently claimed to be an effective strategy for the removal of bacteria, endotoxins and particulates associated with intravenous therapy in adults (Ball 2003; Kunac 1999), and more favourable patient outcomes, such as shorter hospital length of stay (Koekenberg 1983). Several adult studies have shown that intravenous in-line filtration significantly reduces the incidence (Chee 2002; Roberts 1994) and delays the onset of phlebitis (Chee 2002; Allcutt 1983; Roberts 1994), resulting in extended-line survival (Roberts 1994), fewer recannulations (Chee 2002) and lower costs. The use of in-line filters in adults has been shown to be effective in the removal of particulates, especially those precipitates caused from the administration of drugs, such as antibiotics (Ball 2003; Chee 2002; Roberts 1994). In addition, a large randomised trial found that in-line filtration reduced severe complications and length of stay in the paediatric intensive care unit (Jack 2012).

Why it is important to do this review

Several authors have challenged the benefits of using intravenous in-line filters in the adult population. The Centre for Disease Control and Prevention recommends the filtration of all infusates during the manufacturing process in preference to the use of intravenous in-line filters as a more cost-effective and practical way to remove particulates (O'Grady 2011; Newell 1998; Pearson 1996). In support of this recommendation, Friedland 1985, reported that some solutions caused a reduction in flow rate or clogging of the filter and that certain drugs, such as antibiotics, may be retained in the filters, causing a reduction in potency. There are no known adverse effects from the use of intravenous in-line filters. The need to change the filters when they become blocked may lead to the need for increased manipulation of the intravenous administration set, increasing the risk of bacterial contamination. However, blocking of the filter is claimed to be indicative of complications such as those associated with microprecipitation occurring within the intravenous line which is a potentially harmful source of particulate matter which may then become dislodged entering the venous circulation (Bethune 2001). Friedland 1985, also argued that filters could not reduce the risk of infection caused by contaminants entering the line below the in-line filter. A study by Newell 1998, found no difference in the rate of septicaemia between children in an oncology unit who had filters fitted and those who did not. They concluded from their results that the added cost of using intravenous in-line filters was not warranted.

Intravenous in-line filters are recommended for use in neonates (Bethune 2001; Kunac 1999). Therefore, the aim of this review is to

systematically assess the evidence on the effectiveness of in-line filters on intravenous lines in neonates.

OBJECTIVES

To determine the effect of in-line filters on intravenous lines on morbidity and mortality in neonates.

We will carry out the following prespecified subgroup analyses.

1. Type of filter (approximate diameter 0.2 micron, 1.2 micron).
2. Gestation: term and preterm (defined as < 37 weeks) or extreme preterm (defined as < 30 weeks gestation).
3. Type of intravenous line (central or peripheral).
4. Type of intravenous fluid (crystalloid solutions, total parenteral nutrition, antibiotics, lipids).

METHODS

Criteria for considering studies for this review

Types of studies

We included RCTs or quasi-RCTs in the review.

Types of participants

Neonates with intravenous infusions who were randomised in the neonatal period (< 29 days post delivery).

Types of interventions

Intravenous in-line filter versus placebo or nothing.

Types of outcome measures

Primary outcomes

1. Mortality from any cause.
2. Proven septicaemic infection; positive bacterial or fungal blood culture.

Secondary outcomes

1. Localised phlebitis; redness, inflammation and tenderness at location of cannula.
2. Duration of cannula patency (days).
3. Number of catheters inserted.
4. Suspected septicaemic infection; clinical symptoms consistent with septicaemia but not proven.
5. Thrombus, local (cannula insertion site); diagnosed by ultrasound.
6. Thrombus, systemic; diagnosed by ultrasound.
7. Proven necrotising enterocolitis; Bell's stage two or greater.
8. Suspected necrotising enterocolitis; clinical symptoms consistent with necrotising enterocolitis, but not proven.
9. Periventricular leukomalacia; cystic changes in the periventricular areas.
10. Neurodevelopment assessed up to two years corrected age as measured by a validated assessment tool.
11. Financial costs.
12. Length of stay in hospital (days).
13. Adverse effects reported in the trials (if any).

Search methods for identification of studies

Electronic searches

We searched the electronic databases of the Cochrane Central Register of Controlled Trials (CENTRAL; Issue 5, 2015); MEDLINE (from 1966 to May, 2015), EMBASE (from 1980 to May 2015), and CINAHL (from 1982 to May 2015). We did not impose any language restrictions. We used the following MeSH terms: infant OR newborn AND text terms 'intravenous catheter' OR 'infusion filter' OR 'filtration' OR 'in-line filter' OR 'infusions' OR 'endotoxins' OR 'bacterial' OR 'particulate contamination', OR 'phlebitis' OR 'infection', OR 'intravenous infusion'.

Searching other resources

We examined the references in all studies identified as potentially relevant. We searched the abstracts from the annual meetings of the Pediatric Academic Societies (1993 to 2014), the European Society for Pediatric Research (1995 to 2014), the UK Royal College of Paediatrics and Child Health (2000 to 2014) and the Perinatal Society of Australia and New Zealand (2000 to 2014). We did not identify any new trials. We also searched clinical trials registries for ongoing or recently completed trials (clinicaltrials.gov; controlled-trials.com; and who.int/ictrp).

Data collection and analysis

We followed the procedures of the Cochrane Neonatal Review Group throughout.

Selection of studies

Two review authors (JF and RR) screened the title and abstract of all studies identified by the above search strategy. We reassessed the full text of any potentially eligible reports and excluded those studies that did not meet all of the inclusion criteria. We discussed all disagreements until we achieved consensus.

Data extraction and management

We used a data collection form to aid extraction of relevant information from each included study. Two review authors (JF and RR) extracted the data separately. The two reviewers (JF and RR) independently assessed the trials for their methodological quality and subsequent inclusion in the review. We discussed all disagreements until we achieved consensus. If data from the trial reports were insufficient, we contacted the investigators for further information.

Assessment of risk of bias in included studies

Two review authors planned to independently assess trials for methodological quality. We evaluated the following issues and enter the findings into the 'Risk of bias' tables ([Higgins 2011](#)):

1. Sequence generation (checking for possible selection bias): For each included study, we categorised the method used to generate the allocation sequence as: Low risk (any truly random process e.g. random number table; computer random number generator); High risk (any non random process e.g. odd or even date of birth; hospital or clinic record number); Unclear risk.
2. Allocation concealment (checking for possible selection bias): For each included study, we categorised the method used to conceal the allocation sequence as: Low risk (e.g. telephone or central randomisation; consecutively numbered sealed opaque

- envelopes);High risk (open random allocation; unsealed or non-opaque envelopes; alternation; date of birth);Unclear risk.
3. Blinding (checking for possible performance bias): For each included study, we categorised the methods used to blind study participants and personnel from knowledge of which intervention a participant received. We planned to categorise blinding separately for different outcomes or classes of outcomes. We categorised the methods as:Low risk, high risk, or unclear risk for participants;Low risk, high risk, or unclear risk for personnel;Low risk, high risk, or unclear risk for outcome assessors.
 4. Incomplete outcome data (checking for possible attrition bias through withdrawals, dropouts, protocol deviations): For each included study and for each outcome, we described the completeness of data including attrition and exclusions from the analysis. We noted whether attrition and exclusions were reported, the numbers included in the analysis at each stage (compared with the total randomised participants), reasons for attrition or exclusion where reported, and whether missing data were balanced across groups or were related to outcomes. Where sufficient information was reported or supplied by the trial authors, we planned to re-include missing data in the analyses. We categorised the methods as:Low risk (< 20% missing data);High risk (≥ 20% missing data);Unclear risk.
 5. Selective reporting bias: For each included study, we described how we investigated the possibility of selective outcome reporting bias and what we found. We assessed the methods as:Low risk (where it is clear that all of the study's pre-specified outcomes and all expected outcomes of interest to the review

- have been reported);High risk (where not all the study's pre-specified outcomes have been reported; one or more reported primary outcomes were not pre-specified; outcomes of interest are reported incompletely and so cannot be used; study fails to include results of a key outcome that would have been expected to have been reported);Unclear risk.
6. Other sources of bias: For each included study, we described any important concerns we had about other possible sources of bias (e.g. whether there was a potential source of bias related to the specific study design or whether the trial was stopped early due to some data-dependent process). We assessed whether each study was free of other problems that could put it at risk of bias as:Low risk;High risk;Unclear risk.

Measures of treatment effect

We followed the procedures of the Cochrane Neonatal Review Group for statistical analysis. We expressed dichotomous data as risk ratios (RRs) with 95% confidence intervals (CIs), risk differences (RDs) with 95% CIs, and number needed to treat (NNT) for dichotomous outcomes. We analysed continuous variables using weighted mean differences (WMDs) and 95% CIs. We estimated the heterogeneity of studies using the I² statistic.

Unit of analysis issues

The unit of analysis was the participating infant in individually randomised trials, except for outcomes where an individual infant may have experienced the event more than once. These include: rates of proven sepsis (Figure 1) in which case the unit of analysis will be the number of events over a given time period.

Figure 1. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.7 Proven necrotising enterocolitis.

Assessment of heterogeneity

If more than one trial was included in a meta-analysis, we examined the treatment effects of individual trials and heterogeneity between trial results by inspecting the forest plots. We calculated the I² statistic for each analysis to quantify inconsistency across studies and describe the percentage of variability in effect estimates that may be due to heterogeneity rather than sampling error. If we detected moderate (I² > 50%) heterogeneity, we explored the possible causes (for example, differences in study design, participants, interventions, or completeness of outcome assessments) in sensitivity analyses.

Data synthesis

We used the fixed-effects model in Review Manager 5.3 (RevMan 2014) for meta-analysis.

RESULTS

Description of studies

See tables: [Characteristics of included studies.](#)

Results of the search

Four published studies met the inclusion criteria. We excluded one trial. A total of 704 neonates were included in these studies (range 63 to 442). The details of each of these four studies are given in the table of [Characteristics of included studies.](#)

Included studies

van den Hoogen 2006 evaluated the effect of using 0.22 micron Pall Posidyne ELD96™ in-line filters versus no filter in 442 neonates on mortality, sepsis, phlebitis, number of catheter days and financial cost. The manufacturer recommends using this filter for the elimination of particles, microbes, air and endotoxins.

All intravenous fluids in the study group (with the exception of lipids which were administered through a 1.2 micron Lipipor™ filter) were given through the 0.22 micron in-line filter, and the administration sets were changed every four days. The intravenous sets in the control group and the Lipipor™ filters (that are not able to retain endotoxins) were changed daily. The filters were positioned at the distal end of the intravenous administration catheter after a series of stopcocks. The authors noted that this construction guaranteed that all clear fluids, including intravenous medication were administered via the filter. The Lipipor™ filter was placed distally to the 0.22 micron in-line filter. No information on cannula site preparation was provided.

[van Lingen 2004](#) studied 88 neonates to evaluate the effectiveness of the 0.22 micron Pall Posidyne ELD96™ in-line filters with no filters to prevent complications such as bacteraemia, phlebitis, extravasation, thrombosis, septicaemia and necrotising enterocolitis in neonates who required an intravenous catheter. [van Lingen 2004](#) also evaluated the economic impact of the use of intravenous in-line filters. All intravenous fluids in the study group (with the exception of lipids, blood or blood products) were given through the in-line filter and the administration sets were changed every four days. The intravenous sets in the control group were changed daily. In the study group, bacterial cultures were obtained at the time of change from both sides of the discarded filter and from the lipid solution. For the control group, bacterial cultures were obtained from the intravenous fluids every four days. In addition, catheter tips were cultured after removal. Blood was cultured only when sepsis was suspected. No information was provided on cannula site preparation. [van Lingen 2004](#) reported that four patients in the control group died from "causes unrelated to catheter usage" i.e. necrotising enterocolitis, pulmonary bleeding, severe intraventricular haemorrhage, circulatory insufficiency. However, these four neonates were included in the mortality outcome in this review.

[Thomas 1989](#) assessed the effect of in-line filters on duration of cannula patency in 63 neonates requiring intravenous fluids. [Thomas 1989](#) used a 0.2 micron Cathivex™ filter that is only recommended for the removal of particulates and air. The filters in the study group were positioned before the cannulae, except where fluids such as blood, plasma protein fraction, fresh frozen plasma or emulsions were being administered. On these occasions, the filter was positioned upstream of the three way tap used for adding such fluids to the primary infusion line. In the control group, an extension set was substituted for the filter. This was included as it provided an equal number of connections and manipulations in the lines for both groups. The intravenous lines and filters were changed every 24 hours in the control and study groups. Cannula site preparation was limited to swabbing the skin with isopropyl alcohol. Following cannulation, the site was covered with a sterile dressing. No extra cannula site care was performed (such as application of antibiotic cream or spray) during the study. Cannula life was assessed by duration of patency and volume of intravenous fluid passed by the site. Nursing staff observations of the infusion site were used to subjectively determine the end point. Nursing staff routinely checked and recorded the condition of the intravenous cannula sites and the volume of fluid delivered every hour. No information was provided on the length of the study period.

[Bennion 1991](#) assessed the effect of intravenous in-line filters on serum gentamicin level results, incidence of necrosed areas at the infiltration site, and cost of administration sets, with and without an intravenous in-line filter in 111 neonates. [Bennion 1991](#) used a 0.22 micron Pall Posidyne ELD96™ that was used by [van Lingen 2004](#) and [van den Hoogen 2006](#). The intravenous sets were changed every four days in the treatment group, and daily in the control group. A record of the administration sets was made each day together with serum gentamicin level results for each baby and any necrosed areas that developed. Serum gentamicin levels were checked on the third dose of the antibiotic. No information was provided on cannula site preparation.

All studies were single centre studies. All four studies used 0.2 micron filters. The [Bennion 1991](#) and [Thomas 1989](#) studies used peripheral catheters, and the [van Lingen 2004](#) and [van den Hoogen 2006](#) studies used central venous (percutaneous or umbilical) catheters to deliver the intravenous fluids. While all the studies compared the use of in-line filters with no in-line filter, the outcomes that were measured varied.

There were no other identified studies that assessed whether intravenous in-line filters prevent morbidity and mortality in neonates.

Excluded studies

There was one excluded study (see [Characteristics of excluded studies](#)). [Jack 2012](#) was a single centre, prospective RCT, that randomised 807 critically ill children admitted to a paediatric intensive care unit, either to control (n = 406) or filter group (n = 401), with the latter receiving in-line filtration. The study included subjects less than 18 years of age (mean age 5 to 6 years). The primary endpoint was reduction in the rate of overall complications, which included the occurrence of systemic inflammatory response syndrome, sepsis, organ failure (circulation, lung, liver, kidney) and thrombosis. Secondary objectives were a reduction in the length of stay in the paediatric intensive care unit and overall hospital stay. Duration of mechanical ventilation and mortality were also analysed.

Risk of bias in included studies

Details of the methodological quality of each trial are given in the table [Characteristics of included studies](#).

Allocation

Only the study of [van Lingen 2004](#) was randomised (computer-generated randomisation with sealed numbered envelopes that were opened on admission of each neonate). Three studies ([Bennion 1991](#); [Thomas 1989](#); [van den Hoogen 2006](#)) were quasi-randomised (alternate allocation).

Blinding

A placebo was not used in any of the four studies and, therefore, there was no blinding of the intervention. Information on outcome measurements was inadequately described in all of the studies.

Incomplete outcome data

The four studies examined short-term outcomes and accounted for all neonates in the intervention and control groups. Thirteen per cent of the neonates in the [van den Hoogen 2006](#) study

were excluded from the study following randomisation because of incomplete data, either because the infant died or the patient was discharged soon after birth.

Effects of interventions

See: [Summary of findings for the main comparison Intravenous in-line filter for preventing morbidity and mortality in neonates](#)

Comparison: Intravenous in-line filter versus placebo

We did not identify any studies for this comparison.

Comparison: Intravenous in-line filter versus no filter

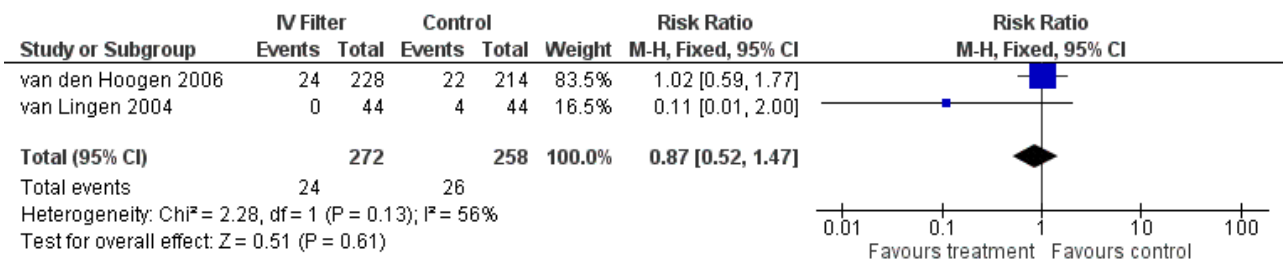

We identified four studies for this comparison ([Bennion 1991](#); [Thomas 1989](#); [van Lingen 2004](#); [van den Hoogen 2006](#)).

Primary outcomes

1) Mortality from any cause during hospitalisation (Outcome 1.1)

Mortality was reported in two of the studies. For the [van Lingen 2004](#) study of 88 infants, there were four deaths in the control group and none in the treatment group. For the [van den Hoogen 2006](#) study of 442 infants, there were 22 deaths in the control group and 24 in the treatment group. There was no statistical difference for mortality in either of the studies (typical RR 0.87, 95% CI 0.52 to 1.47; typical RD -0.01, 95% CI -0.06 to 0.04; 2 studies, 530 infants) ([Figure 2](#))

Figure 2. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.1 Mortality during hospitalisation.

2) Proven septicaemic infection (positive bacterial or fungal blood culture) (Outcomes 1.2 and 1.3)

Proven septicaemic infection was reported as number of infants with events in two of the studies. There was no statistical difference

found in the [van Lingen 2004](#) study of 88 infants and in the [van den Hoogen 2006](#) study of 442 infants (typical RR 0.86, 95% CI 0.59 to 1.27; typical RD -0.02, 95% CI -0.09 to 0.04; 2 studies, 530 infants) ([Figure 3](#)).

Figure 3. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.2 Risk of proven septicaemia per infant.

One study [van den Hoogen 2006](#) reported rates of proven septicaemic infection as number of events per group (intravenous in-line filter group; 22 events; control group; 28 events) over a

specified follow-up period (intravenous in-line filter group; 11 days; control group; 10 days), rate ratio (0.86 [0.49, 1.51] (Rate Ratio 0.86, 95% CI 0.49 to 1.51) and found no difference in rates ([Figure 4](#)).

Figure 4. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.3 Rates of proven septicaemia per 1000 catheter days.

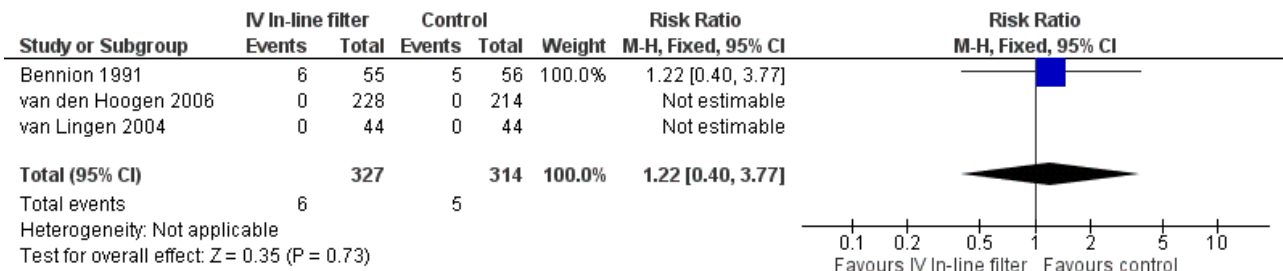

Secondary outcomes

1) Localised phlebitis (redness, inflammation and tenderness at location of cannula) (Outcome 1.4)

Localised phlebitis was reported in three studies. Bennion 1991 reported the incidence of localised necrosis (undefined) in 111

infants with no statistical difference between the treatment and control groups. Phlebitis did not occur in the van den Hoogen 2006 or van Lingen 2004 studies (typical RR 1.22, 95% CI 0.40 to 3.77; typical RD 0.01, 95% CI -0.05 to 0.08; 3 studies, 641 infants) (Figure 5).

Figure 5. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.4 Localised phlebitis.

Thomas 1989 reported the incidence of 'tissuing' (undefined by authors, but regarded as infiltration or leaking of fluids into the area surrounding the vein) related to number of cannulations, rather than number of neonates and, therefore, could not be included in the above analysis. There were 59 incidences of phlebitis from 81 cannulations in the treatment group (n = 30) compared to 67 incidences of phlebitis from 86 cannulations in the control group (n = 33). There was no difference between the treatment and control groups.

2) Duration of cannula patency

Three studies reported on duration of cannula patency. In the van Lingen 2004 study, the total duration for the catheters remaining in place for all neonates in the study group (n = 44) was a total of 525 patient days (mean 8.1 days per neonate). In the control group, the total duration for the catheters remaining in place for all neonates (n = 44) was a total of 493 patient days (mean 8.8 days per neonate). A difference between the treatment and control groups was not found.

In the Thomas 1989 study, the median duration of catheter patency in the treatment group was 59 hours compared to 49 hours in the control group. The authors reported a statistical difference between the two groups (log rank test $\chi^2 = 4.024$, $P < 0.05$) with a median increase in cannula patency of 20% in the treatment group compared to the control group. van den Hoogen 2006 compared

the number of catheter days for umbilical venous, percutaneous and central venous catheters and found no difference between the treatment and control groups.

3) Number of catheters inserted

Two studies reported on the number of catheters inserted (Thomas 1989; van Lingen 2004). There was no difference between the treatment and control groups. In the van Lingen 2004 study there was a total of 65 intravenous catheter insertions. These were reported as 23 percutaneous and 42 umbilical central venous catheter insertions (43 first, 17 second and 5 third) for the neonates in the study group (n = 44). There were 56 (40 percutaneous and 16 umbilical) catheter insertions (42 first, 12 second and 2 third) for the neonates in the control group (n = 44). For the Thomas 1989 study there was a total of 81 catheter (peripheral) insertions in the study group (n = 30) compared to 86 catheter (peripheral) insertions in the control group (n = 33). Standard deviations were not provided and, therefore, a weighted mean difference could not be performed.

4) Suspected septicaemic infection (clinical symptoms consistent with septicaemia, but not proven) (Outcome 1.5)

The van Lingen 2004 study of 88 infants was the only study to report suspected septicaemic infection and found no difference (typical RR 0.57, 95% CI 0.18 to 1.81; typical RD -0.07, 95% CI -0.21 to 0.07; 1 study, 88 infants) (Figure 6).

Figure 6. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.5 Suspected septicaemia.

5) Local thrombosis (cannula insertion site, diagnosed by ultrasound) (Outcome 1.6)

Local thrombosis was only reported in the [van Lingen 2004](#) study. No significant difference was found (typical RR 0.20, 95% CI 0.01

to 4.05; typical RD -0.05, 95% CI -0.12 to 0.03; 1 study, 88 infants) ([Figure 7](#)).

Figure 7. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.6 Localised thrombi.

6) Systemic thrombus (diagnosed by ultrasound)

No data were available.

7) Proven necrotising enterocolitis (Bell's stage two or greater) (Outcome 1.7)

Proven necrotising enterocolitis was only reported in the [van Lingen 2004](#) study, and there were no significant differences (typical RR 0.20, 95% CI 0.01 to 4.05; typical RD -0.05, 95% CI -0.12 to 0.03; 1 study, 88 infants) ([Figure 1](#)).

8) Suspected necrotising enterocolitis (clinical symptoms consistent with necrotising enterocolitis, but not proven)

No data were available.

9) Periventricular leukomalacia (cystic changes in the periventricular areas)

No data were available.

10) Neurodevelopment (assessed up to two years corrected age, as measured by a validated assessment tool)

No data were available.

11) Financial costs

[van den Hoogen 2006](#) compared the costs of disposable materials per patient per four days. In the study group, two filters (clear fluid and lipid) and intravenous sets were changed every 96 hours and the intravenous sets in the control group were changed daily. The total cost per neonate in the control group was EUR 241.76 and EUR 238.63 in the study group, showing that the cost of using an in-line filter was compensated by the reduced consumption of intravenous administration sets. [van den Hoogen 2006](#) also used filters for fat emulsions that had to be changed daily. Without the inclusion of these filters in the calculation, costs of disposable materials in the in-line filter group would have been much lower at EUR 107.73 over the four day period, less than half that in the control group. This study also found that the time necessary for changing the intravenous administration sets was significantly longer in the non-filter group: the mean time was 14 minutes plus +/- 7 minutes in the non-filter group, compared to 10 minutes +/- 5 minutes in the filter group (P = 0.000).

For the [van Lingen 2004](#) study, costs attributable to patients in both control and study groups were calculated on a 'cost of disposables' basis during a standard eight day stay. Additionally, the time taken for line change was calculated by 'direct assessment', and an estimate of the relative nursing costs was built into the analysis. In the study group, filters and intravenous sets were changed every 96 hours and in the control group, the intravenous sets were changed daily. However, unlike the [van den Hoogen 2006](#) study, lipid filters were not included in the calculation. The total cost per neonate in the control group was EUR 85.75 and for the study group was EUR 37.44, showing a saving of EUR 48.31 per neonate, over a period of eight days.

The [Bennion 1991](#) study reported the average cost of an administration system as approximately GBP 17.28 per day for the control group compared to GBP 8.84 per day in the study group (showing a daily saving of GBP 8.44 in the treatment group). This was calculated by dividing the total cost of the equipment used by the number of cot days occupied by infants in each group. The intravenous sets were changed every 96 hours in the control group and daily in the study group.

12) Adverse affects reported in the trials

In the [Bennion 1991](#) study, precipitate was found to clog the filter and the flow of intravenous fluids. The intravenous in-line filter also became blocked in one patient in the [van den Hoogen 2006](#) study; that was reported to be possibly due to the administration of very high glucose concentrations (50%).

There were no data available to be able to perform subgroup analyses on type of filter, gestation, type of intravenous line, or type of intravenous fluid.

13) Composite thrombus, proven or unproven sepsis and necrotising enterocolitis.

A composite outcome for thrombi, proven or unproven sepsis, and necrotising enterocolitis was not prespecified in this review and is therefore reported post hoc. [van Lingen 2004](#) reported a statistically significant reduction in the combined risk of thrombi proven sepsis, or NEC (typical RR 0.38, 95% CI 0.19 to 0.77; typical RD -0.30, 95% CI -0.48 to -0.11) ([Figure 8](#)).

Figure 8. Forest plot of comparison: 1 Intravenous in-line filter versus no filter, outcome: 1.8 Composite thrombus, proven or unproven sepsis, necrotising enterocolitis.

DISCUSSION

Summary of main results

There was no statistically significant difference in any of the outcomes of mortality, proven or suspected septicaemia, localised phlebitis, localised thrombi, necrotising enterocolitis, length of stay, duration of cannula patency or number of catheters inserted between infants receiving intravenous therapy using in-line intravenous filters or those receiving intravenous therapy without in-line intravenous filters.

A composite outcome for thrombi, proven or unproven sepsis, sepsis and necrotising enterocolitis was not prespecified in this review and is therefore reported post hoc. [van Lingen 2004](#) reported a statistically significant reduction in the combined risk of thrombi proven sepsis, or NEC (RR 0.38 (95% CI 0.19 to 0.77), RD -0.30 (95% CI -0.48 to -0.11), or just over two thirds reduction in risk in favour of intravenous in-line filtration.

Cost savings were reported by [Bennion 1991](#), [van Lingen 2004](#) and [van den Hoogen 2006](#). We found no data available from RCTs that compared periventricular leukomalacia, incidence of systemic thrombus, and neurodevelopmental outcomes.

Overall completeness and applicability of evidence

Low to moderate quality evidence from four randomised trials is insufficient to support or refute the use of intravenous in-line filters in preventing line-related morbidity and mortality in neonates.

In-line intravenous filters combined with less frequent changing of the intravenous sets (every four days) were not effective in reducing the risk of morbidity, mortality, or adverse events compared with daily changing of unfiltered intravenous administration sets.

Quality of the evidence

Four trials of low to moderate quality were included in the review ([Bennion 1991](#); [Thomas 1989](#); [van Lingen 2004](#); [van den Hoogen](#)

[2006](#)). (Refer [Risk of bias in included studies](#) and [Summary of findings for the main comparison](#)).

Although blinding of the intervention is not likely to be easily achieved, future studies could improve quality by performing and reporting blinded outcome assessment, randomisation/allocation sequences, and pre-registration of trial protocols using trial registries.

AUTHORS' CONCLUSIONS

Implications for practice

There is insufficient evidence to recommend the use of intravenous in-line filters to prevent morbidity or mortality in neonates. However, cost savings were found with the less frequent changing of the intravenous sets when a 0.2 micron intravenous in-line filter (that removes endotoxins) was used, without an increase in adverse outcomes.

Implications for research

Further trials are needed to be able to assess the effectiveness of 0.22 micron positively charged 96-hour intravenous in-line filters and 1.2 micron intravenous in-line filters used for lipid administration for use in term and preterm neonates. These trials should include the outcomes of periventricular leukomalacia, necrotising enterocolitis, systemic and local thrombus and local phlebitis.

CHARACTERISTICS OF STUDIES

Characteristics of included studies [ordered by study ID]

Bennion 1991

Methods	Parallel, quasi-randomised controlled trial
Participants	111 neonates receiving IV fluids via peripheral venous line Gestation: 28 - 37 weeks Birth weight: 1170 - 3240 gm No exclusions
Interventions	Experimental group: 0.22 micron intravenous in-line filter (N = 55) Control group: No filter or placebo. Administration set changed daily in control group and every 96 hours in treatment group (N = 56)
Outcomes	1. Effect of IV in-line filters on gentamicin level results 2. Incidence of necrosed area at infiltration site 3. Cost of administration sets when an in-line filter is used, compared to the cost when a filter is not used 4. Duration of IV in progress 5. Duration of IV infusion in progress
Notes	Sample size calculation: Not reported

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Each baby that required IV infusion was entered into the study with alternate babies having an in-line filter
Allocation concealment (selection bias)	High risk	No
Blinding (performance bias and detection bias) All outcomes	High risk	No
Blinding of participants and personnel (performance bias) All outcomes	High risk	No
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not described
Incomplete outcome data (attrition bias) All outcomes	Low risk	No missing outcome data
Selective reporting (reporting bias)	Unclear risk	We were unable to obtain the study protocol

Thomas 1989

Methods	Parallel, quasi-randomised controlled trial
---------	---

Thomas 1989 (Continued)

Participants	63 neonates requiring IV fluids via peripheral venous line Mean gestation: 34.13 - 34.91 weeks Mean birth weight: 2230 - 2350 gm No exclusions
Interventions	Experimental group: 0.2 micron intravenous filter (N = 30) Control group: No filter but extension set substituted for filter (N = 33) Administration sets changed every 24 hours in treatment and control groups
Outcomes	1. Duration of cannula patency 2. Extravasation 3. Leaking at infusion site 4. Number of catheter insertions
Notes	Sample size calculation: Not reported

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Each baby that required intravenous infusion was entered into the study with alternate babies having an in-line filter

van den Hoogen 2006

Methods	Parallel, quasi-randomised controlled trial
Participants	442 neonates requiring IV fluids via an umbilical or percutaneous central venous catheter or a catheter inserted in the subclavian or femoral vein. All neonates admitted to the neonatal intensive care unit and required fluids via a central venous catheter were eligible Gestation: 25 - 43 weeks

van den Hoogen 2006 (Continued)

Birth weight: 600 - 4640 gm

Interventions	Experimental group: 0.22 micron intravenous filter (N = 228) Control group: No filter (N = 214) Catheter tips cultured after removal Administration set changed daily in the control group. Administration set changed every 96 hours in treatment group
Outcomes	1. Mortality 2. Phlebitis: defined as 'signs of local infection and a positive culture from the infected site' 2. Proven Sepsis: defined as 'occurrence of clinical signs of local infection and a positive blood culture' 3. Number of catheter days 4. Length of stay in hospital 5. Financial costs
Notes	Sample size calculation: Not reported

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Each baby that required intravenous infusion was entered into the study with alternate babies having an in-line filter
Allocation concealment (selection bias)	High risk	No
Blinding (performance bias and detection bias) All outcomes	High risk	No
Blinding of participants and personnel (performance bias) All outcomes	High risk	No
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Not described
Incomplete outcome data (attrition bias) All outcomes	Low risk	Data for 65 infants were excluded post randomisation 'because the patient was discharged soon after birth, died after a few days, or because of incomplete data (approximately 14% loss to follow-up).
Selective reporting (reporting bias)	Unclear risk	We were unable to obtain the study protocol. There was incomplete reporting on reasons for catheter removal and reinsertion for both treatment and control group

van Lingen 2004

Methods	Parallel, randomised controlled trial
Participants	88 neonates requiring IV fluids via an umbilical or percutaneous central venous line. Premature infants with respiratory distress syndrome (RDS) and term infants with asphyxia or pneumonia/septicaemia were eligible

Intravenous in-line filters for preventing morbidity and mortality in neonates (Review)

van Lingen 2004 (Continued)

Gestation: 26.3 - 42.3 weeks
Birth weight: 585 - 4100 gm
Ineligible if congenital malformation present and infants < 26 weeks gestation

Interventions	Experimental group: 0.22 micron IV filter (N = 44) Control group: No filter or placebo (N = 44) Full blood count on admission Catheter tips cultured after removal Administration set changed daily in the control group. Administration set changed every 96 hours in treatment group
Outcomes	1. Phlebitis 2. Extravasation 3. Thrombosis 4. Proven sepsis: 'characteristic clinical symptoms' positive blood culture, and abnormal tests, (leucocytosis, leucopenia, granulocytopenia, C-Reactive Protein (CRP) > 10 mg/L) 5. Unproven sepsis: 'characteristic clinical symptoms' and negative blood culture and abnormal tests 6. Necrotising enterocolitis 7. Duration of cannula patency 7. Number of catheter insertions 8. Duration of catheter insertion 9. Secondary septicaemia
Notes	Sample size calculation: To achieve a reduction in infection rate from 30% to 5% by using an in-line filter with power of 80% and at 5% significance would require at least 36 infants in each group

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer-generated randomisation was carried out by one of the neonatologists who did not participate in the study
Allocation concealment (selection bias)	Low risk	Sealed numbered envelopes were opened on admission of the neonate; neonates allocated to either study or control group
Blinding (performance bias and detection bias) All outcomes	High risk	No
Blinding of participants and personnel (performance bias) All outcomes	High risk	No
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	Not described
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Not reported
Selective reporting (reporting bias)	Unclear risk	Routinely measured outcomes are reported

Characteristics of excluded studies [ordered by study ID]

Study	Reason for exclusion
Jack 2012	<p>Jack 2012: Single centre, prospective, randomised controlled trial that randomised 807 critically ill children admitted to paediatric intensive care unit either to control (n = 406) or filter group (n = 401), with the latter receiving in-line filtration</p> <p>The study included subjects less than 18 years of age (mean age 5 to 6 years). The primary endpoint was reduction in the rate of overall complications, which included the occurrence of systemic inflammatory response syndrome, sepsis, organ failure (circulation, lung, liver, kidney) and thrombosis. Secondary objectives were a reduction in the length of stay in the paediatric intensive care unit and overall hospital stay. Duration of mechanical ventilation and mortality were also analysed</p> <p>Analysis demonstrated a significant reduction in the overall complication rate (n = 166 [40.9 %] vs n = 124 [30.9 %]; P = 0.003) for the filter group. In particular, the incidence of systemic inflammatory response syndrome was significantly lower (n = 123 [30.3 %] vs n = 90 [22.4 %]; P = 0.01). Moreover the length of stay in paediatric intensive care unit (3.89 [95 % confidence interval 2.97-4.82] vs 2.98 [2.33-3.64]; P = 0.025) and duration of mechanical ventilation (14.0 [5.6-22.4] vs 11.0 [7.1-14.9] h; P = 0.028) were significantly reduced.</p>

IV: intravenous

DATA AND ANALYSES
Comparison 1. Intravenous in-line filter versus no filter

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Mortality during hospitalisation	2	530	Risk Ratio (M-H, Fixed, 95% CI)	0.87 [0.52, 1.47]
2 Risk of proven septicaemia per infant	2	530	Risk Ratio (M-H, Fixed, 95% CI)	0.86 [0.59, 1.27]
3 Rates of proven septicaemia per 1000 catheter day	1		Rate Ratio (Fixed, 95% CI)	0.79 [0.45, 1.37]
4 Localised phlebitis	3	641	Risk Ratio (M-H, Fixed, 95% CI)	1.22 [0.40, 3.77]
5 Suspected septicaemia	1	88	Risk Ratio (M-H, Fixed, 95% CI)	0.57 [0.18, 1.81]
6 Localised thrombi	1	88	Risk Ratio (M-H, Fixed, 95% CI)	0.2 [0.01, 4.05]
7 Proven necrotising enterocolitis	1	88	Risk Ratio (M-H, Fixed, 95% CI)	0.2 [0.01, 4.05]
8 Composite thrombus, proven or unproven sepsis, necrotising enterocolitis	1	88	Risk Ratio (M-H, Fixed, 95% CI)	0.38 [0.19, 0.77]

Analysis 1.1. Comparison 1 Intravenous in-line filter versus no filter, Outcome 1 Mortality during hospitalisation.

Analysis 1.2. Comparison 1 Intravenous in-line filter versus no filter, Outcome 2 Risk of proven septicaemia per infant.

Analysis 1.3. Comparison 1 Intravenous in-line filter versus no filter, Outcome 3 Rates of proven septicaemia per 1000 catheter day.

Analysis 1.4. Comparison 1 Intravenous in-line filter versus no filter, Outcome 4 Localised phlebitis.

Analysis 1.5. Comparison 1 Intravenous in-line filter versus no filter, Outcome 5 Suspected septicaemia.

Analysis 1.6. Comparison 1 Intravenous in-line filter versus no filter, Outcome 6 Localised thrombi.

Analysis 1.7. Comparison 1 Intravenous in-line filter versus no filter, Outcome 7 Proven necrotising enterocolitis.

Analysis 1.8. Comparison 1 Intravenous in-line filter versus no filter, Outcome 8 Composite thrombus, proven or unproven sepsis, necrotising enterocolitis.

WHAT'S NEW

Date	Event	Description
8 July 2015	New search has been performed	This updates the review "Intravenous in-line filters for preventing morbidity and mortality in neonates" Foster 2006 .
22 May 2014	New citation required but conclusions have not changed	Search updated in May 2015, no new trials identified. New additional author.

HISTORY

Protocol first published: Issue 2, 2005
Review first published: Issue 2, 2006

Date	Event	Description
20 January 2013	Amended	Contact details updated.
2 April 2011	New search has been performed	This updates the review "Intravenous in-line filters for preventing morbidity and mortality in neonates" (Foster 2006). Updated search in April 2011 did not identify any new studies. Conclusions remain the same.
15 February 2011	Amended	Contact details updated.
4 December 2008	New search has been performed	This updates the review "Intravenous in-line filters for preventing morbidity and mortality in neonates" published in The Cochrane Library, Issue 2, 2006 (Foster 2006). One eligible trial was found and has been included in this review.
18 September 2008	Amended	Converted to new review format.

CONTRIBUTIONS OF AUTHORS

Jann Foster (JF), Robyn Richards (RR) and Marian Showell (MS) independently assessed studies for inclusion in this review. JF and RR wrote the review with the assistance of MS and LJ. JF acts as guarantor for the review.

DECLARATIONS OF INTEREST

JF: There are no potential conflicts of interest.

RR: There are no potential conflicts of interest.

MS: There are no potential conflicts of interest.

LJ: There are no potential conflicts of interest.
