1 **Abstract**

2 Little is known about the MIS-C risk with different SARS-CoV-2 variants. In Southeast England, MIS-C
3 rates per confirmed SARS-CoV-2 infections in 0-16 years-olds were 56% lower (rate ratio, 0.34;
4 95%CI, 0.23-0.50) during pre-vaccine Delta, 66% lower (0.44; 0.28-0.69) during post-vaccine Delta
5 and 95% lower (0.05; 0.02-0.10) during the Omicron period.

6 **Key words:** SARS-CoV-2, coronavirus, COVID-19, PIMS-TS, MIS-C

ACCEPTED MANUSCRIPT

1 **Introduction**

2 Multisystem Inflammatory Syndrome in Children (MIS-C, also known as PIMS-TS) is an acute
3 inflammatory disorder, sharing features of Kawasaki disease and toxic-shock syndrome, typically
4 occurring 2-6 weeks after SARS-CoV-2 exposure, mainly in children and young people (CYP). First
5 described in England in April 2020,¹ this condition is now reported worldwide. Early estimates
6 suggested a risk of MIS-C of 1 in 3-4,000 infected children.^{2,3} Whether this risk is sustained with new
7 SARS-CoV-2 variants remains unknown. We compared daily cases of MIS-C against SARS-CoV-2
8 infection in children in a defined geographical area of Southeast England to determine relative rates
9 of MIS-C during Alpha, Delta and Omicron waves over a 22-month period.

10

11 **Methods**

12 Data Sources

13 We utilised prospective hospital admission data from the NHS South Thames Paediatric Network
14 (STPN), which manages all MIS-C cases amongst 1.5 million children in South-East England, to assess
15 trends over time. All patients 0–16 years with suspected MIS-C in the Network are discussed in a
16 daily multi-disciplinary meeting, with diagnosis made according to RCPCH criteria, unchanged since
17 September 2020.⁴

18 We compared MIS-C cases with two independent SARS-CoV-2 infection datasets. We used publicly
19 available UK Health Security Agency (UKHSA) case numbers aggregated for age bands 0–4, 5–9 and
20 9–14 years across London and South East England, which records daily positive PCR and rapid-
21 antigen tests from both healthcare and community testing within defined geographical regions.⁵

22 These were matched to STPN catchment, weighting cases to reflect child population distributions
23 according to area population estimates from Office for National Statistics (ONS).⁶ Since this dataset
24 could potentially be biased by evolving changes in testing behaviour, we also compared MIS-C cases
25 to community infection rates in 2-11 year olds, obtained from ONS COVID-19 Infection Survey.⁷ This

1 survey randomly selects individuals in private households for fortnightly PCR tests, deriving
2 estimates of proportions infected in different age-groups irrespective of symptom status.

3 Normalisation and Data Presentation

4 All three datasets were independently normalised to the peak of the Alpha variant wave in January
5 2021, allowing comparison with future waves, and plotted against time. MIS-C cases were
6 smoothed over 7 days and plotted against a date corresponding to 40 days prior to their hospital
7 admission, allowing for the lag from SARS-CoV-2 infection to hospitalisation. This interval provided
8 the closest parallel in rise of SARS-CoV-2 infection and MIS-C cases during the Alpha variant wave.

9 Definition of Variant Wave time periods

10 Using publicly available data on relative incidence of SARS-CoV-2 variants, we defined conservative
11 time periods for each variant wave as the dates the specific variant was responsible for $\geq 90\%$ of
12 typed cases in both the London and SE England regions.^{8,9,10} These correspond to 28 December 2020
13 to 7 March 2021 (Alpha), 13 June 2021 to 5 December 2021 (Delta) and 25 December 2021 to 1 Feb
14 2022 (Omicron). To control for the possible contribution of vaccination to changing MIS-C rates, an
15 even more conservative period of Delta variant wave was defined by restricting the time period until
16 12 September 2021 (week 36, 2021), when COVID-19 vaccination was first recommended for 12-15-
17 year-olds in England.

18 Calculation of relative incidence of MIS-C

19 We calculated MIS-C incidence rates in two ways, using both the reported SARS-CoV-2 infection
20 rates and community SARS-CoV-2 positivity rates as independent denominators. MIS-C cases were
21 used as raw case numbers in the defined time periods as above. SARS-CoV-2 infection rates
22 published by UKHSA and smoothed over 30 days were used as denominators to calculate MIS-C
23 rates for each of the time periods above.

1 In the second analysis, the ONS COVID infection Survey provided estimates of percentage positivity
2 at fortnightly time points. These values were imputed on an unchanged basis to the prior 13 days,
3 and then summed over each of the defined time-periods to estimate infection rates, which were
4 then used to calculate MIS-C rates. Using Alpha period as baseline, we calculated relative rate ratios
5 with 95% confidence intervals (CI) in MIS-C rates during pre-vaccine Delta, post-vaccine Delta and
6 Omicron periods.

7

8 **Results**

9 Compared with Alpha wave, we found fewer MIS-C cases relative to SARS-CoV-2 infections during
10 both pre-vaccine Delta, post-vaccine Delta and Omicron waves in CYP (Figure 1). Using confirmed
11 SARS-CoV-2 infection cases as the denominator, MIS-C cases were 56% lower (rate ratio, 0.34;
12 95%CI, 0.23-0.50; $P < 0.001$) during pre-vaccine Delta period compared to Alpha period, 66% lower
13 (0.44; 95%CI, 0.28-0.69; $P < 0.001$) during post-vaccine Delta and 95% lower (0.05; 95%CI, 0.02-0.10;
14 $P < 0.001$) during Omicron period compared to Alpha variant wave (1 in 432 cases during Alpha, 1 in
15 977 during pre-vaccine Delta, 1 in 1260 during post-vaccine Delta and 1 in 8315 during Omicron).
16 Using community infection positivity rates in 2–11-year-olds from ONS COVID Infection Survey as the
17 denominator, the relative rates were 59%, 62% and 94% lower, respectively.

18

19 **Discussion**

20 Testing for SARS-CoV-2 infection was not widely available during the first pandemic wave caused by
21 the wild-type Wuhan strain in Spring 2020. Consequently, we did not include the first wave in this
22 analysis and, instead, used the Alpha wave as a benchmark. Free, accessible community PCR testing
23 became widely available in England since June 2020 and, from March 2021, secondary school-aged
24 students (11–18 year-olds) were asked to undertake twice-weekly home testing using rapid-antigen
25 tests and report their results online. Despite the increased testing practices, patterns of reported

1 infections closely matched those of the ONS COVID-19 Infection Survey, which captured both
2 symptomatic and asymptomatic infections in each age-group in the community every two weeks
3 throughout the surveillance period. Reassuringly, MIS-C rates in children were very similar with both
4 denominators, indicating true change in relative incidence of MIS-C during the different SARS-CoV-2
5 variant waves. The UK RCPCH definition of MIS-C (PIMS-TS)⁴ differs from CDC and WHO definitions
6 in not requiring evidence of recent SARS-CoV-2 infection. This may overestimate cases compared to
7 these definitions. This did not change during the duration of this study so relative differences over
8 time remain internally valid. There were proportionately fewer paediatric intensive care unit
9 admissions in Delta compared to Alpha, likely reflecting earlier recognition and treatment. This
10 could have led to over-diagnosis amongst less severely ill children, and would give rise to even
11 greater differences between waves than we report here.

12 The lower MIS-C incidence during the pre-vaccine Delta wave was unlikely to be due to immunity
13 from prior SARS-CoV-2 infection because nearly all Delta variant infections in children were primary
14 infections and re-infections with Delta variant in children were uncommon during that period.¹¹
15 Recent studies have shown that mRNA vaccination against COVID-19 helps protect against MIS-C.
16 For this reason, we assessed MIS-C risk during the Delta wave before and after COVID-19 vaccination
17 was recommended for 12-15 year-olds in England. The lower MIS-C rate in the pre-vaccine Delta
18 period in comparison to the Alpha wave is, therefore, unlikely to be due to vaccination. Additionally,
19 compared to many other countries, COVID-19 vaccine uptake among adolescents in England has
20 been low, with only half of 12-15 years receiving the first dose by the end of 2021,¹² while
21 vaccination for 5–11-year-olds is planned for spring 2022. This likely explains the similar MIS-C rate
22 reductions in the pre-vaccine and post-vaccine Delta periods compared to the Alpha wave. While
23 prior infection and vaccination are unlikely to explain the lower MIS-C rates in the Delta wave, a
24 more likely explanation may be viral mutations in key antigenic epitopes responsible for triggering
25 the hyper-inflammatory response observed with MIS-C.

1 The more recent Omicron wave, which first emerged in November 2021, was associated with very
2 high cases numbers but we found an even lower relative MIS-C risk compared with previous
3 variants. When the Omicron variant emerged in England more than half the primary school-aged
4 children (up to 11 years) and nearly all secondary-school aged children (12-15) had SARS-CoV-2
5 antibodies consistent with prior infection and/or vaccination.¹³ Omicron possesses a number of new
6 mutations in addition to those present in the Alpha, Beta and Delta variants, which allows the
7 variant to at least partially evade both natural and vaccine-induced immunity, resulting in high rates
8 of re-infections in previously-infected and vaccinated populations.¹⁴ Mutations such as N679K may
9 diminish superantigenicity reducing risk of MIS-C.¹⁵ Consequently, the relative contributions of host
10 immunity and viral changes to the even lower MIS-C rates during the Omicron wave are obscured.

11 Both of the denominator data sets used have limitations. Changing testing behaviour as a bias of
12 community infection rates is controlled for by using the ONS COVID Infection Survey data, which
13 estimates infection rates by age group irrespective of symptom status and provides regionally- and
14 nationally-representative community infection rates at fortnightly intervals. The finding of very
15 similar rate reductions with the different variants using two independent denominators provides
16 confidence that these findings are real and reflect true ongoing changes in incidence in the
17 community which is consistent with our clinical experience on the frontline.

18 As more children become immune through natural SARS-CoV-2 infection and/or vaccination, and
19 with the on-going boosting of immunity following reinfections with the omicron variant, we predict
20 that MIS-C will behave as a sporadic condition occurring mainly in immunologically naive and
21 genetically susceptible infants and toddlers.
