ABSTRACT Influenza virus infections are thought to be initiated in a small number of cells; however, the heterogeneity across the cellular responses of the epithelial cells during establishment of disease is incompletely understood. Here, we used an H1N1 influenza virus encoding a fluorescent reporter gene, a cell lineage-labeling transgenic mouse line, and single-cell RNA sequencing to explore the range of responses in a susceptible epithelial cell population during an acute influenza A virus (IAV) infection. Focusing on multiciliated cells, we identified a subpopulation that basally expresses interferon-stimulated genes (ISGs), which we hypothesize may be important for the early response to infection. We subsequently found that a population of infected ciliated cells produce most of the ciliated cell-derived inflammatory cytokines, and nearly all bystander ciliated cells induce a broadly antiviral state. From these data together, we propose that variable preexisting gene expression patterns in the initial cells targeted by the virus may ultimately affect the establishment of viral disease.

IMPORTANCE Influenza A virus poses a significant threat to public health, and each year, millions of people in the United States alone are exposed to the virus. We do not currently, however, fully understand why some individuals clear the infection asymptomatically and others become severely ill. Understanding how these divergent phenotypes arise could eventually be leveraged to design therapeutics that prevent severe disease. As a first step toward understanding these different infection states, we used a technology that allowed us to determine how thousands of individual murine lung epithelial cells behaved before and during IAV infection. We found that small subsets of epithelial cells exhibited an antiviral state prior to infection, and similarly, some cells made high levels of inflammatory cytokines during infection. We propose that different ratios of these individual cellular responses may contribute to the broader antiviral state of the lung and may ultimately affect disease severity.

KEYWORDS single cell, interferon-stimulated genes, gene expression, RNA sequencing, transgenic mouse, reporter virus

Influenza viruses cause significant morbidity and mortality each year, with an estimated 290,000 to 650,000 deaths globally (1). With relatively limited available therapeutics, significant effort has been focused on defining the mechanisms of viral pathogenesis to explore alternate avenues of intervention. One area of particular interest is in defining why seemingly similar individuals exhibit different courses of disease. While viral and host genetics certainly play a role, some models suggest that stochastic variability within early innate responses may also be a contributing factor (2). A limitation to testing this hypothesis is that the field currently has an incomplete understanding of the heterogeneity in cellular responses after the initiation of viral infection.

Since its introduction, single-cell RNA sequencing (scRNA-seq) has been used to resolve tissue heterogeneity in a variety of environments (3–5). It has also been used

to study host-influenza interactions both *in vitro* and *in vivo* (2, 6–17). Previous *in vitro* studies in immortalized cell lines have primarily focused on understanding how coinfection, genetic variability in viral populations, and infection with different strains of influenza virus influence the cellular innate immune response (2, 6, 7, 10, 15). *In vivo* studies profiling the entire lung have identified changes in inflammatory responses throughout infection, described broad viral tropism, and found interferon-dependent and independent gene modules (8, 9). Few, mostly *in vitro* studies, have focused on the responses of epithelial cells, the main targets of IAV infection (12, 13, 16). Even less understood is the heterogeneity across responses by genetically defined subsets of epithelial cells *in vivo*.

A complicating factor in defining the responses of epithelial cell subsets using scRNA-seq is that their transcriptional profiles are dramatically altered by infection, often due to high viral burden and degradation of host mRNAs (9, 18, 19). Additionally, damage to the lung results in the differentiation of progenitor populations or dedifferentiation of cells to repair and regenerate the respiratory epithelium, often beginning within the first several days of injury (20–23). Consequently, it can be difficult to assign transcriptional profiles to specific cell populations with certainty by detecting cell type-specific marker gene transcripts alone (24).

As a first step in understanding how differences in cellular responses may ultimately influence infection outcomes, we explored how a single, highly susceptible epithelial cell population responded to IAV infection. We generated a fluorescent reporter virus and identified ciliated cells as a major target of the pdmH1N1 A/California/04/2009 (Cal09) influenza strain *in vivo*. We then used a transgenic mouse model to genetically label ciliated cells prior to infection and track them throughout the establishment of viral disease. Finally, we used scRNA-seq to interrogate gene expression in mock-infected, bystander, and influenza virus-infected ciliated cells from matched infected animals. Interestingly, we found expression of type I and type III interferons in a subset of ciliated cells, which we hypothesize may be linked to the basal expression of antiviral genes prior to infection. Additionally, there was notable expression of strong interferon-stimulated gene (ISG) transcriptional profiles in almost all bystander cells within 48 h of infection, indicating the sensitivity of these cells to inflammatory cytokines. These data support the growing literature showing variability in the response to infection, and we propose that divergent gene expression before exposure to influenza virus could potentially contribute to disease pathogenesis.

RESULTS

Epithelial ciliated cells are a main target of a reporter H1N1 virus in the upper respiratory tract. Our initial aim was to understand the potential heterogeneity of responses by a single population of epithelial cells to a nonlaboratory-adapted influenza virus. We therefore generated a fluorescent reporter virus in the prototype pdmH1N1 A/California/04/2009 genetic background (Cal09-superfolder green fluorescent protein [sfGFP]) to allow for the identification of infected cells based on fluorescence. We modified the eighth viral segment to eliminate splicing and encode NS1, sfGFP, and NEP as a single open reading frame (ORF), with 2A autoproteolytic cleavage sites separating the proteins cotranslationally (Fig. 1A).

Although we and others have previously used this genetic strategy to generate experimentally useful reporter viruses (25, 26), genetically modified viruses can fail to express the reporter protein or be significantly attenuated (27, 28). To determine reporter expression and the degree of attenuation for our reporter virus, we performed single-cycle infections and multi-cycle growth curves of Cal09-sfGFP and wild-type Cal09. We could detect a statistically significant increase in GFP expression in infected MDCK cells relative to background by 6 h postinfection (hpi), indicating this virus functions as a sensitive reporter of viral infection (Fig. 1B and C). We also found our reporter virus grew to similar titers and with similar kinetics as wild-type Cal09 in embryonated chicken eggs, suggesting only slight attenuation (Fig. 1D). As we ultimately wanted to investigate IAV infection in a mouse model, we next asked whether Cal09-sfGFP could
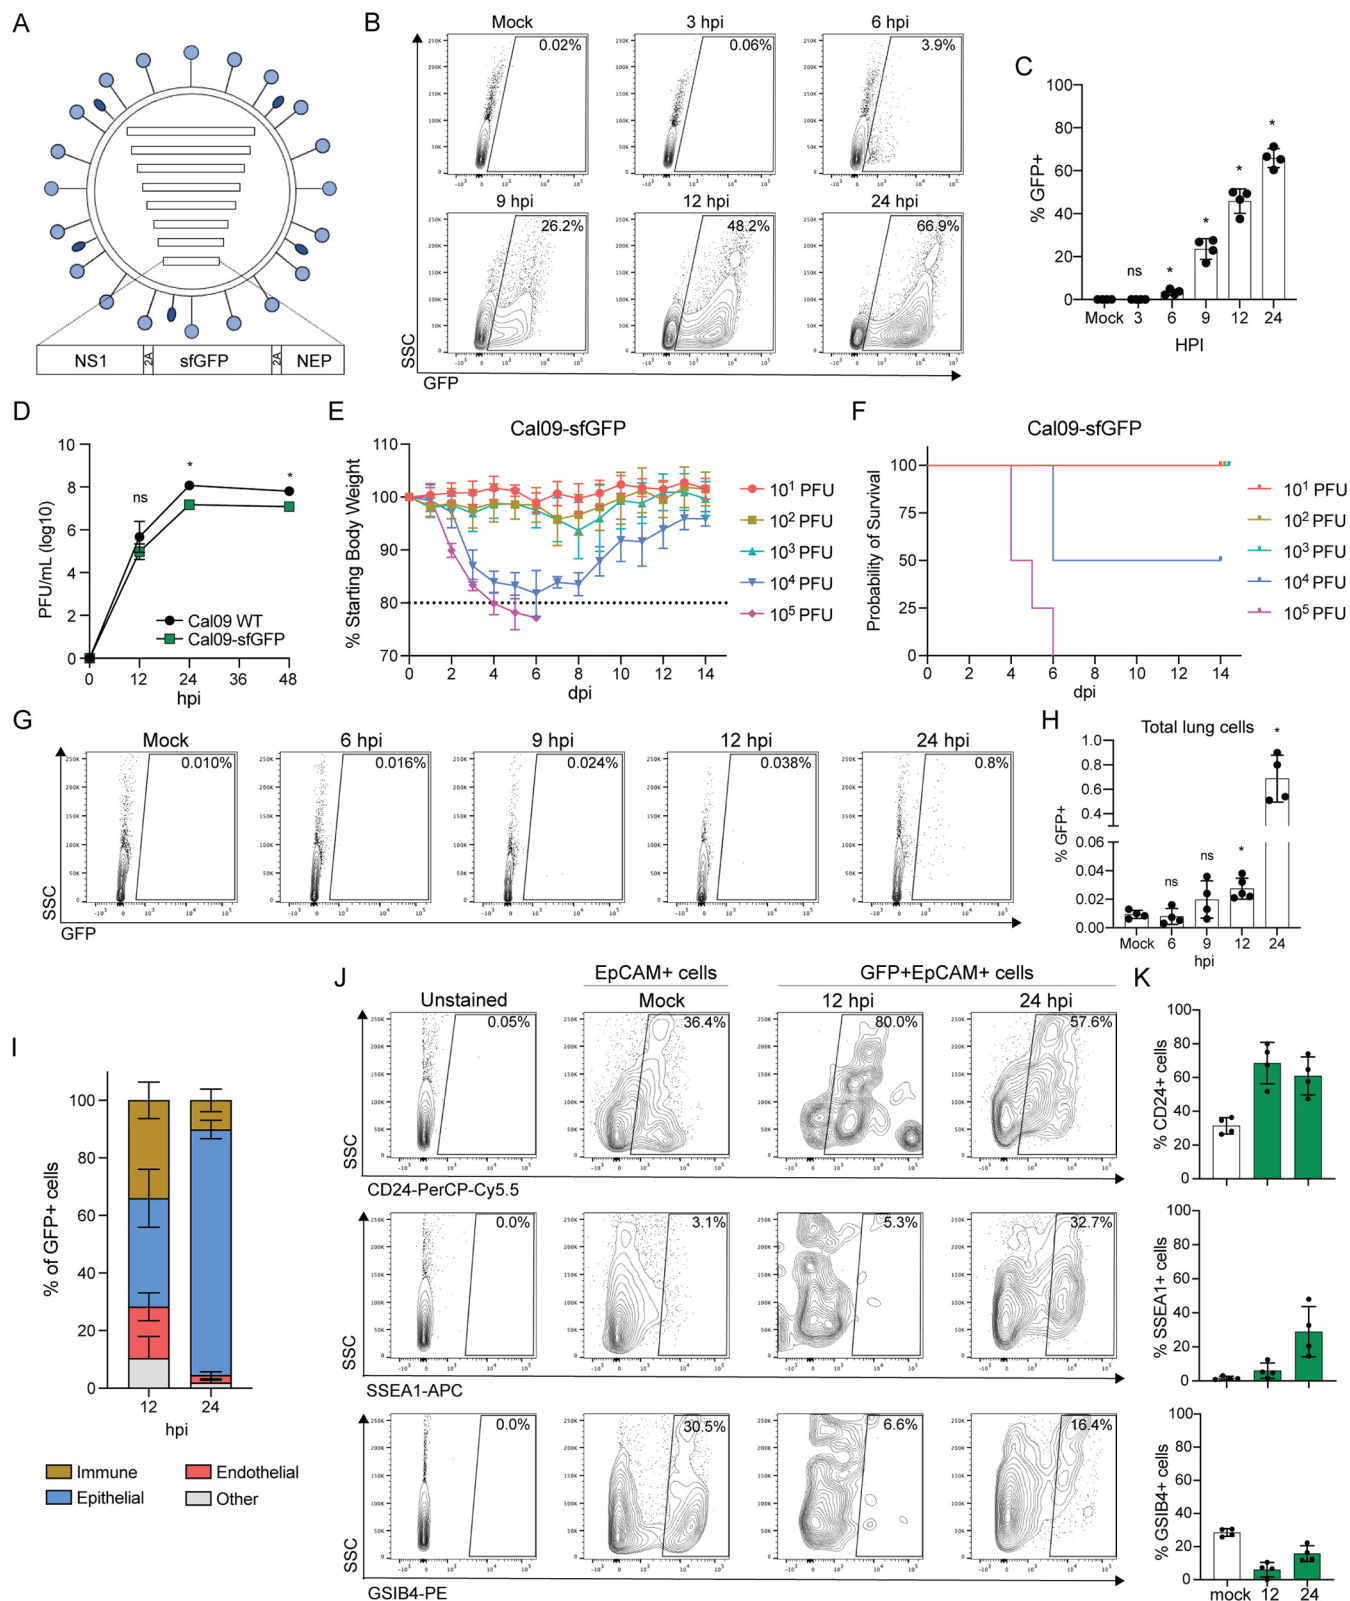

FIG 1 Ciliated cells are a target of a Cal09 reporter virus in the murine upper respiratory tract. (B) Representative flow cytometry of GFP⁺ cells collected at the indicated time points following infection with Cal09-sfGFP (MDCK cells, MOI = 0.5, single-cycle infection). hpi, hours postinfection. (C) Quantification of flow cytometry in panel B. Means with SDs are shown; n = 4 independent experiments; Mann-Whitney U test. (D) Viral titer after replication in embryonated chicken eggs for the time indicated for wild-type Cal09 or Cal09-sfGFP (1,000 PFU), measured using plaque

establish disease *in vivo*. We infected mice and found a dose-dependent decrease in body weight and survival following infection (Fig. 1E and F). Finally, we wanted to determine the earliest time points at which we could reliably identify GFP-positive (GFP$^+$) cells *in vivo*. To do so, we infected mice and then collected lung and tracheal cells at several time points following infection for flow cytometry analysis. We could detect a significant increase in GFP signal above the background beginning 12 hpi, with an additional 25-fold increase in fluorescent cells by 24 hpi (Fig. 1G and H).

With our reporter virus functioning appropriately, we next turned our attention to identifying the types of cells targeted by the virus during the establishment of infection. Although the tropism of pdmH1N1 viruses has been described previously, there are conflicting reports depending on the method used for assessment (29–31). We therefore collected cells from the upper respiratory tract of our Cal09-sfGFP-infected animals and stained them for markers of immune (CD45$^+$), epithelial CD45$^-$ EpCAM$^+$), and endothelial (CD45$^-$ CD31$^+$) cells (32–34). As expected, epithelial cells represent most of the infected cells at both 12 (average, 37%) and 24 hpi (average, 85%) (Fig. 1I). We detected a sizeable population of apparently infected immune cells at 12 hpi; however, because our assay cannot distinguish between infected immune cells and those that have phagocytosed GFP, we focused on the epithelial compartment. To determine the types of epithelial cells infected, we repeated this experiment but stained cells for markers of the major respiratory epithelial cell types, ciliated (EpCAM$^+$ CD24$^+$), secretory (EpCAM$^+$ SSEA1$^+$), and basal (EpCAM$^+$ GSIB4$^+$) (35–38). At both 12 and 24 hpi, we found that ciliated cells accounted for more than 50% of infected epithelial cell population (Fig. 1J and K). We therefore concluded that ciliated cells were a relevant *in vivo* target during murine infection with Cal09-sfGFP and thus decided to focus additional study on this population of the epithelium during influenza virus infection.
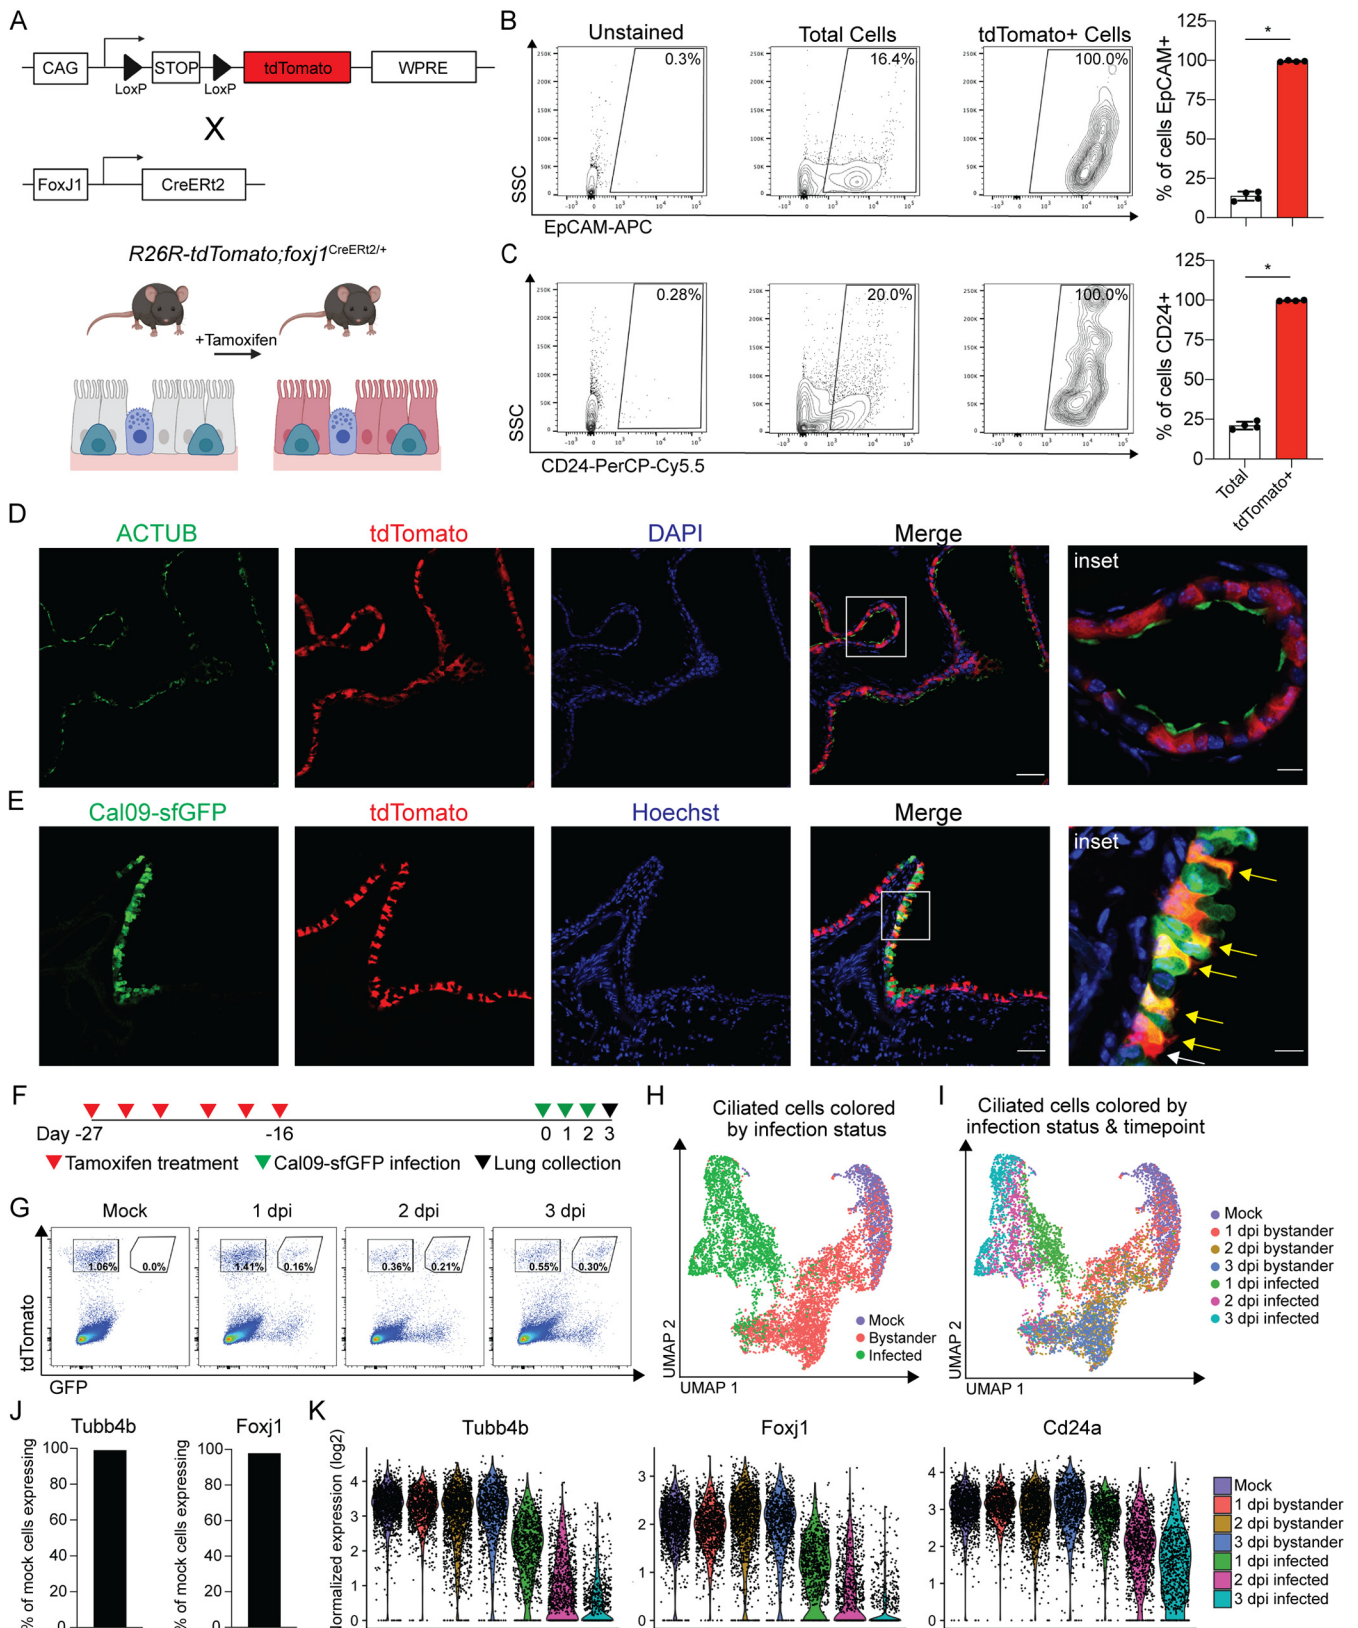

A transgenic model to genetically label epithelial ciliated cells for scRNA-seq. To understand heterogeneity in the ciliated cell response to IAV infection, we wanted to perform scRNA-seq on mock-infected, influenza virus-infected, and bystander ciliated cells. However, we and others have documented that ciliated cells lose expression of canonical markers during acute viral infection (35, 39–41), which could affect our ability to collect or analyze them during infection. Furthermore, progenitor cells could begin to differentiate into ciliated cells during infection experiments, and the intermediate gene expression profile could confound our capacity to define virally induced gene signatures. To circumvent these challenges, we employed an inducible lineage tracing strategy to fluorescently label ciliated cells prior to infection. We crossed mice that contained a Cre-responsive reporter cassette (tdTomato mice) to mice that expressed tamoxifen-inducible Cre recombinase under the promoter of the ciliated cell-specific transcription factor Foxj1 (*foxj1*$^{CreERt2/+}$ mice) (42). When tdTomato;*foxj1*$^{CreERt2/+}$ mice (further referred to as tdT;foxj1 mice) are treated with tamoxifen, Cre recombinase expressed in ciliated cells enters the nucleus and induces recombination, allowing for constitutive tdTomato expression (Fig. 2A). Importantly, in this system, cells are only labeled during the tamoxifen treatment window, and expression of tdTomato in labeled cells is permanent.

To validate that this model specifically labeled ciliated cells, we stained lung cells from tamoxifen-treated tdT;foxj1 mice for the ciliated cell markers EpCAM and CD24. We found nearly 100% of tdTomato$^+$ cells were positive for EpCAM or CD24 compared

to less than 25% of total lung cells (Fig. 2B and C). We then cross-sectioned lungs from tdT;foxj1 mice and found tdTomato⁺ cells to be positive for expression of acetylated tubulin, a component of cilia (Fig. 2D). Based on these data and the timing of tamoxifen treatment, we considered any cell with tdTomato expression to be a bona fide ciliated cell prior to infection. To verify our previous results of viral infection of ciliated cells in this model, we collected the lungs from tdT;foxj1 mice 1 day postinfection (dpi) with Cal09-sfGFP. Using confocal microscopy, we identified distinct populations of tdTomato⁺ GFP⁺ cells in infected mice (Fig. 2E).

To perform single-cell RNA sequencing of ciliated cells, we infected tamoxifen-treated tdT;foxj1 mice with Cal09-sfGFP or phosphate-buffered saline (PBS) as a mock control and then collected the lungs 1, 2, and 3 dpi for ciliated cell isolation using fluorescence-activated cell sorting (FACS) (Fig. 2F and G). We prepared the sorted cells for scRNA-seq using the 10× Genomics platform and then sequenced the resulting cDNA libraries. As a first test of the quality of our data, we explored the dimensionality of our data set with Uniform Manifold Approximation and Projection (UMAP) dimension reduction; as expected, cells grouped predominantly by their infection status (Fig. 2H). We also found that within bystander or infected cell groupings, cells from the same time point tended to group with each other (Fig. 2I). We next quantified expression of ciliated cell markers to confirm that we had collected ciliated cells and found that 98.98% and 97.88% of tdTomato⁺-sorted cells from uninfected animals had at least one transcript detected of *Tubb4b* and *Foxj1*, respectively (Fig. 2J). Consistent with previous work showing ciliated cells downregulate genes related to ciliogenesis or ciliated cell morphology during infection, expression of *Tubb4b* and *Foxj1* decreased over time in infected cells but was stable in bystander cells (Fig. 2K) (35, 39–41). Although expression of *Cd24a* decreased, it remained detectable in infected cells, which suggested CD24 can be used as a marker for ciliated cells throughout infection (Fig. 2K).

Identification of a subpopulation of ciliated cells with basal ISG expression. Next, we performed unbiased clustering on ciliated cells from uninfected animals (Fig. 3A) but restricted our analyses to mock cells containing at least one transcript of *Foxj1* to exclude any potentially missorted cells (Fig. 3B). These cells clustered into five discrete groups, although most uninfected ciliated cells displayed similar gene expression profiles with varied expression of genes related to negative regulation of the cell cycle and cytoskeletal and tight junction maintenance (e.g., *Ccnd2*, *Cdkn1c*, *Tmsb4x*, and *Cldn18*) (Fig. 3B and C). However, we observed a subpopulation of ciliated cells (cluster 5) which displayed high levels of the antiviral interferon-stimulated gene (ISG) *Ifitm1* (Fig. 3C and D). ISGs are a set of genes expressed by cells in response to interferon signaling and induce an antiviral state within the cell (43–45). More in-depth analysis revealed that additional ISGs were disproportionately expressed by this cluster of ciliated cells (e.g., *Bst2* and *Ifit1*), but in all ciliated cell clusters, we could identify cells with basal ISG expression (Fig. 3D). Thus, basal ISG expression can be detected in some

(B) UMAP dimensionality reduction plot showing clusters of mock ciliated cells containing at least one transcript of *Foxj1*. (C) Heat map of the top 10 most variably expressed genes by each mock ciliated cell cluster. Genes are ordered based on *P* value. The scale of the heat map shows the expression of a gene by each cell relative to the mean expression by all cells in the sample. (D) Violin plots showing the normalized expression of each ISG by the cells in each cluster. The width of each violin represents the frequency of that expression level. (E) Normalized expression of the ISGs *Bst2* and *Ifit1* plotted against normalized expression of *Isg15* in mock cells containing at least one transcript of *Isg15*. Pearson's correlation coefficient, ρ, was used to measure the linear correlation of expression. (F) Schematic of experiments used to evaluate basal ISG expression in ciliated cells in panels G to L. (G) Representative flow cytometry of ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$) isolated from mock-infected mice stained for BST2/tetherin. The BST2 gate was set using fluorescence minus one (FMO) control as shown on the left side of the panel. (H and I) qRT-PCR of mRNA isolated from FACS-sorted BST2$^+$ or BST2$^-$ ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$) was used to quantify transcripts for ciliated cell marker genes (*EpCam, Tuba1a*) (H) and ISGs (*Bst2, Isg15, Ifitm3,* and *Ifit1*) (I). Gene expression was quantified based on a standard curve and normalized to endogenous 18s expression. Means with SDs are shown. *n* = four independent mice; Mann-Whitney U test. AU, arbitrary units. (J) Quantification of flow cytometry. Ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$) were isolated from untreated IFNAR1$^{-/-}$ IFNGR1$^{-/-}$ or tdTomato mice and stained for BST2. Means with SDs are shown; *n* = 5 mice per group; Mann-Whitney U rest. (K) Quantification of flow cytometry. Ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$) were isolated from mock-infected or Cal09-sfGFP-infected (1.4e5 PFU) mice 7 hpi and stained for BST2. Means with SDs are shown; *n* = at least 6 mice per group from two independent experiments; Mann-Whitney U test. (L) Quantification of flow cytometry. GFP expression by BST2$^+$ or BST2$^-$ ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$) isolated from mice 7 hpi with Cal09-sfGFP (1.4e5 PFU) was measured. Means with SDs are shown. *n* = 7 mice from two independent experiments; Mann-Whitney U test. For all panels, ns, not significant, and *, *P* ≤ 0.05.

uninfected ciliated cells; however, the magnitude of expression of these genes is insufficient to drive clustering, at least under our analysis parameters.

In order to understand if the ISG expression in these cells was stochastic or if they have a more broadly active antiviral state, we performed a correlation analysis of cells

expressing either *Bst2* or *Ifit1* and another ISG, *Isg15*. A strong correlation between the ISG transcripts (Fig. 3E) is consistent with the idea that these ciliated cells are likely to have upregulated a canonical antiviral response. To experimentally validate the existence of this subpopulation of cells, we collected ciliated cells from mock-infected mice to analyze ISG expression (Fig. 3F). By performing flow cytometry for the surface-expressed ISG BST2-tetherin, we identified a small population (~3 to 6%) of ciliated cells with BST2 expression (Fig. 3G). This proportion was consistent with the percentage of mock ciliated cells with >1 transcript for *Bst2* (6.5%) in our single-cell data set. To verify that this preinfection BST2+ subpopulation also expressed the other ISGs, we isolated BST2+ and BST2− ciliated cells from mock-infected mice for reverse transcription-quantitative PCR (qRT-PCR) analysis of key transcripts. While ciliated cell markers were unchanged between the two populations (Fig. 3H), the levels of the other ISGs tested were higher in BST2+ cells (Fig. 3I).

This population of ISG-expressing cells could be explained by a low level of authentic IFN signaling in the epithelium, likely produced by lung-resident immune cells (46). To test this hypothesis, we collected epithelial cells from untreated animals deficient in the type I and type II interferon receptors, the two classes of interferon predominantly produced by immune cells (47–53). We observed a significant decrease in basal ciliated cell BST2 expression in INFAR1−/− IFNGR1−/− mice relative to tdTomato mice, suggesting that these interferons drive most of this phenotype (Fig. 3J). Finally, we wanted to understand how these basally innate immune-activated cells could affect viral infection. We hypothesized that they could either be resistant to infection (and contribute to "bystander" cell phenotypes) or they could be infected by IAV and potentially contribute to heterogeneity in the infected cell responses. We therefore infected animals with Cal09-sfGFP, and at a time point before BST2 expression was significantly induced (Fig. 3K), we looked for GFP signal in the BST2+ cells. Relative to the BST2− ciliated cells, we were unable to observe a decrease in infection (Fig. 3L). Because we cannot formally rule out that some of the detected GFP+ BST2+ cells may have resulted from rapid antiviral protein expression after infection, we can only interpret these data to indicate that basal ISG expression in ciliated cells is likely insufficient to make these cells completely refractory to infection. Further, any gene expression changes resulting from the basal transcriptional profiles of these cells likely manifest phenotypically in the infected cell population.

Bystander ciliated cells robustly, and mostly uniformly, respond to interferon signaling. Next, we wanted to understand the potential spread of gene expression in the uninfected bystander ciliated cell population from our broader experiment (Fig. 4A). We performed unbiased clustering of GFP− cells harboring less than 10 viral transcripts at all three infection time points to focus on truly uninfected cells. This strategy yielded 6 individual clusters (Fig. 4B), and further analysis revealed that clusters 1 to 3 were largely composed of ciliated cells from 2 and 3 dpi, while clusters 4 to 6 were mostly made of cells from 1 dpi (Fig. 4C). This suggested that gene expression differences across bystander cells were likely primarily driven by the inflammatory state of the lung rather than basal heterogeneity in the ciliated cell population. Consistent with this idea, a heat map of the top 10 most variably expressed genes in each cluster showed that clusters 4 to 6 were dominated by expression of genes found in mock cells (e.g., *Cdkn1c*, *Cldn18*, *Calml3*, and *Esm1*), while clusters 1 to 3 are marked by expression of genes related to stress response (*Xbp1*, *Nupr1*) and interferon signaling (*Socs3*, *Ifitm1*, and *Ccl20*) (Fig. 4D and E).

We were surprised to see, however, how few of the "classic" ISGs appeared in the heat map, as these cells were presumably in a highly inflammatory environment. Specific interrogation of ISGs revealed widespread expression, as nearly all bystander cells at 2 and 3 dpi expressed ISGs, including *Ifitm3*, *Isg15*, *Bst2*, and *Ifit3* (Fig. 4F). This broad expression pattern explained why they did not appear in the list of differentially expressed genes (Fig. 4D). To experimentally validate what our analysis predicted would essentially be the ubiquity of ISG expression in bystander cells, we stained lung sections from mock-infected and Cal09sfGFP-infected mice for ISG15 and found robust
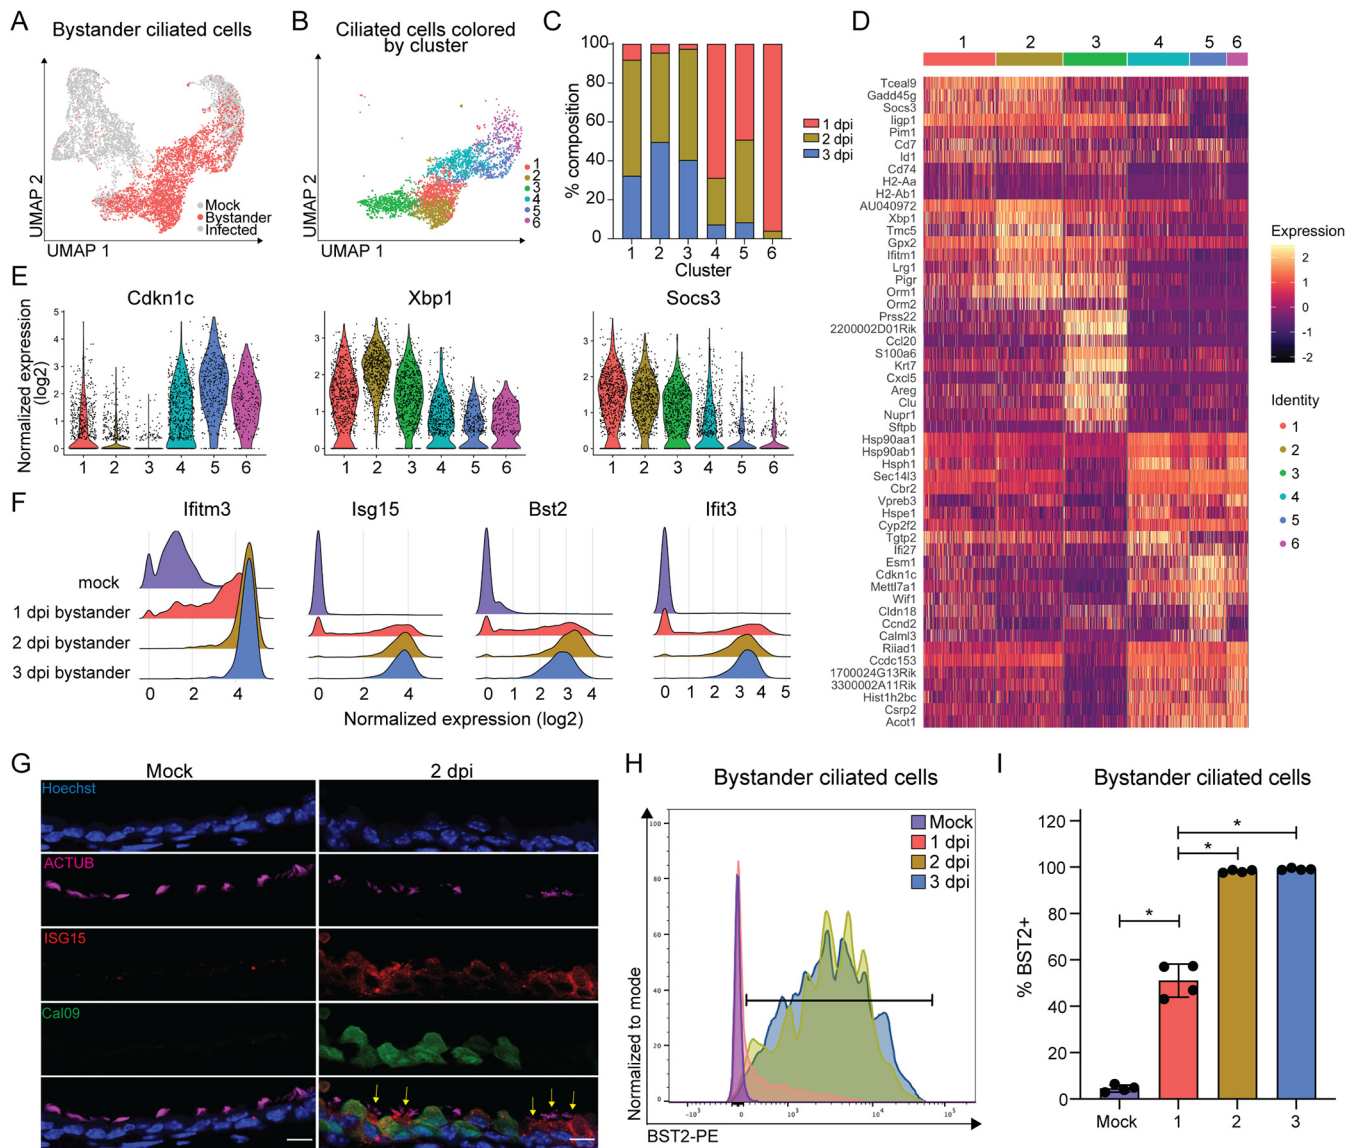

FIG 4 Uninfected bystander ciliated cells respond homogenously to pulmonary inflammation during IAV infection. (A) UMAP dimensionality reduction plot showing bystander cells. (B) UMAP dimensionality reduction plot showing unbiased clustering of bystander GFP− ciliated cells. GFP− ciliated cells were considered bystander cells if they had less than 10 viral transcripts. (C) Stacked bar graph plotting the percentage of each cluster that belongs to each time point. (D) Heat map of the top 10 most variably expressed genes by each cluster of bystander GFP− ciliated cells. Genes are ordered based on P value. The scale of the heat map shows the expression of a gene by each cell relative to the mean expression by all cells in the sample. (E) Violin plot showing the normalized expression of *Cdkn1c* (negative regulation of cell cycle), *Xbp1* (stress response), and *Socs3* (interferon signaling). The width of each violin represents the frequency of that expression level. (F) Ridge plots depicting normalized expression of ISGs, grouped by sample. Ridge height indicates the frequency of expression level. (G) Microscopy of cross-sectioned lung epithelial cells from mock- or Cal09-sfGFP-infected mice (2 dpi) stained for ACTUB and ISG15. Scale bar, 10 μm. Yellow arrows indicate ISG15+ bystander ciliated cells. Image representative of sections from three mice from two independent experiments. (H) Flow cytometry of bystander ciliated cells (CD45− CD31− CD24+ GFP−) stained for BST2. Ciliated cells were isolated from the lungs of mock-infected or Cal09-sfGFP-infected mice at the indicated times postinfection. Gate for BST2 was set using FMO control. (I) Quantification of flow cytometry in panel H. Means with SDs are shown; n = 4 mice per group; Mann-Whitney U test. For all panels, ns, not significant, and *, $P \leq 0.05$.

expression in bystander (GFP−) ciliated cells, even more so than in infected (GFP+) cells (Fig. 4G). For a more quantitative approach, we used flow cytometry to measure BST2 expression in bystander (GFP−) ciliated cells and found over 97% were BST2+ at both 2 and 3 dpi (Fig. 4H and I). Thus, despite some minor differences in the response profiles of bystander ciliated cells during infection, the innate antiviral response is mostly homogenous and consistent with the idea that basal gene expression differences in ciliated cells had little to no effect on their responses.

Viral burden in infected ciliated cells increases throughout infection. We next turned our attention to the influenza virus-infected ciliated cells collected during our
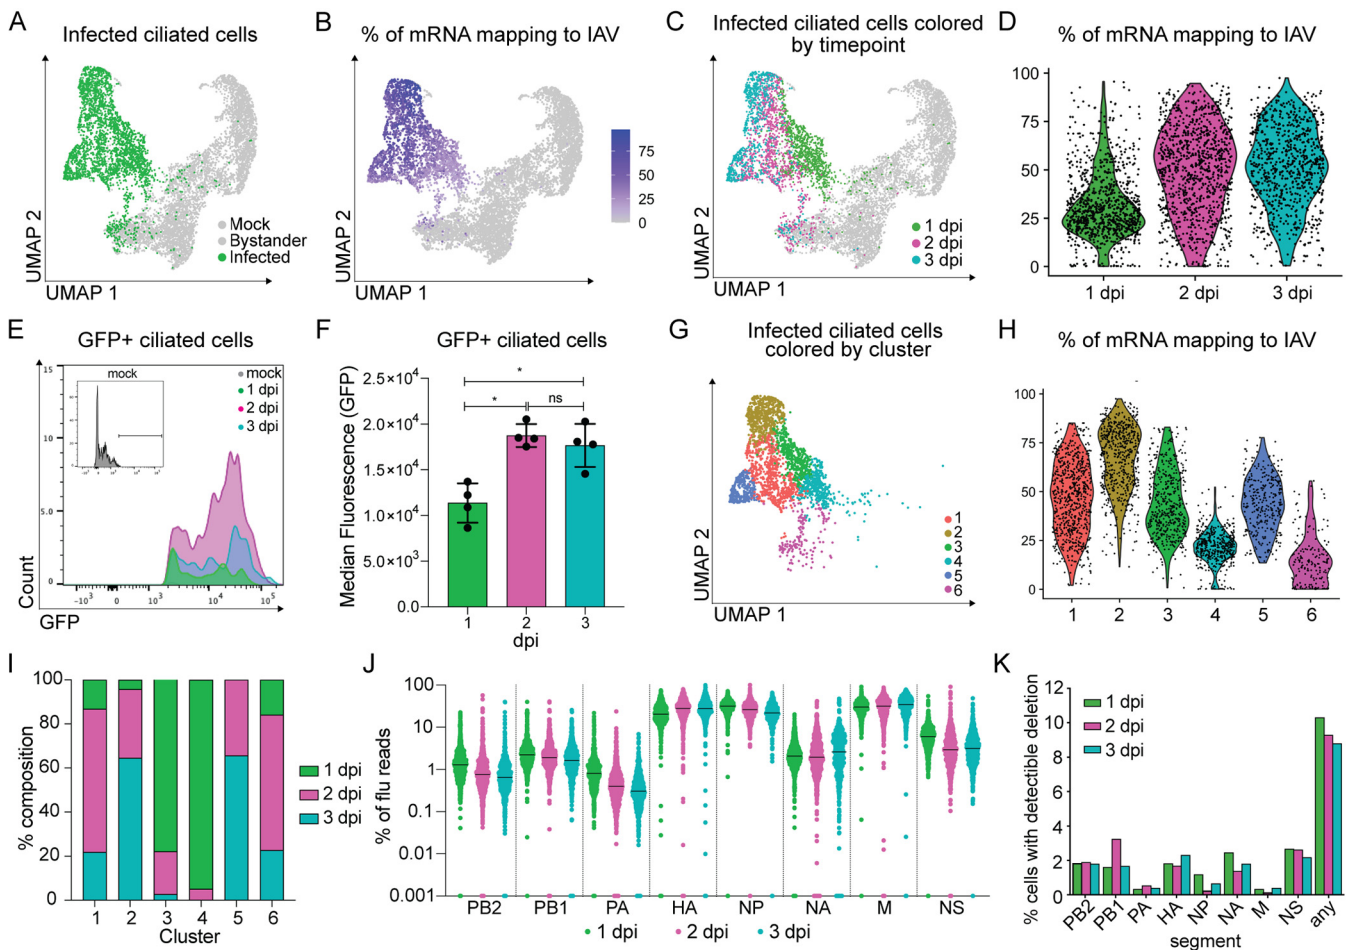

FIG 5 Viral replication characteristics across ciliated cells during the first 3 days of infection. (A) UMAP dimensionality reduction plot depicting infected ciliated cells. (B) UMAP dimensionality reduction plot of total ciliated cells shaded based on the fraction of total mRNA transcripts that are viral. (D) Violin plot showing the fraction of total mRNA transcripts that are viral for each GFP$^+$ cell grouped by sample. Violin width indicates the frequency of the percentage level. (E) Representative flow cytometry histogram of GFP$^+$ ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$). Ciliated cells were isolated from mock-infected or Cal09-sfGFP-infected mice at the indicated times postinfection. (F) Quantification of the median fluorescence (GFP) of GFP$^+$ ciliated cells in panel E. Means with SDs are shown; $n = 4$ mice per time point; Mann-Whitney U test. (G) UMAP dimensionality reduction plot depicting clusters of infected cells (GFP$^+$, ≥10 viral transcripts), which are colored by cluster identity. (H) Violin plot showing the fraction of total mRNA transcripts that are viral for each GFP$^+$ cell grouped by cluster identity. Violin width indicates the frequency of the percentage level. (I) Quantification of the fraction of cells from each time point that make up each cluster. Cells were clustered based on host and viral gene expression. (J) Plot showing the fraction of total viral transcripts belonging to each influenza segment in infected GFP$^+$ cells, grouped by time point. GFP$^+$ cells were classified as infected based on the presence of 10 or more viral transcripts. If a fraction for a gene was 0, it was set to 0.001 for inclusion in the plot. (K) Bar graph depicting the percentage of infected cells (GFP$^+$, ≥10 viral transcripts) with detectable deletions (>15 reads, >75 nt deletion, final product > 150 nt) in each flu segment or any segment.

time course experiment (Fig. 5A). It has been reported that lung epithelial cells, both *in vitro* and *in vivo*, can have a high viral burden during IAV infection (6, 9, 15). In agreement with previous studies, we found viral mRNAs comprised from less than 1 to over 90% of the total cell transcriptome (Fig. 5B). Interestingly, we could observe a "gradient" of viral gene expression across our population of infected cells (Fig. 5B); labeling infected cells by time point revealed that viral RNA levels were generally associated with the infection time point (Fig. 5C and D). We experimentally validated this phenomenon by infecting mice with Cal09-sfGFP and measuring fluorescence of infected cells at different time points. Consistent with the scRNA-seq, we saw a larger amount of virally expressed reporter protein per cell at days 2 to 3 compared to day 1 (Fig. 5E and F).

We next performed unbiased clustering on the infected cells (Fig. 5G). This analysis revealed that, in contrast to the bystander cells, clusters did not appear to predominately group by infection time points. We found viral burden between clusters of infected cells

varied and that clusters spanned multiple time points (Fig. 5H and I). Additionally, the relative expression of viral genes was similar to those seen in influenza virus-infected A549 cells (M > NP ~ HA > NS > NA > PB1 ~ PB2 ~ PA), apart from NS, which may be due to our genetic manipulations in this segment (Fig. 5J) (6, 7).

Next, we performed an analysis for deletions within the IAV genomic segments. While the scRNA-seq methodology we employed sequenced the 3′ end of viral transcripts and thus poorly sampled total viral genetic diversity, some variants were nevertheless captured. One form of variation that can still be partially assessed in our analysis is the presence of large internal deletions in any given segment, a hallmark of defective influenza A virus populations and whose presence can be associated with altered infection outcome (54, 55). Setting an empirical threshold of deletion abundance and size based on rarefaction curves, we found deletions throughout all eight viral segments (Fig. 5K; see Table S1 in the supplemental material), although the majority of infections did not meet our thresholds for positive identification of large deletions.

Rare production of interferons by infected ciliated cells at later time points. Finally, we turned our attention to understanding the variability in the cell response to IAV infection. We performed unbiased clustering on the GFP$^+$ populations of cells with 10 or more viral transcripts across all three time points. For this analysis, we generated a new gene expression matrix in which viral genes were removed to ensure viral RNA levels would not confound our analysis of the host response. However, this strategy revealed clusters (Fig. 6A) that were highly similar to those generated by the matrix, including both host and viral genes (Fig. 5G).

Analysis of the top 10 most variably expressed genes by cluster revealed a number of cellular responses after viral infection, including one subpopulation (cluster 1) which expressed multiple chemokines (*Cxcl1*, *Cxcl2*, and *Cxcl5*) and another (cluster 6) which expressed genes involved in epithelial cell integrity (*Lgals3bp*, *Krt7*, and *Krt8*) (Fig. 6B). However, one subpopulation of ciliated cells (cluster 5) displayed high expression of both type I and type III IFN in addition to other inflammatory cytokines such as *Il6* and *Ccl5* (Fig. 6B and C). Further analysis of gene expression in this cluster revealed a correlation between type I and type III IFN expression (Spearman's correlation coefficient (r_s) = 0.405, $P < 0.0001$), which had been previously reported during IAV infection *in vitro* but not *in vivo* (Fig. 6D) (2). Interestingly, cluster 5 was comprised of cells from 2 and 3 dpi, but not 1 dpi (Fig. 6E). Thus, a time-dependent subpopulation of infected ciliated cells has the potential to not only respond to, but also contribute to, the inflammatory cytokines in the infected lung.

We next asked what could be driving the expression of cytokines in this IFN$^+$ subpopulation. We found average expression levels of viral genes in the IFN$^+$ cluster, which suggested IFN expression was not due to high or low viral burden (Fig. 6F). We therefore compared the average expression of each segment in this cluster to total infected cells, as the IAV protein NS1 is a known interferon antagonist, and the absence of NS in single cells has been shown to be associated with interferon expression (2, 7). We found a slight decrease in NS expression along with PA and NA (Fig. 6G) and measured a statistically significant negative correlation between NS and *Ifnb1* expression ($r_s = -0.268$, $P < 0.0001$) (Fig. 6H). However, the IFN$^+$ cells were not predominantly derived from NS-negative viral particles, as we did detect NS expression in nearly every *Ifnb1*$^+$ cell. This population of NS-negative cells may, in fact, exist but would be missed in our experimental system, as our fluorescent infection reporter was encoded in this segment. Finally, we explored whether *Ifnb1*$^+$ cells contained viral genes with internal deletions, as infection with defective viruses can induce IFN (15, 56–59). While we cannot definitively claim any given infection did not contain a segment with an internal deletion, in those infections in which we identified such variants, we did not see any enrichment for *Ifnb1* expression (Fig. 6I). Taken together, these results suggest that interferon expression by infected ciliated cells cannot be entirely explained by differences in viral gene expression and is likely dictated at least in part by the specific transcriptional state of the infected cell.
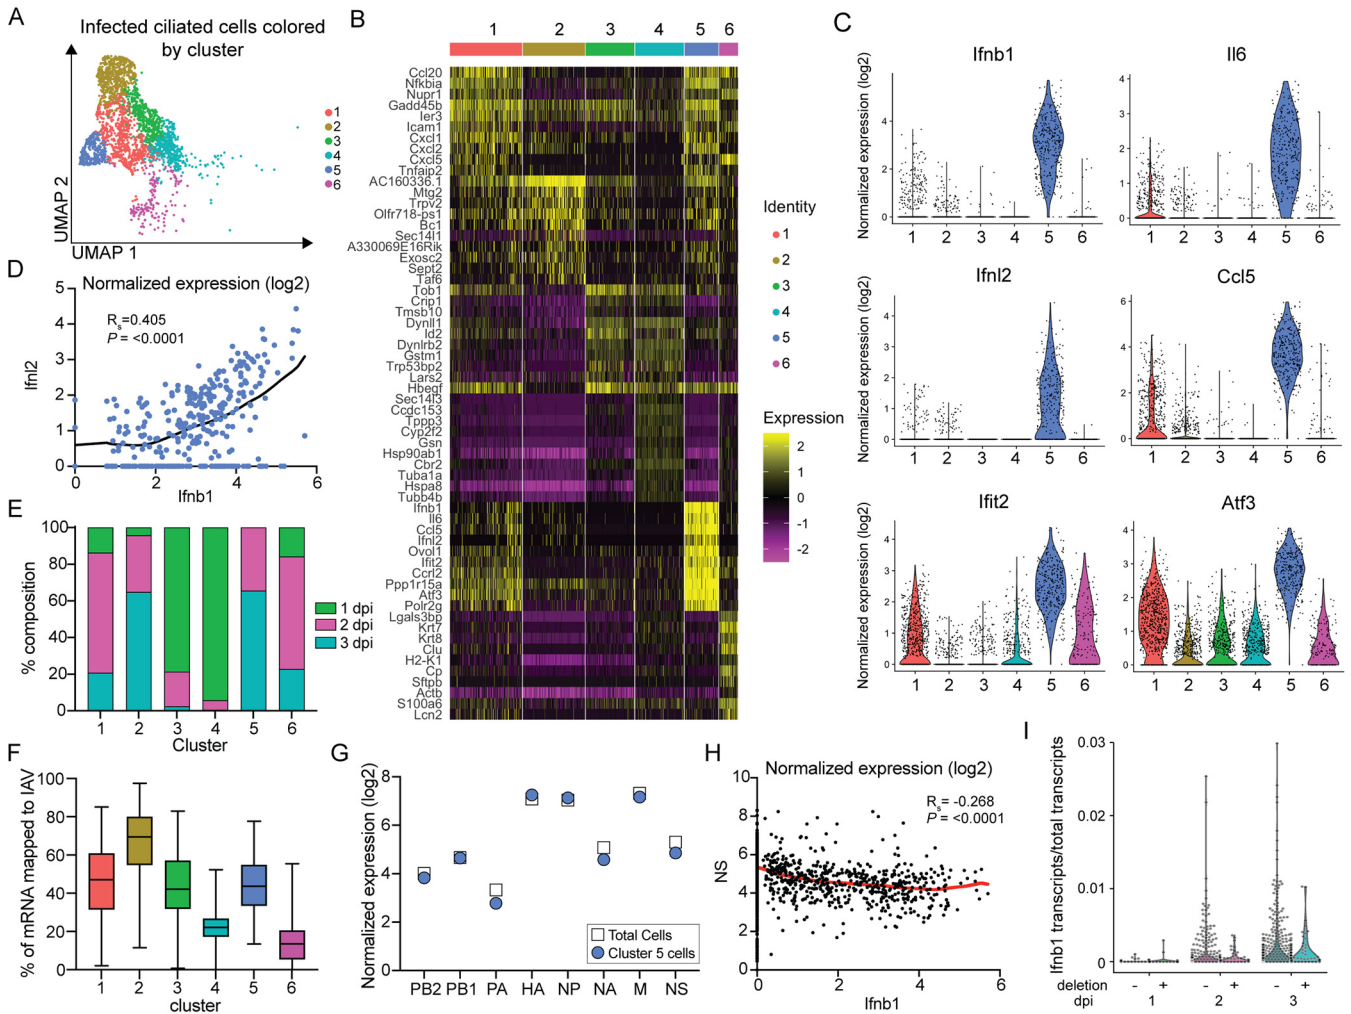

FIG 6 Inflammatory antiviral responses are restricted to a subpopulation of infected ciliated cells during infection. (A) UMAP dimensionality reduction plot showing unbiased clustering of infected GFP$^+$ cells. GFP$^+$ cells were classified as infected based on the presence of 10 or more viral transcripts. Clustering was based on the expression of host genes only. (B) Heat map of the top 10 most variably expressed genes by each cluster of infected GFP$^+$ ciliated cells. Cells are clustered based on host gene expression only. Genes are ordered based on P value. The scale of the heat map shows the expression of a gene by each cell relative to the mean expression by all cells in the sample. (C) Violin plots of normalized expression for 6 of the top 10 most variably expressed genes in cluster 5. Violin width indicates the frequency of the expression level. (D) Plot of the normalized expression (log$_2$) of *Ifnb1* versus *Ifnl2* by cells in cluster 5. A locally weighted scatterplot smoothing (LOWESS) curve was fitted to visualize the relationship of expression. Spearman's rank order correlation, $P < 0.0001$; we reject the null hypothesis that there is no correlation between *Ifnb1* and *Ifnl2* expression. (E) Stacked bar graph showing the percentage of each cluster in panel A that belongs to each of the three GFP$^+$ time points. (F) Box-and-whisker plot showing the fraction of total mRNA transcripts that are virally grouped by cluster. Clustering was based on the expression of host genes only. Box extends from 25th to 75th percentiles with a line representing the median value for each cluster. Whiskers extend to the minimum and maximum value. (G) Plot of average normalized expression of each viral gene for total infected GFP$^+$ cells and cluster 5 cells. (H) Plot of the normalized expression of *Ifnb1* versus NS for total infected GFP$^+$ cells. A LOWESS curve was fitted to visualize the relationship of expression. Spearman's rank order correlation, $P < 0.0001$; we reject the null hypothesis that there is no correlation between *Ifnb1* and NS expression. (I) Distribution of *Ifnb1* transcripts normalized to total cellular transcripts in GFP$^+$ infections in which deletions were ($+$) and were not ($-$) detected according to our thresholds. For all panels: ns, not significant, and *, $P \leq 0.05$.

DISCUSSION

In this study, we sought to understand variability in the host response to IAV infection. To do so, we used a fluorescent H1N1 virus, a transgenic mouse model, and scRNA-seq to explore the heterogeneity of gene expression in response to influenza virus infection in a single, highly susceptible epithelial cell population. Our analyses support several findings from prior single-cell studies focused on IAV infection but provide further insights into the dynamic interplay between virus and host *in vivo*. Our data set revealed that a small population of ciliated cells expressed ISGs before infection, which we were able to validate using qRT-PCR and flow cytometry. During acute infection, we found a small population of ciliated cells not only produce the majority of cytokines

but also multiple cytokines at once. Finally, we found that ciliated cells are highly responsive to interferon signaling, as nearly all bystander ciliated cells had induced expression of ISGs by 2 dpi.

Despite our in-depth analysis of the ciliated cell-specific response to IAV infection, there remain several outstanding questions. For example, in the infected (GFP$^+$) ciliated cell samples, we identified a subpopulation of ciliated cells with high expression of inflammatory cytokines, including type I and III IFN, *Il6*, and *Ccl5* (Fig. 6B and C). These data support the concept that epithelial cells *in vivo* may be relevant producers of cytokines during IAV infection (60–63). We do not know, however, whether cytokine expression was a stable characteristic of this population of cells or if at any given time, infected cells have the potential to transiently upregulate these genes. Additionally, the mechanism of the observed increased viral "burden" in infected cells over time remains unclear (Fig. 5D to F). We favor a model in which the initiation of lytic cell death is delayed *in vivo* relative to cell culture after infection, allowing for more complex patterns of viral protein accumulation. Future studies will be required to determine if the "rates" of virally induced cell death are different across different experimental systems, however, or if a completely different mechanism may explain this observation.

We also identified a subpopulation of ciliated cells with basal ISG expression prior to infection (Fig. 3G to I), but the biological significance of this population currently remains unknown. Despite the upregulation of *Ifitm3* and *Ifitm1*, genes encoding proteins known to prevent viral entry (64–66), we were unable to detect a block in the infection of these cells (Fig. 3L). We therefore hypothesize that this subpopulation of cells is primed to become the cells that produce interferon and other inflammatory mediators after infection. Along these lines, an independent study recently showed that epithelial cells in the upper respiratory tract of uninfected children expressed higher basal levels of viral-sensing and antiviral genes than adults (67). The authors hypothesized this may be linked to basal expression of type II IFN in the airways and could explain why children have reduced replication and increased clearance of SARS-CoV-2 relative to adults. Further investigation will be required, however, to understand if there is truly any functional link between basal gene expression signatures in epithelial cells and phenotypically differential responses to infection.

We also made some experimental analysis choices that may be important for interpretation of our data. First, we captured contaminating lymphocytes and cells which concurrently expressed both ciliated cells and other epithelial cell markers in our single-cell samples. This is not uncommon, as cells with expression of markers for multiple epithelial cell types have been described in single-cell data sets (12, 24, 68). We excluded cells with high expression of secretory cell marker *Scgba3a* and alveolar type I/II cell markers *Pdpn* and *Ager*, which could have led us to exclude rare, but real, populations of ciliated cells. Along similar lines, in our infected cell analysis, we defined infected cells as those that were GFP$^+$ and contained 10 or more transcripts of viral genes. This likely resulted in some truly infected cells being thrown out, possibly due to errors in sorting or failure to express GFP.

Additionally, we did not perform full virus genotyping in our infected cells. Although we identified *Ifnb1*$^+$ cells that lacked observable viral gene deletions (Fig. 6I), it is possible there were deletions or mutations in NS in cells with high *Ifnb1* expression that we were unable to detect. Further, the distribution of deletions across viral segments did not match their anticipated abundance from prior studies, predominantly in the three polymerase segments. However, we rarely observed the same deletion between time points, suggesting these may be generated *de novo* over the course of these infections, absent, or at least rare in our initial inoculum. Recent work suggests *de novo* deletion frequencies may be more evenly distributed across the eight segments (69), whereupon selection thereafter leads to their observed distribution (59).

In conclusion, our study provides an in-depth characterization of the ciliated cell response to IAV infection and highlights the power of scRNA-seq to identify small but discrete subpopulations of cells. We also propose that our data are consistent with the

idea that the cell state prior to infection may influence how a cell ultimately responds to infection. Further, we demonstrate the range of gene expression changes that can occur in "bystander" cell populations. These data represent a step toward unraveling the complexities during the establishment of viral replication beginning in a small number of cells after a transmission event. Future studies have the potential to link these types of changes to outcomes of infection and may ultimately allow for a better understanding or prediction of individuals who will have mild or severe influenza disease.

MATERIALS AND METHODS

Cell culture. MDCK cells (ATCC) were grown at 37°C and in 5% CO_2 and maintained in minimal essential medium (MEM) supplemented with 5% fetal bovine serum (FBS), GlutaMAX, HEPES, sodium bicarbonate, and penicillin-streptomycin.

Viruses. Cal09-sfGFP (70) was generated by inserting the gene that encodes sfGFP into segment 8 using the same strategy previously used to encode Cre recombinase in A/Puerto Rico/8/1934 (26). The sequence for each segment matches A/California/04/2009 GenBank accession numbers FJ966079 to FJ966086 with the following nucleotide substitutions noted: PB2, C1170T; PA, G1953A; HA, G6A, G368T, A640G, A716G; NP, T9C, C865T.

Growth curve. Wild-type Cal09 or Cal09-sfGFP virus (1,000 PFU) was injected into 10-day-old embryonated chicken eggs and then incubated until the indicated time points at 37°C to allow for viral replication. Allantoic fluid was collected, serially diluted, and then plaqued on MDCK cells. Plaques were stained using sera from Cal09-infected mice and sheep anti-mouse IgG peroxidase-linked whole antibody (Cytiva; catalog no. NXA931V) and then visualized with KPL TrueBlue peroxidase substrate (SeraCare; catalog no. 5510-0030).

Time course of single-cycle infection in MDCK cells. Confluent MDCK cells were mock infected or infected with Cal09-sfGFP with a multiplicity of infection (MOI) of 0.5 for 1 h at 37°C. Virus was removed, and maintenance medium was added to cells. Cells were collected at the indicated time points and fixed with 2% paraformaldehyde (PFA) before being analyzed.

Mouse lines and tamoxifen treatment. Wild-type C57BL/6, B6.Cg-Gt(ROSA)26Sortm14(CAGtdTomato) Hze/J (tdTomato), and B6.Cg-Ifngr1tm1Agt Ifnar1tm1.2Ees/J (IFNAR1$^{-/-}$ IFNGR1$^{-/-}$) mice were purchased from The Jackson Laboratory. *Foxj1*$^{CreERt2/+}$ mice were developed by Chay T. Kuo (42). tdT; foxj1$^{CreERt2/+}$ litters were genotyped using the following primers: F, TGGCTTGCAGGTACAGGAGG, and R, CCTCATTGTGGCCAACAAACCC. To induce reporter expression, tdT;foxj1 mice were treated with 2 mg of tamoxifen (Sigma-Aldrich; catalog no. T5648-1G) resuspended in corn oil via oral gavage 5 to 6 times over a 2-week period.

Mouse infections. For all infections, mice were anesthetized with 100 μL of ketamine-xylazine and infected intranasally with 40 μL of virus (2.8e4 PFU Cal09-sfGFP for all experiments except Fig. 3K and L (1.4e5 PFU)) diluted in pharmaceutical-grade PBS. The humane endpoint was reaching 80% of starting body weight. Body weight was monitored once daily for 14 dpi or until collection time point. All experiments used a minimum of 3 mice per condition. Male and female mice were used and randomly assigned to experimental and control groups. All experiments were conducted in accordance with Duke IACUC.

Flow cytometry. To isolate murine lung cells for flow cytometry analysis, lungs were perfused with 7 mL PBS, inflated with 0.75 mL Dispase (Corning, catalog no. 354235, or Sigma, catalog no. 4942078001) and 0.75 mL 1% low-melt NuSieve GTG agarose (Lonza; catalog no. 50081) dissolved in water, and covered with an ice pack for 30 s. The lungs were removed and then incubated in 1 mL Dispase for at least 45 min at room temperature before being minced by razor blade in 7 mL Dulbecco's modified Eagle medium (DMEM) with DNase I (Sigma-Aldrich; catalog no. D4527-200KU). For tracheal cell isolation only (Fig. 1I to K), the trachea was removed and incubated in 400 μL of Dispase for at least 45 min before continuing the same protocol. The cells were further homogenized by vigorous pipetting and filtered using a 70-μm cell strainer (Olympus; catalog no. 25-376). Red blood cells were lysed by incubating cells in 1$\times$ Pharm Lyse buffer (BD Biosciences; catalog no. 555899) for 10 min at room temperature. The remaining cells were neutralized in PBS with 2% bovine serum albumin (BSA) (Lampire; catalog no. 7500855) before antibody staining. The following primary antibodies were used: CD45 (BioLegend; clone 30-F11; 1:200), CD31 (BioLegend; clone 390; 1:200), CD326/EpCAM (BD Biosciences; clone G8.8; 1:100), CD24 (BD Biosciences; clone M1/69; 1:200), CD317/BST2 (BioLegend; clone 129C1; 1:100), CD15/SSEA1 (BioLegend; clone MC-480; 1:50), and isolectin B4 (Enzo; catalog no. ALX-650-001B-MC05; 1:1,000). Cells were incubated with primary antibodies for 1 h at 4°C in the dark. For collection of live BST2$^-$ or BST2$^+$ cells, cells were incubated with Live/Dead stain (Thermo Fisher Scientific; catalog no. L34964) prior to primary antibody staining. Cells were analyzed using the FACSCanto II or LSRFortessa X-20 using standard laser and filter combinations. Gates were set using fluorescence minus one (FMO) or unstained controls. Data were analyzed using FlowJo software. If cells were not run the same day as isolation, cells were fixed with 2% PFA after antibody staining and kept at 4°C in the dark for up to 48 h.

Microscopy. Lungs were inflated with 1.5 mL of 1:1 Tissue-Tek OCT (VWR; catalog no. 25608-930) and 8% PFA before the trachea was tied off with suture string. The lungs were fixed overnight at 4°C in 4% PFA before incubation in 30% sucrose in PBS at 4°C for at least 24 h. The lungs were then embedded in OCT and cryosectioned (8-μm sections). Sections were thawed and allowed to dry for 2 h at room temperature before blocking with 3% BSA in PBST (PBS with 0.1% Triton X-100) and 5% normal goat serum (Thermo Fisher Scientific; catalog no. 31872) for 1 h at room temperature. The sections were then

stained with primary antibodies overnight at 4°C and secondary antibodies at room temperature for 2 h (1:1,000). Primary antibodies used include ACTUB (Abcam, clone EPR16772, catalog no. ab179484, 1:1,000, or Sigma-Aldrich, clone 6-11B-1, catalog no. T7451, 1:1,000) and ISG15 (Invitrogen; clone 1H9L21; catalog no. 703132; 1:100). Following incubation with Hoechst 33342 (1:10,000) for 5 min at room temperature and 2 PBST washes, the sections were mounted in Prolong Diamond antifade mountant (Invitrogen; catalog no. P36965). If Hoechst 33342 was not used (Fig. 2D), nuclei were stained using Prolong Diamond antifade mountant with DAPI (4′,6-diamidino-2-phenylindole; Invitrogen; catalog no. P36962). Imaging was performed using a Zeiss 780 upright confocal microscope with consistent settings, and raw images were processed using Fiji software (NIH).

Isolation of ciliated cells for scRNA-seq. Tamoxifen-treated tdT;foxj1 mice were infected with Cal09-sfGFP or mock infected with PBS, and the lungs were collected 1, 2, and 3 dpi (2 mice per condition). Single-cell suspensions were generated as described above, and cells from mice of the same condition were pooled. Single tdTomato$^+$, tdTomato$^+$ GFP$^-$, and tdTomato$^+$ GFP$^+$ cells were isolated using a BD FACSDiVa. The cell suspensions were then counted using a Nexcelom Cellometer K2. The cells were diluted to capture 3,000 cells per sample and loaded into a 10× Genomics Chromium Next GEM chip. cDNA libraries were generated from the GEMs according to the manufacturer's instructions (Chromium Next GEM single-cell 3′ library kit v3.1) and run on an Agilent 4200 tape station for quality control. Libraries were quantified using Qubit high-sensitivity DNA assay (Thermo Fisher; catalog no. Q32854) and then sequenced on an Illumina NovaSeq. The Illumina base call files (BCLs) were demultiplexed into FASTQs, which were then aligned to a custom-concatenated mm10 and Cal09 genome reference file and counted using 10× Genomics CellRanger pipeline (version 3.1.0).

Single-cell data analysis. (i) Data QC. The raw and filtered output files from the CellRanger pipeline were read into SoupX (71) (v1.5.2) to filter reads from lysed cells using the command Load10x. Contaminating reads from lysed cells were estimated using the command autoEstCounts, and the adjusted count table (whole integers) was generated using adjustCounts. The output was then used to make a Seurat (v4.0.4) object using CreateSeuratObject. The count matrices for the 7 samples were merged, and initial QC was performed. Cells that contained fewer than 500 or more than 6,000 genes were excluded in addition to cells whose mitochondrial genes made up more than 20% of the total transcriptome. Cells with fewer than 1,500 or more than 80,000 unique molecular identifiers (UMIs) were also removed.

Following an initial round of unbiased clustering using the standard Seurat workflow (72), clusters with high expression of lymphocyte markers (*Cd52*, *Ctla2a*, *Cd8a*, *Lyz2*, and *Ptprc/CD45*) were removed, along with cells with high expression of secretory cell marker *Scgb3a2* (>5 UMIs) and alveolar type I/II markers *Ager* (>5 UMIs) and *Pdpn* (>5 UMIs). We did not positively select cells based on expression of ciliated cell markers for bystander and infected cell analysis, as expression of these genes decreases dramatically during infection (35, 39). However, the remaining cells were considered ciliated based on >97.88% expression of ciliated cell markers *Foxj1* and *Tubb4b* in the mock population.

(ii) Mock sample analysis. The mock sample was subsetted to make a new Seurat object. The percentage of cells expressing *Tubb4b* and *Foxj1* was calculated using the function PrctCellExpringGene (Ryan-Zhu, Github). For clustering, we restricted our analyses to cells with at least 1 transcript of *Foxj1*.

(iii) Infected sample analysis. The three GFP-positive samples (1, 2, and 3 dpi) were subsetted to make a new Seurat object. To remove GFP$^+$ cells that were considered "uninfected," the raw UMI counts of each flu gene per cell were exported to an Excel sheet, and viral counts were summed. Cells with fewer than 10 total viral transcripts were considered uninfected and removed from the object. To cluster infected GFP$^+$ cells based on host gene expression, a new count matrix with viral genes removed was created. The GFP$^+$ object was then subjected to the standard Seurat workflow for unbiased clustering. The cluster ID for each cell was added to the meta data of the original object containing viral genes to explore the relationship between host and viral gene expression.

(iv) Bystander sample analysis. The three GFP$^-$ samples (1, 2, and 3 dpi) were subsetted to make a new Seurat object. To remove GFP$^-$ cells that were considered "infected," the raw UMI counts of each flu gene per cell were exported to an Excel sheet, and viral counts were summed. Cells with 10 or more total viral transcripts were considered infected and removed from the object. The GFP$^-$ object was then subjected to the standard Seurat workflow for unbiased clustering.

Deletion analysis. All gapped reads mapping to influenza A virus from cellranger-generated BAM files were extracted based on their CIGAR string and converted to FASTA. Critically, these gapped reads use splice scoring and are inappropriate for calling bona fide deletion junctions. Therefore, similar to previous work (59), we remapped these reads using BLASTn against an empirically verified Cal09-sfGFP genome using the following parameters: a percent identity of 90, a word size of 10, a gap open penalty of 5, extend penalty of 2, and an E value cutoff of 0.000001 (73). Files were then parsed to identify potential deletion junctions with the following rules: such reads must map completely with no "missing" bases and must map with the same polarity with no inversion, and repetitive elements, such as 2 nucleotides (nt) repeated at the 5′ and 3′ ends of the junction, which could, in theory, be assigned to either, were assigned to the 5′ end arbitrarily. Each junction-spanning read was compared to the original BAM file, and identical UMIs were collapsed to a single transcript supporting the presence of a junction and thereafter enumerated on a per-cell barcode basis. To set a threshold read support for deletion calling, a rarefaction analysis was performed looking at the fraction of deletions called that were lost as we increased the read depth required for support; a depth of 15 was chosen as the point at which the curve flattened. This presumably will help to reduce template-switching artifacts or lysis-derived deletions, although it will likely come at the cost of missing low-depth deletions and bias our data set toward deletion calling in high-burden infections. A similar rarefaction curve on deletion size revealed a large set of small deletions <75 nt, which comprised 20% of deletions present in our data set. We excluded these deletions as

potentially exhibiting divergent behavior from large internal deletions. Lastly, a small, <150-nt species was observed in the M segment, which may have been either a novel splice product or a template-switching artifact, which was excluded from further analysis, as its relative abundance across many barcodes and incredibly small size made its identity as a large internal deletion unlikely.

qRT-PCR. Live BST2+ and BST2$^-$ ciliated cells (CD45$^-$ CD31$^-$ CD24$^+$ or EpCAM$^+$ CD24$^+$) from tdTomato mice were sorted using the Sony SH800S cell sorter. At least 180 cells were collected for each sample per mouse. cDNA libraries were prepared for each sample using SMART-Seq v4 Ultra Low Input RNA kit for sequencing (TaKaRa Bio; catalog no. 634888). qPCR was performed using TaqMan Universal PCR master mix (Applied Biosystems; catalog no. 43-044-37) and the following TaqMan assays: EpCam (Mm00493214_m1), Tuba1a (Mm01300524_g1), Bst2 (Mm01340357_g1), Isg15 (Mm01705338_s1), Ifitm3 (Mm00847057_s1), and Ifit1 (Mm00515153_m1).

Data analysis. For all experiments, the statistical tests used are noted in the figure legends and were performed in GraphPad Prism (version 9.0.1). *In vitro* experiments were conducted 4 times with 3 technical replicates each. Egg or animal studies used a minimum of $n = 3$ for all groups and were conducted at least twice except for the scRNA-seq experiment ($n = 2$, conducted once).

Data availability. Raw and processed sequencing data are available to download from NCBI GEO via accession number GSE203018.
