Received 24 June 2022; revised 1 August 2022; accepted 9 August 2022; online publish-ahead-of-print 13 August 2022

Aims

Type 2 diabetes (T2DM) in patients with coronavirus disease-19 (COVID-19) is associated with a worse prognosis. We separately investigated the associations between the use of sodium-glucose cotransporter 2 inhibitors (SGLT2i), glucagon-like peptide-1 receptor agonists (GLP-1 RA), and dipeptidyl peptidase-4 inhibitors (DPP-4i), and the risk of COVID-19 hospitalization and death.

Methods and results

Patients with T2DM registered in the Swedish National Patient Registry and alive on 1 February 2020 were included. 'Incident severe COVID-19' was defined as the first hospitalization and/or death from COVID-19. A modified Poisson regression approach was applied to a 1:1 propensity score-matched population receiving vs. not receiving SGLT2i, GLP-1 RA, and DPP-4i to analyse the associations between their use and (I) incident severe COVID-19 and (II) risk of 30-day mortality in patients hospitalized for COVID-19.

Among 344 413 patients, 39 172 (11%) were treated with SGLT2i, 34 290 (10%) with GLP-1 RA, and 53 044 (15%) with DPP-4i; 9538 (2.8%) had incident severe COVID-19 by 15 May 2021. SGLT2i and DPP-4i were associated with a 10% and 11% higher risk of incident severe COVID-19, respectively, whereas there was no association for GLP-1 RA. DPP-4i was also associated with a 10% higher 30-day mortality in patients hospitalized for COVID-19, whereas there was no association for SGLT2i and GLP-1 RA.

Conclusion

SGLT2i and DPP-4i use were associated with a higher risk of incident severe COVID-19. DPP-4i use was associated with higher 30-day mortality in patients with COVID-19, whereas SGLT2i use was not. No increased risk for any outcome was observed with GLP-1 RA.

Keywords

COVID-19 • Sodium-glucose cotransporter 2 inhibitors • Glucagon-like peptide-1 receptor agonists • Dipeptidyl peptidase-4 inhibitors (DPP-4i) • Hospitalization • Mortality

Introduction

The current coronavirus disease 2019 (COVID-19) pandemic, due to the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), is an ongoing challenge.¹ Type 2 diabetes mellitus (T2DM) has been reported as one of the most frequent co-morbidities

associated with severe COVID-19, conferring a two-fold higher relative risk of severe COVID-19 requiring intensive care unit and in-hospital death.² Possible mechanisms behind higher morbidity and mortality with COVID-19 in patients with vs. without T2DM are systemic inflammation, immunodeficit, and hypercoagulability.^{3,4} The cytokine storm in severe COVID-19 involves elevated levels of serum

C-reactive protein, interleukin-6 (IL-6), D-dimer, and ferritin, which are also observed in the chronic inflammation associated with hyperglycaemia.⁵ Angiotensin converting enzyme 2 (ACE2) and dipeptidyl peptidase-4 (DPP-4) are two coronavirus receptor proteins that also have a role in glucose homeostasis regulation.^{6,7} Finally, observational studies suggested that anti-inflammatory agents used in severe COVID-19 pneumonia, e.g. anti-IL-6 agents, might be less effective in the presence of hyperglycaemia.⁸

Novel glucose-lowering medications may reduce adverse COVID-19 outcomes because of their anti-inflammatory properties, but the potential role of different pharmacological classes in adverse COVID-19 outcomes has not been systematically investigated.⁵ DPP-4 inhibitors (DPP-4i) have been suggested to have a beneficial role in T2DM patients hospitalized for COVID-19.^{5,9} Sodium-glucose cotransporter-2 inhibitors (SGLT2i) and glucagon-like peptide-1 receptor agonists (GLP-1 RA) have several anti-inflammatory properties, which might also be linked with better outcomes.^{5,10} Conversely, safety concerns have been raised for SGLT2i and GLP-1 RA since they increase ACE2 expression, which mediates SARS-CoV-2 binding to the cells.¹¹ However, RAAS inhibitor drugs, which also increase ACE2 expression, do not appear to be associated with an increased risk of incident COVID-19 or worse outcomes in prevalent COVID-19.¹²

The aim of the current study was to separately investigate the association between SGLT2i, GLP-1 RA, and DPP-4i use with (I) incident hospitalization/death for COVID-19 and (II) mortality in patients with COVID-19 in a nationwide cohort of T2DM patients in Sweden.

Methods

Data sources

The analyses were performed using the Swedish National Patient Registry (NPR) linked through the personal identification number to the Cause of Death Registry, the Dispensed Drug Registry, and Statistics Sweden.¹³ The NPR, the Cause of Death Registry, and the Dispensed Drug Registry are administered by the Swedish Board of Health and Welfare (www.socialstyrelsen.se), which collects International Classification of Diseases (ICD-10) diagnoses from all residents in Sweden, at hospitalizations as well as at outpatient non-primary care clinics. The Dispensed Drug Registry contains data for all dispensed prescriptions since 2005. Statistics Sweden collects socioeconomic data of Swedish residents.

Study population and outcomes

Adult patients with a diagnosis of T2DM in the NPR after 1997 (when ICD-10 was implemented) and who were alive on 1 February 2020 were included in the analyses. Additional exclusion criteria are reported in Supplementary material online, *Table S1*.

Index date was 1 February 2020 (the first COVID-19 case in Sweden was registered at the end of January 2020). End of follow-up was 15 May 2021.

Outcomes were incident severe COVID-19 in the overall study population and 30-day all-cause mortality in patients with COVID-19. Incident severe COVID-19 was defined as the first occurrence of hospitalization with confirmed COVID-19 as the main diagnosis in the NPR or confirmed COVID-19 as the underlying cause of death in the Cause of Death Registry. In patients hospitalized for COVID-19, subsequent hospitalizations for hypoglycaemia and diabetic ketoacidosis (DKA) were also investigated, with patients censored at death or at end of follow-up.

The percentage of patients still on treatment with the different study drugs was calculated based on those with at least one prescription within 5 months after an incident severe COVID-19.

Detailed definitions for co-morbidities, COVID-19 disease, and treatments are available in Supplementary material online, *Table S2*.

Statistical analysis

Baseline characteristics of patients receiving vs. not receiving SGLT2i, GLP-1 RA, and DPP-4i, separately, were reported as frequencies (percentages) for categorical variables and as medians (interquartile range—IQR) for continuous variables. Differences were evaluated by standardized mean differences (SMD), where a value < 0.1 was considered as non-significant. There were limited missing data from the following variables from Statistics Sweden: country of birth, income, education level, family type (living alone or not), and living in the region of Stockholm or not. Patients with missing data are excluded from all analyses (Supplementary material online, *Table S1*).

Separate analyses were performed for the three investigated drug classes. In the whole study population, the association between treatment and incident severe COVID-19 was evaluated. In a subset of patients hospitalized for COVID-19 and 30-days follow-up available, the association between the treatment and 30-day all-cause mortality was assessed. The associations were investigated by a modified Poisson regression approach,¹⁴ i.e. using generalized estimating equations models with a Poisson distribution and a robust error variance. Adjustment for covariates was performed by propensity score (PS) matching, where the PS for the treatment of interest was estimated for each patient by a logistic regression model including the variables indicated with * in Supplementary material online, *Table S3* as covariates, and where age was modelled using cubic splines with four degrees of freedom. A 1:1 matching without replacement, where the PS was allowed to differ by 0.01 or less, was thereafter performed. The ability of the PS-matching to balance the baseline characteristics was assessed by SMD. A 1:1 PS-matching was deemed the best option when the balance between groups and the number of patients retained in the analysis is considered. The matched pairs were incorporated into the model using an exchangeable correlation structure.

Consistency analyses were performed (1) in the overall (unmatched) population, adjusting for the individual variables indicated with * in Supplementary material online, *Table S3* rather than matching by PS; and (2) for the analysis with COVID-19 as an outcome, using a sub-distributional hazards model (Fine–Gray model) for time to incident severe COVID-19 where non-COVID-19 death was treated as a competing event.

The associations between each treatment and the outcomes in pre-defined subgroups were investigated by including an interaction term in the model. One considered subgroup was the Stockholm region, since the greatest number of cases was registered there. All analyses were performed using R version 4.0.2.

Ethics

Patient consent is not required for registration in the national administrative registries. The current analysis was approved by the Swedish Ethics Review Authority and was conducted in accordance with the Declaration of Helsinki.

Results

Of 365 537 patients with a diagnosis of T2DM recorded in the NPR between 1997 and 1 February 2020, 344 413 were included in our analysis after applying the exclusion criteria (Supplementary material online, *Table S1*). The median age (IQR) of the study population was 72 (62–79), 42.4% were women; 39 172 (11.4%) were treated with SGLT2i, 34 290 (10%) with GLP-1 RA, and 53 044 (15.4%) with DPP-4i.

Baseline characteristics

The baseline characteristics of patients receiving vs. non-receiving SGLT2i, GLP-1 RA, and DPP-4i are reported in *Table 1* and in Supplementary material online, *Table S3*.

SGLT2i users vs. non-users had a higher prevalence of obesity and ischaemic heart disease, with more frequent prior coronary revas-

Categorical variables are presented with *n* (%) and continuous variables with median [q1–q3].

Abbreviations: DPP-4i, dipeptidyl peptidase-4 inhibitors; GLP-1 RA, glucagon-like peptide-1 receptor agonists; MRA, mineralocorticoid receptor antagonists; RASi/ARNi, renin-angiotensin system inhibitors/angiotensin receptor-neprilysin inhibitors; SGLT2i, sodium-glucose cotransporter 2 inhibitors; SMD, standardised mean difference; TIA, transitory ischaemic attack.

cularizations. SGLT2i users were more likely to receive antiplatelet therapy, renin–angiotensin system inhibitors/angiotensin receptor-neprilysin inhibitors (RASi/ARNi), beta-blockers, and lipid-lowering drugs compared with non-users. Moreover, patients receiving SGLT2i were more often treated with other glucose-lowering agents, including oral antidiabetics, insulin, GLP-1 RA, and DPP-4i.

GLP-1 RA users vs. non-users were younger, with higher education levels and income. The prevalence of the analysed co-morbidities was similar in both groups except for history of stroke, atrial fibrillation, previous bleeding events, history of cancer in the last 3 years, dementia and previous stroke being more prevalent among non-users, and obesity being more common among users. GLP-1 RA users were more often treated with RASi/ARNi, lipid-lowering drugs, insulin, metformin, and SGLT2i but not with other oral antidiabetics.

DPP-4i users vs. non-users were older, with a higher prevalence of renal disease, but the other co-morbidities did not substantially differ. RASi/ARNi, beta-blockers, calcium channel blockers, lipid-lowering drugs, diuretics, and oral glucose-lowering agents were all prescribed in higher proportions in users than in non-users.

Baseline characteristics of the subset of patients hospitalized for COVID-19 according to the use of the three different drug classes are shown in Supplementary material online, *Table S4*.

Association between SGLT2i, GLP-1 RA, or DPP-4i use and risk of incident severe COVID-19 (Table 2)

Of the 344 413 patients included in our analysis, 9538 (2.8%) had incident severe COVID-19; among them, 963 (10.1%) were taking SGLT2i, 907 (9.5%) were taking GLP-1 RA, and 1639 (17.2%) were taking DPP-4i.

The risk of incident severe COVID-19 was significantly higher in SGLT2i users vs. non-users, with a risk ratio (RR) [95% confidence interval (CI)] of 1.11 (1.02–1.22). The consistency analyses confirmed this significant difference, and results were similar across all investigated subgroups (*Figure 1*).

The use of GLP-1 RA was not significantly associated with the risk of incident severe COVID-19 [RR (95% CI): 1.05 (0.96–1.15)], which was confirmed by the competing risk analysis. However, in the consistency analysis in the unmatched population, where adjustments were performed according to individual covariates, GLP-1 RA use was associated with a higher risk of incident severe COVID-19 (RR [95% CI]: 1.10 [1.02–1.18]). Among the investigated subgroups, GLP-1 RA treatment was associated with a higher risk of incident severe COVID-19 in the subset without heart failure [RR (95% CI): 1.12 (1.01–1.24); *P*-value for interaction 0.015]. Results were consistent in the other subgroups (*Figure 1*).

The use of DPP-4i was associated with a higher risk of incident severe COVID-19 [RR (95% CI): 1.10 (1.03–1.18)], with similar results in the consistency analyses and in all subgroups (*Figure 1*).

Outcomes in patients hospitalized for COVID-19 (Table 3)

Overall, 2975 (31%) deaths occurred in the 9538 hospitalized patients with COVID-19 as a primary diagnosis, with 2145 deaths (72%) having COVID-19 as the underlying cause of death. In the PS-adjusted analyses, there was no significant difference in the risk of 30-day all-cause death in patients receiving vs. not receiving SGLT2i, with a RR (95% CI) of 1.04 (0.85–1.27), and GLP-1 RA with a RR (95% CI) of 0.88 (0.73–1.07), whereas the risk was higher in DPP-4i users vs. non-users, with a RR (95% CI) of 1.11 (1.00–1.22). These results were overall consistent in the subgroups, except for a statistically significant lower risk of 30-day mortality associated with GLP-1 RA use in patients

Table 2 Association between SGLT2i, GLP1-RA or DPP-4i use, and risk of incident COVID-19 outcome, i.e. presence of a hospitalization with confirmed COVID-19 as main diagnosis in the National Patient Registry or as confirmed COVID-19 as underlying cause of death in the Cause of Death Registry

on concomitant metformin therapy [RR (95% CI): 0.62 (0.45–0.85); interaction $P = 0.003$].

Hospitalizations for hypoglycaemia according to the use of the three different drug classes were very low, with no substantial difference between users and non-users, as presented in Supplemental material online, Table S5. There were no hospitalizations for DKA.

As regards treatment continuation, 285 (78%) of the patients who were prescribed an SGLT2i at the index date were still prescribed after 5 months; the respective results for GLP-1 RA and DPP-4i were 250 (77%) and 400 (78%), respectively.

Discussion

In this nationwide cohort of patients with T2DM, the use of SGLT2i and of DPP-4i was associated with a higher risk of incident severe COVID-19, defined as hospitalization for or death from COVID-19, whereas GLP-1 RA use was numerically associated with an increased risk but without reaching statistical significance. Among patients hospitalized with COVID-19, the use of DPP-4i, but not of SGLT2i or GLP-1 RA, was associated with higher mortality.

The relationship between the use of glucose-lowering agents and COVID-19-related outcomes is paramount in clinical practice and to policymakers because of the high and growing prevalence of T2DM and subsequent cardiovascular complications, the increasing use of novel glucose-lowering drugs, the higher COVID-19 mortality observed in patients with T2DM,¹⁵ and the recurring and unpredictable waves of COVID-19 despite effective vaccines.¹⁶

As regards SGLT2i, clinical practice guidelines recommend the discontinuation in acute illness due to the increased risk of volume depletion and DKA.¹⁷ We observed that their at-home use was associated with an 11% higher risk of incident severe COVID-19, however, no hospitalizations for DKA were observed. These findings might be explained by higher hospitalization rates for COVID-19 in patients treated vs. non-treated with SGLT2i, with the first being at higher CV risk compared with the latter, and therefore more susceptible to a more severe COVID-19. Indeed, in our population, a larger proportion of patients receiving SGLT2i had established atherosclerotic cardiovascular disease and were on treatment with

antiplatelet agents, antihypertensive medications, lipid-lowering drugs, and antidiabetics.¹⁸ Despite extensive adjustments for these and many other patient characteristics, we were not able to directly assess and therefore adjust for other cardiometabolic risk factors such as glycated haemoglobin (HbA1c), or lipid levels, and thus we cannot rule out that residual confounding, e.g. more severe cardiometabolic disease in SGLT2i users, might explain their 11% higher risk of incident severe COVID-19. However, in patients hospitalized for COVID-19, mortality rates were not higher with SGLT2i. Consistent with these findings, the DARE-19 randomized controlled trial showed no difference between dapagliflozin and placebo in 1250 patients with cardiometabolic risk factors as regards the risk of new or worsened organ dysfunction, death, and recovery.¹⁹ Nonetheless, dapagliflozin was well tolerated and no new safety signals were identified, in accordance with the present study, where just two hospitalizations for hypoglycaemia were reported for SGLT2i users (vs. seven in non-users), and there was no hospitalization for DKA. Results of the RECOVERY trial (NCT04381936), which aims to assess whether empagliflozin reduces the risk of death, the length of hospital stay, and the need of mechanical ventilation among patients admitted to hospital with COVID-19, will provide further evidence on SGLT2i.

It has been suggested that the pharmacological inhibition of DPP-4 might hinder virus penetration in the target cells, thus conferring a lower risk of incident COVID-19 in DPP-4i users.²⁰ However, later preclinical studies showed that the binding sites for DPP-4i do not overlap with those for viral spike proteins of SARS-CoV-2.²¹ Observational data are considerably heterogeneous.²² In a large primary care setting in the UK, patients prescribed with SGLT2i had a similar risk of confirmed or clinically suspected COVID-19 compared with patients prescribed with DPP-4i.²³ On the other hand, an observational cohort study on 2.85 million English patients with T2DM reported adjusted hazard ratios for COVID-19-related deaths of 0.94 (0.83–1.07) for GLP-1 RA and 1.07 (1.01–1.13) for DPP-4i inhibitors.²⁴

The current practical recommendations do not mandate the discontinuation of incretin-based therapies in patients with COVID-19,¹⁷ and indeed, most of the patients with incident severe COVID-19 in the present study were prescribed the investigated treatments after discharge. Previous studies on patients with T2DM and confirmed

COVID-19 report mixed findings. Meta-analyses reported that the use of DPP-4i(9) and of GLP-1 RA²⁵ was associated with decreased COVID-19 mortality. In a study conducted in Italy, treatment with sitagliptin was associated with lower mortality and better clinical outcomes compared with standard-of-care treatment.²⁶ Accordingly, a large multinational retrospective cohort study demonstrated that the use of GLP-1 RA and DPP-4i was associated with fewer hospital admissions, respiratory complications, and mortality.²⁷ Other studies suggested no associations between incretin-based therapies used in COVID-19 and outcomes: A registry-based Danish study did not show any difference in the risk of adverse outcomes between GLP-1 RA or DPP-4i users and SGLT2i users.²⁸ In the Spanish SEMI-COVID-19 registry, no significant associations were found between the use of SGLT2i and DPP-4i and the admission to intensive care units, mechanical ventilation, in-hospital death, development of in-hospital complications, and a long-time hospital stay in patients hospitalized for COVID-19.²⁹ A PS-matched analysis of the prospective observational study, CORONADO reported no association between DPP-4i use and the composite primary endpoint (tracheal intubation for mechanical ventilation and death within 7 days of admission).³⁰ Finally, data from 12 446 SARS-CoV-2-positive adults in the National COVID Cohort Collaborative U.S. study showed that GLP-1 RA and SGLT2i use were associated with lower odds of 60-day mortality compared with DPP-4i use.³¹

GLP-1 RA use was not associated with incident severe COVID-19 and mortality in patients hospitalized for COVID-19 in the main analysis (i.e. PS-matched), whereas in the adjusted model including all patients the risk associated with GLP1-RA use was 10% higher. The association of DPP-4i use with incident severe COVID-19 was significant, consistently in the main analysis and in the multi-adjusted analysis. One possible explanation could be that in our study, DPP-4i users were significantly older compared with non-users and with SGLT2i and GLP-1 RA users, in accordance with national recommendations in Sweden. Age by itself is an independent risk factor for COVID-19 morbidity and mortality and might be accompanied by other co-morbidities and frailty which we could not adjust for. Another possible explanation is that, unlike SGLT2i and most GLP1-RA, DPP-4i does not provide cardiovascular protection in patients with T2DM, and this might affect the prognosis in patients with severe COVID-19, who are particularly burdened by adverse cardiovascular outcomes.³² Stronger evidence will be provided by ongoing randomized clinical trials on sitagliptin (SIDIACO-RCT, NCT04365517) and linagliptin (NCT04371978, NCT04341935). However, it must be noted that SGLT2i and GLP-1 RA are very effective in reducing cardiovascular risk, which steadily burdens patients with diabetes at least as much as COVID-19 during the pandemic, thus their benefit justifies their continued use.

The present analysis has several strengths. The inclusion of a large nationwide registry population with full coverage warrants the high generalizability of our findings. The risk of incident severe COVID-19 is addressed in the general population of T2DM patients, providing a large clinical prospective. PS-matched analyses allowed us to adjust for potential known confounders.

Some limitations should be acknowledged. First, the observational nature of this study prevents from assessing causality, i.e. residual confounding and selection bias cannot be ruled out. We made all efforts to address this bias by using different models in consistency analyses, however, the results were not steadily in accordance: In the fully adjusted models, the association between the single class use and risk for incident severe COVID-19 were statistically significant, suggesting high potential for residual confounding, possibly conferred by indication bias and frailty. Second, the number of quality checks on the data obtained by the Swedish Board of Health and Welfare in 2021 was lower than usual due to the urgency of providing information on the pandemics. Third, since patients with COVID-19 were defined

based on hospitalization or death for COVID-19, our results might not be generalizable to COVID-19 patients who were not admitted to the hospital. Although our analyses were adjusted for co-morbidities and pharmacological treatments which might serve as proxies of glycaemic control, data on HbA1c levels were missing thus glycaemic control could not be directly assessed. Finally, patients with T2DM only treated in primary care were not included.

In conclusion, in a nationwide real-world population of patients with T2DM, the use of SGLT2i was associated with a slightly higher risk of incident COVID-19 hospitalization/death, but not with higher 30-day mortality in patients with COVID-19. GLP-1 RA treatment was not significantly associated with a higher risk of COVID-19 hospitalization/death or with increased mortality. The use of DPP-4i was associated with a slightly higher risk of hospitalization/death due to COVID-19 and of 30-day mortality among patients hospitalized with COVID-19. None of the three-drug classes was associated with an increased risk of incident severe COVID-19 or death that exceeded 11%. Thus, these observational results should be interpreted with caution because of the high potential of indication bias, i.e. overall increased vulnerability in patients who are prescribed these drugs.
