Summary

Background Although COVID-19 vaccination decreases the risk of severe illness, it is unclear whether vaccine administration may impact the prevalence of long-COVID. The aim of this systematic review is to investigate the association between COVID-19 vaccination and long-COVID symptomatology.

Methods MEDLINE, CINAHL, PubMed, EMBASE, and Web of Science databases, as well as medRxiv and bioRxiv preprint servers were searched up to June 20, 2022. Peer-reviewed studies or preprints monitoring multiple symptoms appearing after acute SARS-CoV-2 infection either before or after COVID-19 vaccination collected by personal, telephone or electronic interviews were included. The methodological quality of the studies was assessed using the Newcastle-Ottawa Scale.

Findings From 2584 studies identified, 11 peer-reviewed studies and six preprints were included. The methodological quality of 82% (*n*=14/17) studies was high. Six studies (*n*=17,256,654 individuals) investigated the impact of vaccines before acute SARS-CoV-2 infection (vaccine-infection-long-COVID design). Overall, vaccination was associated with reduced risks or odds of long-COVID, with preliminary evidence suggesting that two doses are more effective than one dose. Eleven studies (*n*=36,736 COVID-19 survivors) investigated changes in long-COVID symptoms after vaccination (infection-long-COVID-vaccine design). Seven articles showed an improvement in long-COVID symptoms at least one dose post-vaccination, while four studies reported no change or worsening in long-COVID symptoms after vaccination.

Interpretation Low level of evidence (grade III, case-controls, cohort studies) suggests that vaccination before SARS-CoV-2 infection could reduce the risk of subsequent long-COVID. The impact of vaccination in people with existing long-COVID symptoms is still controversial, with some data showing changes in symptoms and others did not. These assumptions are limited to those vaccines used in the studies.

Funding The LONG-COVID-EXP-CM study supported by a grant of Comunidad de Madrid.

Keywords: Post-COVID syndrome; Long-COVID symptoms; Vaccine; SARS-CoV-2

Introduction

COVID-19 caused by SARS-CoV-2 is the deadliest communicable healthcare outbreak of the 21st century. COVID-19 vaccines have significantly reduced the risk

Research in context

Evidence before this study

We searched PubMed and Web of Science databases for studies published until April 1, 2022, using keywords "long-COVID", OR "post-COVID" AND "vaccine" OR "vaccination". We identified different studies analyzing the impact of COVID-19 vaccination in long COVID symptoms, but no systematic review was available in the literature.

Added value of this study

This first systematic review evaluating evidence to date about the impact of vaccines on long COVID supports that vaccination before SARS-CoV-2 infection is able to reduce the risk of developing long-COVID. The impact of vaccination in people with long-COVID symptomatology is controversial, with data showing changes in symptoms and others did not.

Implications of all the available evidence

Current results support that COVID-19 vaccines can be used as preventive strategy for decreasing the risk of long-COVID, but data about its effects on people with current long-COVID needs further research. Questions about the impact on hospitalised/non-hospitalised, males/females and the impact of vaccine boosters is clearly needed.

of developing the severe or critical forms of disease, as well as mortality brought by COVID-19.[1] Nonetheless, vaccines seem unable to fully reduce the spread of SARS-CoV-2 variants of concerns (VOCs).[2]

Following the COVID-19 outbreak, leading to hundreds of millions of acute cases and six million deaths, healthcare professionals are in front of another crisis brought about by development and/or persistence of symptoms after the acute phase of SARS-CoV-2 infection (typically after 3 months), a condition conventionally called long-COVID[3] or post-COVID.[4] More than 100 symptoms can appear after a SARS-CoV-2 acute infection, affecting multiple systems, *e.g.*, cardiovascular, respiratory, musculoskeletal, or neurological.[5] Several meta-analyses observed that almost 50% of COVID-19 survivors had a lingering plethora of symptoms lasting for weeks or months[6–8] but also one year[9,10] after SARS-CoV-2 infection.

As of August 2022, more than 12.4 billion COVID-19 vaccine doses have been administered globally.[11] Although vaccination decreases the risk of severe COVID-19, it is unclear whether vaccination before or after an acute infection improves or reduces the prevalence of long-COVID symptoms. In fact, vaccinated people can still be infected and suffer from asymptomatic, mild or moderate COVID-19, especially when the infection is sustained by VOCs (namely Omicron). Since long-COVID can arise even after a mild or asymptomatic SARS-CoV-2 infection,[12] it is in question what real impact vaccines will have on long-COVID.[13–16] This review is the first to date to systematically investigate the impact of COVID-19 vaccination on long-COVID symptoms. Therefore, the research question of this review was: "what is the impact of COVID-19 vaccines on the risk of developing long-COVID or on existing long-COVID in COVID-19 survivors?

Methods

This systematic review adheres to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement,[17] and was prospectively registered in the Open Science Framework (OSF) database (https://osf.io/34djr). No ethical committed is needed for a systematic review.

Search strategy and selection criteria

Electronic literature searches were conducted by two different authors on the following databases: MEDLINE, CINAHL, PubMed, EMBASE, and Web of Science databases, as well as on preprint servers medRxiv and bioRxiv, for studies published until June 20, 2022. Database search strategies were conducted with assistance of an experienced health science librarian. We also screened the reference list of identified papers for capturing black literature. Searches were limited to human studies and English language citations by using the following combinations of terms: "long-COVID", "long-COVID symptoms", "long hauler", "post-COVID-19" OR "post-acute COVID-19 syndrome" OR "post-acute COVID-19 symptoms" OR "COVID-19 sequelae" AND "vaccine" OR "vaccination" OR "COVID-19 vaccines" OR "SARS-CoV-2 vaccine". The search strategy combined these terms using Boolean operators for the main databases is detailed in Supplementary Table.

The inclusion and exclusion criteria were formulated using the Population, Intervention, Comparison and Outcome (PICO) principle:

Population: Adults (>18 years) infected by SARS-CoV-2 and diagnosed with real-time reverse transcription-polymerase chain reaction (RT-PCR) assay. Individuals could have been hospitalised or not by SARS-CoV-2 acute infection.

Intervention: Any type of COVID-19 vaccine. We included the following types of COVID-19 vaccines: BNT162b2 ("Pfizer/BioNTech"), AZD1222 ("Oxford-AstraZeneca"), mRNA-1273 ("Moderna"), and Ad26.COV2.S ("Janssen"). Vaccine doses can be administered before or after SARS-CoV-2 acute infection.

Comparison: Individuals not receiving any COVID-19 vaccine.

Outcome: Collection of multiple symptoms (post-COVID-19 or long-COVID) developed after a SARS-CoV-2 acute infection (https://www.nhs.uk/conditions/coronavirus-covid-19/long-term-effects-of-coronavirus-long-covid/) by personal, telephone, or electronic interviews. We included any type of symptom appearing after the infection e.g., physical (fatigue, pain), cognitive (brain fog, memory loss), respiratory (dyspnea, palpitations, cough), gastrointestinal (diarrhoea, stomachache, vomiting) or mental problems (depression, anxiety, sleep disturbances). Due to the different definitions of long-COVID, no specific follow-up period for the presence of symptoms after the acute infection was determined. Studies monitoring solely changes in immunologic or serologic biomarkers without assessment of post-COVID symptoms were excluded.

This review included observational cohort, cross-sectional, and case-control studies where samples of COVID-19 survivors, either hospitalised or non-hospitalised, were followed for presence of symptoms appearing after a SARS-CoV-2 acute infection before or after COVID-19 vaccination. Editorials, opinion, and correspondence articles were excluded.

Two authors reviewed the title and abstract of those publications identified in the databases. Duplicates were then removed. The title and abstract were screened for eligibility and posterior full-read text. Data including authors, country, sample size, setting, vaccination status, type of vaccine, clinical data, and post-COVID symptoms before and after vaccination were extracted from each study. Authors had to reach consensus on data extraction. Discrepancies between reviewers at any stage of screening process were resolved by asking a third author, when necessary.

Data analysis

The methodological quality of the studies was independently assessed by two authors using the Newcastle-Ottawa Scale, a star rating system evaluating the risk of bias of case-control and cohort studies.[18] The Newcastle-Ottawa Scale evaluates the following sections in cohort studies: case selection (*i.e.,* representativeness of the cohort, selection of non-exposed cohort, case definition, outcome of interest), comparability (*i.e.,* proper comparison by controlling for age, gender, or other factors, between-groups) and exposure (*i.e.,* outcome assessment, long enough follow-up, adequate follow-up). Some of these items are adapted if the studies used case-control design. For instance, case selection item includes adequate case definition or selection of controls. In cohort studies using longitudinal design or case-control studies, a rating of 7 to 9 stars indicates high quality, 5 to 6 medium quality, and less than or equal to 4 is of low quality. In cohort studies using cross-sectional design, a maximum of 3 stars can be awarded. Studies scoring 3 stars are considered of good quality, 2 stars of fair quality, and 1 star of poor quality. Methodological quality was initially evaluated by two authors. If there is disagreement, a third researcher arbitrated a consensus decision.

Meta-analysis was not deemed appropriate due to the high heterogeneity between studies. Accordingly, we conducted a synthesis of the data reported by addressing population, vaccine status related to acute infection, limitations, and methodological quality.

Role of the funding source

The sponsor had no role in the design, collection, management, analysis, or interpretation of the data, draft, review, or approval of the manuscript or its content. The authors were responsible for the decision to submit the manuscript for publication, and the sponsor did not participate in this decision. All authors had access to the data. Kin Israel Notarte and César Fernández-de-las-Peñas verified the data set. All authors were responsible for making the decision to submit this manuscript.

Results

Study selection

The electronic search identified 2584 titles for initial screening. After removing duplicates (n= 138) and papers not directly related to vaccines and long-COVID (n=2396), 50 studies remained for abstract examination. 29 were excluded after abstract examination: not available in English text (n=3), case reports and case series studies (n=5), review articles (n=7), full text not available (n=4), and not focused on vaccines and long-COVID (n=10).

A total of 13 published and 8 preprint full-text articles were assessed for eligibility[19–38] (Figure 1). Two articles were excluded because they were government summary reports.[36,37] One preprint was excluded because it was a study protocol.[39] Lastly, one preprint[38] was excluded because the same study was previously published in a peer-reviewed journal.[23] Finally, a total of 11 peer-reviewed studies and 6 preprints were included in the systematic review.[19–35]

Study characteristics

We identified two types of studies according to the relationship between vaccination and acute infection: (1) studies investigating the development of long-COVID symptoms in people who had received COVID-19 vaccine before being infected (vaccine - infection - long COVID); and (2) studies investigating changes in long-

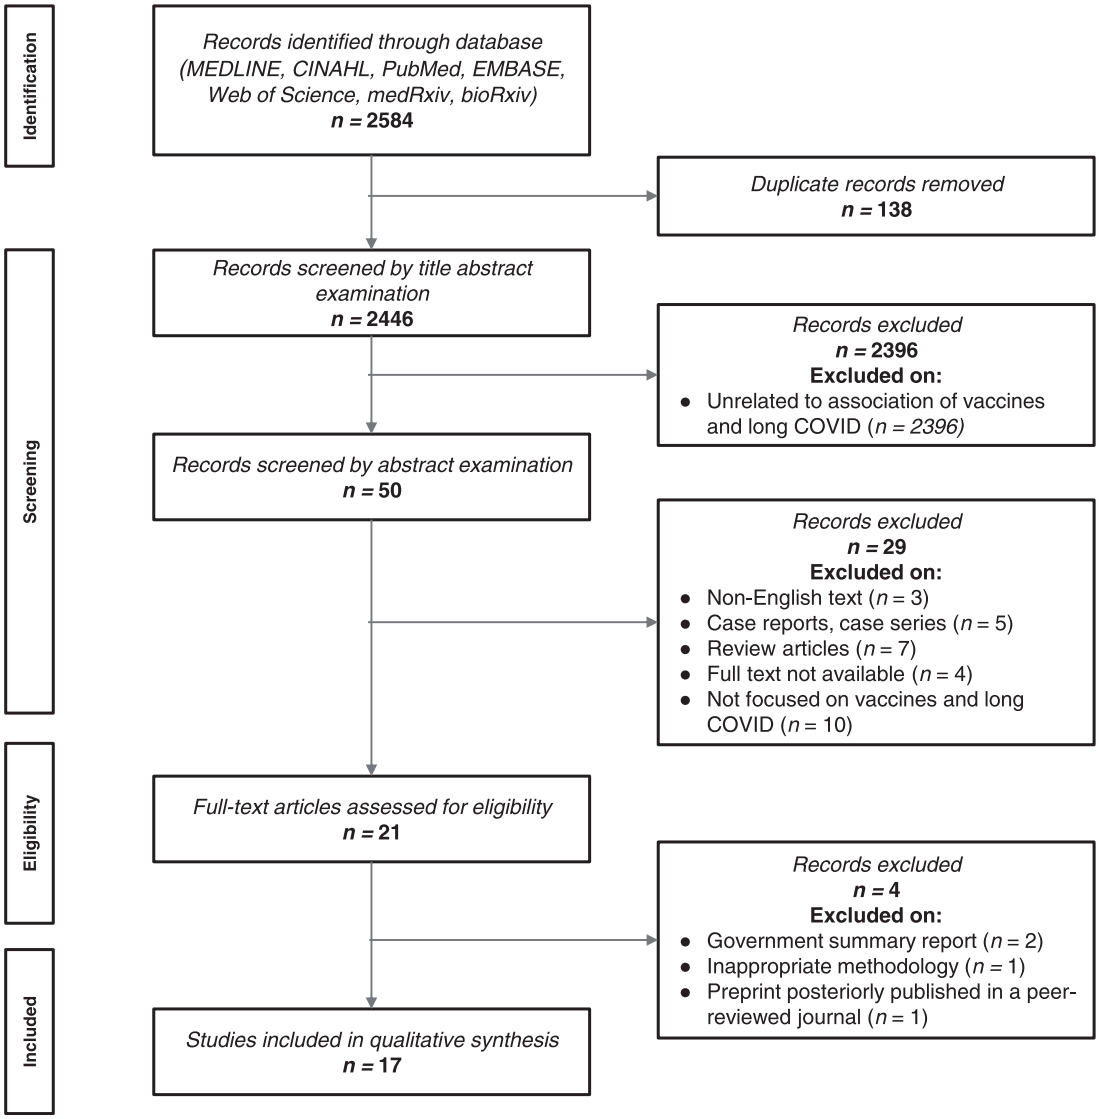

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) Flow diagram.

COVID symptoms in people who had previously been infected, developed long-COVID, and then received vaccine after (infection - long COVID - vaccine).

The characteristics of the 'vaccine - infection - long COVID' studies are shown in Table 1 (total sample *n*=17,256,654 participants). Five[19,20,22–24] out of six articles provided data on mRNA and vector vaccines while the remaining study[21] did not list the specific vaccine included. The countries of origin for these studies were the United States of America (USA), United Kingdom (UK), and India. Three papers[20–22] investigated patients who have had at least 2 doses of vaccine while the remaining three[19,23,24] papers only required at least one dose of vaccine.

For the 'vaccine - infection - long COVID' studies, the impact of vaccine on long-COVID symptoms was presented as odds ratio (OR), adjusted odds ratio (aOR), and hazards ratio (HR). Two articles[23,24] used HR, two 19[20] used purely OR, one[22] used aOR, and another[21] used both aOR and OR for expressing differences in long-COVID development between vaccinated and non-vaccinate people.

Overall, all six articles[19–24] agreed that vaccination before SARS-CoV-2 acute infection was associated with reduced risks or odds of long-COVID. There was high heterogeneity in the time from vaccination to infection, suggesting that people who had been vaccinated a month before being infected has lower risk of developing long-COVID symptoms. Antonelli et al.[24] and Taquet et al.[24] further posit that two doses could be more effective for reducing the risk of long-COVID than a single dose. Al-Aly et al.[24] concluded that

Author and Country of Origin	Study Design and Study Period	Sample Size	Median Age (Range)	Cases	Controls	Objective Assessment of Symptoms	Post-Acute Symptoms Reported	Vaccine Information (Product, Dose, Follow-up Period)	Impact of Vaccine on Symptoms Associated with long-COVID

***Table 1*: Summary of results for 'vaccine - infection - long COVID' studies.**

ND - no data; aOR - adjusted odds ratio; SD - standard deviation; OR - odds ratio; HR - hazard ratio; RR - risk ratio; BTI - breakthrough infections

BNT162b2 ("Pfizer/BioNTech") and mRNA-1273 ("Moderna") vaccines were more effective for mitigating the risk of long-COVID compared to Ad26.COV2.S ("Janssen") vaccine. Five[19–21,23,24] papers listed specific symptoms, while the remaining[22] did not specify any particular post-COVID symptom. The most common post-COVID symptoms analysed in the 'vaccine-infection-long COVID' papers were fatigue (*n*=5), muscle and joint pain (*n*=5), abdominal pain (*n*=4), diarrhoea (*n*=4), along with cough (*n*=4). Neurological symptoms and mental health problems including headache (*n*=4), brain fog or memory loss (*n*=2), anxiety (*n*=2), depression (*n*=1), altered mental state (*n*=2), and mood disorder (*n*=1) were also noted.

The characteristics of the 'infection - long COVID - vaccine' studies are shown in Table 2, involving 36,736 COVID-19 survivors and encompassing eleven papers.[25–35] With respect to the geographical distribution, four articles were from the UK, two from the USA, one each from France, Italy, Israel, Japan, and Switzerland. Three out of 11 articles[26,32,33] gathered data on mRNA vaccines only, seven articles[25,27,29–31,34,35] on mRNA and viral vector vaccines, while one article[28] did not mention the type of vaccine. All studies included patients with at least a single dose of vaccine.

There was heterogeneity in the presentation of results for the 'infection-long COVID-vaccine' studies. Six out of the 11 articles[25–30] made use of percentage in reporting the outcomes, one study[31] used OR, one[33] aOR, one[35] mean difference, one[32] risk ratio (RR), and the last one[34] all measures: mean difference, HR, and risk difference for the presentation of results. Seven articles[26,27,30–34] agreed that there was improvement in long-COVID symptoms at least one dose post-vaccination, two of which[30,32] reported that two doses of vaccines restored the reported symptoms back to baseline. On the contrary, four studies[25,28,29,35] reported no change of long-COVID symptoms in the majority of participants. Tran et al.[34] stated that vaccination doubled the remission rate of long-COVID. On the contrary, Tsuchida et al.[28] noted that those participants worsening their long-COVID symptoms were reported to have increased antibody titer ratio resulting from excessive immune response to vaccination.

Seven out of the 11 articles[28–33,35] listed changes in post-acute symptoms manifested by the patients, while 5 studies[25–27,30,33] reported improvement, unchange, or worsening of the long-COVID symptoms. The most common long-COVID symptoms evaluated in the 'infection-long COVID-vaccine' papers were fatigue (*n*=6), anosmia (*n*=6), and dysgeusia (*n*=4). Neurological symptoms and mental health problems including headache (*n*=5), anxiety (*n*=4), depression (*n*=2), brain fog (*n*=2), insomnia (*n*=2) and memory loss (*n*=1) were also reported.

Finally, the definition of long-COVID was not consistent. Seven articles described long-COVID in accordance with the WHO[4] as having COVID-19 symptoms usually 3 months from the onset of COVID-19 and that lasts for at least 2 months and cannot be explained by an alternative diagnosis.[19,22,28-32] Two papers defined long-COVID in having persistent symptoms lasting for more than 4 weeks and the lack of an alternative diagnosis,[20,27] and the remaining articles did not specify a particular definition of long-COVID, doing follow-up periods ranging from 1 month to 6 months after hospital discharge.[21,23-26,33-38]

Methodological quality

Two studies (11.8%)[20,27] used a case-control design and were of high (8/9 stars) and medium methodological quality (6/9 stars). The remaining fifteen (88.2%) were cohort studies, with six using a cross-sectional[21,26,28,30,32,33] (*n*=6/17, 35.3%) and nine a longitudinal[19,22,24,25,29,31,34,35,38] (*n*=9/17, 52.9%) design. Fourteen were of high methodological quality (3/3 stars or 7/9 stars, as appropriate) and one was of medium quality (6/9 stars). No disagreement between authors was observed. Tables 3-4 present the Newcastle-Ottawa Scale scores for each study and a summary of every item.

Discussion

This is the first systematic review to date aimed at summarising data about the impact of COVID-19 vaccine on long-COVID, to our knowledge. Low level of evidence (grade III, case-controls, cohort studies) suggests that vaccination before SARS-CoV-2 infection could reduce the risk of subsequent long-COVID; however, the influence of vaccination in people with previous long-COVID remains controversial, with evidence reflecting symptoms improving and others not. Our results agree with current opinions questioning the real impact the vaccines may have on current long-COVID symtptoms.[13–16,40]

The first situation is to assess if vaccines prevent long-COVID development. We identified six level III studies of moderate to high methodological quality investigating if vaccination before SARS-CoV-2 acute infection reduces the risk of developing long-COVID after (vaccine-infection-long COVID design). All studies found that vaccines reduced the risk of developing long-COVID in people with mild to moderate COVID-19, supporting the hypothesis that vaccination could be used as a preventive strategy for reducing long-term symptoms. However, most studies assessed the "short-term" effect of vaccines, since most included patients infected from one week to one month after vaccination. Only two studies investigated follow-up periods of six months after vaccination.[23,24] Further, the definition of long-COVID was inconsistent between studies. Additionally, preliminary data suggest that two doses could

be more effective than one single dose[24] and that BNT162b2 ("Pfizer/BioNTech") or mRNA-1273 ("Moderna") vaccine could be more effective than Ad26. COV2.S ("Janssen") vaccine[24] for reducing the risk of developing long-COVID, in keeping with previous data showing that the efficacy of mRNA-based vaccines on the risk of developing severe illness may be higher compared to adenoviral vaccines. No study investigated the impact of vaccine boosters on long-COVID.

The mechanisms underlying a potential risk reduction of long-COVID in people previously vaccinated are unknown. Two hypotheses are proposed. First, since vaccines reduce the severity of acute SARS-CoV-2 infection, this may then translate into lower risk of developing organ or systemic derangements, and thus symptoms onset and duration. However, the association of long -COVID with COVID-19 severity remains controversial.[41] A second hypothesis is that vaccines may accelerate clearance of the remaining SARS-CoV-2 virus in the human body (viral remnant hypothesis of long-COVID) or could also reduce the exaggerated inflammatory and/or immune response associated with long-COVID development (immune/inflammatory hypothesis of long-COVID).[42] Future studies investigating the underlying mechanisms of vaccines on long-COVID would be needed to clarify these issues.

The second topic is to know if COVID-19 vaccines represent a risk for those individuals with ongoing long-COVID symptomatology. We identified eleven level III studies of moderate to high methodological quality investigating the impact of vaccine on individuals who had previously suffered from COVID-19 and developed long-COVID (infection-long COVID-vaccine design). The results here were less consistent, since 63% of the studies (n=7/11) found that vaccination improved ongoing symptoms of long-COVID, whereas 36% (n=4/11) reported small changes or even worsening in some patients. Again, the definition of long-COVID among the studies was inconsistent. This heterogeneity in the response against vaccines of individuals with long-COVID could be related to the complexity of this condition. For instance, Tsuchida et al.[24] identified that people experiencing a worsening of long-COVID symptoms after vaccination are those also showing excessive immune response to vaccination, with higher increased rate of antibody titers. On the contrary, Peghin et al.[24] observed that COVID-19 vaccines did not produce an altered humoral response in individuals with current long-COVID. Discrepancies between these studies could be related to the fact that numerous autoantibodies may be produced after SARS-CoV-2 infection[43] and, accordingly, COVID-19 vaccines effects could be dependent on the host immune response. Further, since long-COVID includes a myriad of >100 different multiorgan symptoms,[5] it is possible that vaccines influence could be related to some specific long-COVID symptoms. Accordingly, COVID-19

vaccination may help to reduce long-COVID by eradicating the viral reservoir or by resetting a deregulated immune response to primary acute infection, and this effect could be host-dependent. Overall, although current evidence is inconclusive, available data suggest that COVID-19 vaccines are important factors for further immunological protection against potential reinfections.

The results of this systematic review should be considered according to potential strengths and limitations. Among the strengths, we conducted a deep systematic search of all the available evidence about the impact of vaccines on long-COVID. This led to identification of six non-peer reviewed, preprint articles. Considering the rapid emergence which represents the COVID-19 pandemic, the volume of preprint research could be expected given the need for rapid data dissemination. Second, this is the first time that the methodological quality of published studies is conducted. Interestingly, albeit heterogeneity in the concepts and designs, the quality of most study designs (82%) was high.

Three main limitations should be recognised. First, the effects of vaccines on long-term post-COVID symptoms are scarce, since most studies identified in this review investigated the risk of long-COVID in people infected the first month after being vaccinated. Second, there was no consistent definition of long-COVID in the published literature. In most studies, symptoms were assessed during the first month after the infection, which could not represent the reality of long-COVID, where symptoms can persist during months and years.[9,10] We included all studies investigating changes in any symptom appearing after a SARS-CoV-2 infection. In fact, just seven studies (41%) used the WHO definition of post-COVID-19 condition.[4] Future studies including the WHO definition of post-COVID-19 condition[4] should be conducted to get better stratification of the population. In addition, it should be considered that vaccinated individuals were older than non-vaccinated, probably because worldwide vaccination strategies firstly focused on vulnerable individuals. Third, no study differentiated between hospitalised and non-hospitalised patients or sex-differences between males and females. Similarly, no evidence is available on the SARS-CoV-2 variants that caused acute infections, since no study summarise the VoC included in their population samples; so that a bias on long-COVID burden and characteristics attributable to infection with different VOCs cannot be ruled out. Therefore, studies investigating the impact of COVID-19 vaccines in 1, hospitalised or non-hospitalised patients; 2, males and females; and 3, the different VoC and potential reinfections are now needed. Finally, no study investigated the impact of vaccine boosters in long-COVID symptomatology. Since booster programs have been increasingly implemented in several countries, particularly in vulnerable individuals, the impact of third or fourth booster dose on long-COVID should be investigated.

In conclusion, low level of evidence suggests that vaccination before SARS-CoV-2 infection could reduce the risk of developing subsequent long-COVID. It seems that two doses of vaccine could be more effective than just one dose, although data are preliminary and based in just two studies. No data on vaccine boosters are still available. The impact of vaccination in people who had been infected, had developed long-COVID symptoms, and, then vaccinated is inconsistent, with both positive and negative impact. This conclusion is based on grade III studies (case-controls, cohort studies). These assumptions are also limited to those vaccines used in the studies. This highlights the need for more studies better defining the participants involved, the inclusion of different SARs-CoV-2 VoC, and a proper definition of long-COVID.
