Massive hemoptysis is a highly morbid medical condition with up to 75% mortality with conservative treatment. Bronchial artery embolization has emerged as the common treatment for both acute massive hemoptysis and chronic hemoptysis. This article will review the clinical presentation, bronchial artery anatomy, embolization procedure, complications, and expected outcomes.

Massive hemoptysis is a medical condition associated with high morbidity and mortality. Historically there was greater than 75% mortality reported with conservative therapy,¹ with the cause of death usually from asphyxiation, not exsanguination. However, outcomes have improved with advances in bronchoscopy; advances in surgical and endovascular techniques; with mortality rates now ranging from 13 to 17.8%.^{2–4}

There is no consensus on the definition of massive hemoptysis, with authors using criteria ranging from 100 to 1,000 mL of expectorated blood in 24 hours.^{5–9} The volume of the conducting dead space in the lungs (from trachea to terminal bronchioles) is approximately 150 mL.¹⁰ Therefore, seemingly small volumes of blood can be deadly if not cleared sufficiently. Given the nature of hemoptysis, it can be difficult to quantify the expectorant volume. Recently, there has been a shift to define massive hemoptysis by considering the clinical picture: rate of bleeding, underlying physiologic/respiratory reserve, and ability of the patient to protect their airways.¹¹

Bronchial artery embolization (BAE) for the treatment of massive hemoptysis, first described in 1973,¹² has now become common therapy for massive hemoptysis or ongoing chronic hemoptysis.¹³ Although BAE is not without risk, it has been shown to be a safe and effective treatment for massive hemoptysis. A recent systematic review found that BAE was successful in 70 to 99% of cases with major complication rates of 0 to 6.6%.¹⁴ Surgery remains a treatment option, but it is associated with high morbidity and mortality.

Therefore, surgery is often reserved for specific etiologies: hydatid cyst, bronchial adenoma, and aspergilloma which has failed prior treatment.¹⁵

Clinical Presentation

Hemoptysis is not uncommon, presenting in 0.1% of ambulatory patients and 0.2% of inpatients; however, most (90%) is minor and self-limited.^{16–18} Hemoptysis is seen in approximately 20% of patients with lung cancer. While malignancy can present with massive hemoptysis, it is more commonly persistent, defined as ongoing for more than 2 weeks.¹⁹ Despite thorough clinical workup and evaluation, approximately 7 to 25% of patients have no known etiology for hemoptysis, termed cryptogenic hemoptysis.²⁰

Massive hemoptysis has a different clinical trajectory and often requires emergent intervention. Common etiologies of massive hemoptysis vary depending on geographic region but include tuberculosis (TB), fungal infections, pneumonia, malignancy, bronchiectasis, cystic fibrosis, and vascular etiologies such as Rasmussen aneurysm.^{1,9} Worldwide, TB is the most common cause of massive hemoptysis.²¹

Patients presenting with massive hemoptysis should first be stabilized, including hemodynamic support, airway protection and intubation, and escalation of level of care as needed. Patient workup should include history with evaluation for an etiology: infection, TB exposure or history, and underlying pulmonary disease. Surgical history and the uses of anticoagulants or antiplatelet medications should be

Table 1 Common bronchial artery origins

Type	Percentage	Right	Left
1	40.6	Single vessel originating from the common intercostobronchial trunk	Two vessels originating directly from the aorta
2	21.3	Single vessel originating from the common intercostobronchial trunk	Single vessel originating directly from the aorta
3	20.6	One vessel originating from the common intercostobronchial trunk One vessel originating directly from the aorta	Two vessels originating directly from the aorta
4	9.7	One vessel originating from the common intercostobronchial trunk One vessel originating directly from the aorta	Single vessel originating directly from the aorta

elicited. Blood originating from the nasopharynx or upper gastrointestinal tract should be excluded, as these causes of pseudo-hemoptysis require a different treatment algorithm altogether.

If possible, the bleeding should be localized. This can be done via computed tomography angiography (CTA) or bronchoscopy, depending on the acuity of the patient and available resources. In the setting of outpatient pulmonology clinics, CTA has been shown to be more efficacious for the localization of bleeding, obviating the need for bronchoscopy in some stable patients or patients with chronic hemoptysis.¹⁹ CTA can also be helpful for delineating the bronchial artery anatomy or origins.

In unstable patients with massive hemoptysis, urgent intubation and bronchoscopy are prudent. The patient should be positioned in the lateral decubitus position with the side of bleeding down to allow for better aeration of the unaffected side. Intubation should be done with a large bore endotracheal tube to allow for bronchoscopy with evacuation of clot and/or balloon occlusion.²² Selective intubation in the left or right mainstem bronchus can also be performed to aid in the protection of the unaffected side. Additional therapeutic procedures can be performed during bronchoscopy, such as cryoprobe clot extraction, iced saline lavage, epinephrine or norepinephrine administration, endobronchial stent placement, electrocautery, glue, thrombin, or Nd-YAG laser ablation.^{1,23–25} While endobronchial therapies can be durable, they are often used as a bridge to stabilize the patient for BAE.

BAE can be performed effectively to treat bleeding in the setting of not only acute massive hemoptysis but also chronic recurrent hemoptysis. The latter are commonly due to cystic fibrosis, bronchiectasis, malignancy, or TB.^{26–29}

Anatomy

Conventional

The lungs have dual blood supply from the bronchial arteries and the pulmonary artery. The bronchial arteries traditionally originate directly from the aorta, usually from the level of T3 to T8 with the majority between T5 and T6. On fluoroscopy, this is approximately 1 cm above or below the left main stem bronchus.³⁰ These vessels are small, receiving approxi-

mately 1% of cardiac output. They supply the bronchi, posterior mediastinum, vagus nerve, visceral pleura, aortic and pulmonary artery vasa vasorum, and the middle third of the esophagus.^{31–33} There is great variation to bronchial artery anatomy. There are four main configurations described in cadavers by Cauldwell and Siekert (►Table 1).³⁴ Bronchial arteries often arise from a common intercostal artery trunk. These vessels tend to arise more dorsal laterally off the aorta. Alternatively, the bronchial artery can arise alone directly from the aorta, often with a more ventral origin.³⁵

Variant Anatomy

Ectopic bronchial arteries, defined as a vessel originating outside of the aortic level of T5 to T6, are very common, with studies reporting up to 56% prevalence (►Figs. 1 and 2).³⁶ The most common site for ectopic bronchial artery is from the underside of the aortic arch.^{37,38} Other possible origins include the descending aorta, internal mammary artery, thyrocervical trunk, brachiocephalic artery, subclavian artery, phrenic artery, gastric artery, carotid artery, and even coronary artery.^{36,39,40}

Embolization

If available, the interventionalist should review the CTA as part of preprocedural planning to evaluate for location and size of the bronchial arteries. BAE should be performed with sedation, either nurse-administered moderate sedation or with monitored anesthesia support, depending on the clinical scenario. The patient may arrive already intubated from prior bronchoscopy, or to protect the airway. Whether the patient is intubated or not, it is important to have the ability to suspend respirations or have the patients hold their breath to obtain good angiographic imaging in the thorax. Most interventionalists perform BAE utilizing a common femoral artery access. In select cases of anomalous bronchial arteries, such as an origin from the subclavian, thyrocervical trunk, or internal mammary, it may be easier to access the bronchial arteries via a radial artery approach (►Fig. 2).

There is controversy in the literature on the need for a flush thoracic aortogram.^{9,14} While this can be helpful for identifying the origins of the bronchial arteries, it is less necessary in patients with a preprocedural CTA (►Figs. 3

Fig. 1 Ectopic bronchial arteries. (a) A 59-year-old man with massive hemoptysis in the setting of recent pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension was found to have multiple ectopic bronchial arteries (shown originating from the right internal mammary artery—arrow). (b) An ectopic left bronchial artery originating from the left gastric artery in the same patient. (c) The ectopic left bronchial originating from the left internal mammary artery in the same patient. (d) An ectopic left bronchial artery from the left phrenic in the same patient (arrow). (e) A 26-year-old woman with cystic fibrosis found to have an ectopic right bronchial artery from the right phrenic artery (arrow).

Fig. 2 A 59-year-old man with massive hemoptysis from the right lung. (a) The patient was found to have an ectopic right bronchial artery originating from the brachiocephalic artery (arrow). (b) Right radial access was subsequently utilized to successfully select and embolize the ectopic bronchial artery (arrow).

Fig. 3 (a) Flush thoracic aortogram demonstrates bilateral hypertrophied bronchial arteries in a 25-year-old man with cystic fibrosis and massive hemoptysis. Note the right bronchial artery has an ectopic origin from the underside of the aortic arch (arrow). (b) Selective angiogram of the abnormal, hypertrophied left bronchial artery. (c) Selective angiogram of the ectopic right bronchial artery shows a dilated, ectatic vessel with hyperemia.

Fig. 4 Flush aortogram prior to bronchial artery embolization shows bilateral intercostal arteries and an abnormal right bronchial artery with conventional anatomy (arrow).

and 4). The bronchial artery should then be selected. This is often done using a 4- or 5-Fr Cobra 2-shaped catheter or a reverse curve catheter such as a Simmons 1, Mickelson, or Headhunter. Selective digital subtraction angiography should be performed with special care taken to look for the anterior spinal artery. This vessel has a characteristic hairpin appearance (► **Fig. 5**) and can arise from the common

Fig. 5 A 61-year-old man presented with massive hemoptysis with angiogram of the left superior bronchial artery showing opacification of the anterior spinal artery with the characteristic hairpin turn (arrow). No embolization was performed of this vessel.

intercostal bronchial trunk.⁹ The bronchial artery should subsequently be more selectively catheterized with a microcatheter and wire. Imaging findings on selective angiography for hemoptysis include enlarged hypertrophied arteries, bronchial artery aneurysm, neovascularity, hyperemia, or active extravasation (► **Fig. 6**). It should be noted that active extravasation is not frequently seen and its absence should not preclude embolization.

Numerous embolics have been used for BAE. Gelatin sponge has several benefits including being widely available, easy to use, and inexpensive. However, gelatin sponge embolization will recanalize which can lead to recurrent hemoptysis. A recent study out of Japan comparing BAE with gelatin sponge found recurrence of hemoptysis after 1 year in 62% of pulmonary aspergillosis patients and 28% of patients

Fig. 6 A 41-year-old woman with history of cystic fibrosis presenting with massive hemoptysis. (a) CT angiogram reveals enlarged, ectatic bronchial arteries with one origin from the ventral thoracic aorta at the level of the carina (arrow). (b) Selective angiogram demonstrates enlarged right and left bronchial arteries with a common origin from the aorta. (c) Selective angiogram of the right bronchial artery post-embolization shows pruning of the vasculature.

who underwent BAE for other etiologies.⁴¹ Cases of recanalization and recurrent hemoptysis may necessitate repeat embolization.⁴²

Particles are commonly used for BAE. Particles greater than 300 μm in size should be selected to prevent passage of particles through the bronchopulmonary anastomosis, which have a mean diameter of 325 μm . This will decrease the risk of pulmonary infarct and systemic embolization.^{9,33} Additionally, larger particles decrease the risk of distal occlusion, which could lead to necrosis of numerous structures fed by the bronchial arteries. Polyvinyl alcohol (PVA) has traditionally been the particle embolic of choice for BAE. The recommended size is at least 300 to 500 μm . If prominent shunting is seen to the pulmonary arterial system, the size of the embolic should be increased (– Fig. 7). This is believed to decrease the risk of infarction of the anterior spinal artery as well.⁴³ Due to its irregular size and shapes, PVA tends to

Fig. 7 An 87-year-old man with a history of pulmonary embolism presenting with hemoptysis with angiogram showing significant left bronchial artery (black arrow) to pulmonary artery shunting (white arrow).

behave similarly with larger sized spherical embolics and can clump in the catheters and vessels, potentially making it difficult to complete embolization. Several studies have shown the more uniform tris-acryl microspheres (Embo-sphere) to be safe and effective for BAE. Reported sizes ranged from 500 to 700 and 700 to 900 μm with high rates of technical success.^{44,45} There are reports of other hydrogel microspheres, such as Embozene, being utilized successfully for BAE.⁴⁶ The interventionalist should choose whatever particle embolic they have available and are comfortable using, keeping in mind size parameters to mitigate the risk of ischemic complications or shunting into the pulmonary system.

The use of liquid embolics has also been described in the BAE literature. A study by Woo et al demonstrated the safety and efficacy of N-butyl-2-cyanoacrylate (NBCA) when compared with PVA. They showed that NBCA embolization resulted in fewer cases of recurrent hemoptysis and found no significant difference in technical success, short-term clinical success, or complications.⁴⁷ Similarly, ethylene vinyl alcohol has also been shown to be safe and effective for BAE, with high technical success and low rates of recurrence.⁴⁸ Liquid embolics can be technically challenging to use, so should only be used in the bronchial arteries by operators with experience with the agent, given the possible devastating complications of non-target embolization in this location.

Coils are rarely indicated for BAE as proximal embolization will preclude further access to the bronchial arteries if the patient has recurrence of bleeding. However, in the setting of a bronchial artery aneurysm, coils are often the embolic agent of choice and allows for successful occlusion of the aneurysm.⁴⁹ Coils have also been used in combination with other embolic agents in the setting of nonbronchial systemic collaterals or shunting.

Complications

While BAE can be a life-saving procedure, it is not without risk of complications. The most common complications are temporary back pain, chest pain, dysphagia, and post-embolic syndrome (fever, leukocytosis, and pain). Vascular

Fig. 8 A 57-year-old man status post-BAE for massive hemoptysis with paralysis. MRI demonstrates the classic high T2 signal “owl-eye appearance” on axial T2-weighted imaging (circle) seen with infarction of the anterior spinal artery. (Image courtesy of Keith Quencer, MD.)

injury can occur at the access site, or at the bronchial artery, resulting in pseudoaneurysm, dissection, or vessel perforation.

The most dreaded complication of BAE is non-target embolization. There are reports of claudication resulting from non-target embolization of particles to the lower extremities.^{50,51} Also reported are cases of bronchoesophageal fistula and ischemic colitis.⁹ Strokes are very rare but have been reported after BAE.^{52–54} This can result from shunting from bronchial arteries to pulmonary veins, or backflow of embolic. While also extremely rare, cortical blindness can also occur via similar mechanisms. While most cases are transient, there is a report of permanent cortical blindness after BAE.^{55,56}

Spinal cord ischemia is a well-documented serious complication of BAE and results from inadvertent embolization of the anterior spinal artery (► **Fig. 8**). This can lead to temporary or permanent paralysis with rates reported ranging from 0.19 to 6.5%.^{35,57} Given the seriousness of these sequelae, some authors consider visualization of the anterior spinal artery an absolute contraindication to BAE, while others advocate for subselective embolization in this setting. However, just because the interventionalist does not visualize the anterior spinal artery does not mean that the patient is safe; there are reports of paralysis after BAE where the anterior spinal artery cannot be visualized even on retrospective review of imaging.^{35,58}

Outcomes

Overall reported technical success rates for BAE range from 81 to 100%.¹⁴ BAE has been shown to be efficacious in specific patient populations. BAE can aid patients with lung cancer and hemoptysis; one study showed a complete clinical

success rate of 63.1% and partial clinical success in 19%.⁵⁹ It should be noted, however, that patients with lung cancer and hemoptysis have poor overall survival and will often have recurrent hemoptysis. Studies have also shown BAE to be safe and effective in patients with cystic fibrosis. One study showed a 3-year clinical success rate of 75%.⁶⁰

Recurrence can occur even after a technically successful BAE. This can be due to incomplete embolization, recanalization, or recruitment of new collateral vessels. In the setting of malignancy or cystic fibrosis, recurrence can also be due to progression of the underlying disease processes. Several factors have been associated with increased rates of recurrence: lung cancer, non-bronchial systemic collaterals, aspergilloma, reactivation or multidrug-resistant TB, and prominent vascular shunting.^{26,58,59,61,62}

Conclusion

Bronchial artery embolization has become mainstay therapy for many patients with both acute massive hemoptysis and chronic hemoptysis from a variety of etiologies. While this procedure can be lifesaving, with high rates of clinical and technical success, recurrence and complications can occur. The interventionalist needs to be familiar with classic and variant anatomy of the bronchial arteries, technical aspects of the procedure, and possible pitfalls and complications.
