ABSTRACT

Background: Studies indicate that muscle strength is associated with good mental health. However, it remains unclear whether muscle strength is directly correlated with psychological symptoms in Chinese adolescents. Given the declining muscle strength and worrying mental health status of Chinese adolescents, the present study aimed to estimate the correlation between muscle strength and psychological symptoms as well as explore the gender differences in those correlations in Chinese adolescents.

Method: From April to July 2018, a total of 14,344 Chinese adolescents from eight provinces were selected using a stratified clustered sampling method. Psychological symptoms were evaluated using the Multidimensional Sub-health Questionnaire of Adolescents (MSQA), a verified and validated questionnaire that assesses three psychological areas: emotional symptoms, behavioral symptoms, and social adaptation difficulties. Muscle strength was assessed using grip strength, sit-ups, and standing long jump. The Chi-square test was used to compare the detection rates of the different categories of psychological symptoms. A logistic regression analysis was used to analyze the correlations between muscle strength and psychological symptoms and explore the gender differences in those correlations in Chinese adolescents.

Results: In general, the detection rate of psychological symptoms for Chinese adolescents was 21.39%. Males had a higher detection rate of psychological symptoms (22.12%) than females (20.66%, $p < 0.05$). Psychological symptoms were present in significantly fewer Chinese adolescents with a muscle strength index $>P75$ (19.26%) than among Chinese adolescents with a muscle strength index $\leq P25$ (23.00%) ($\chi^2 = 23.417$, $p < 0.01$). Compared with females, the OR values for males in most groups were over one (OR = 1.04–1.43), indicating that males have a higher risk of psychological symptoms than females.

Conclusions: The psychological symptom detection rate of Chinese adolescents is correlated with muscle strength. Psychological symptoms were more correlated to muscle strength in males than in females. The significance of the present study lies in the important insights for integrated mental and physical fitness intervention strategies that promote muscle strength and psychological symptoms simultaneously.

INTRODUCTION

Adolescence is a difficult stage of life involving profound individual, biological, and social changes (Sawyer *et al.*, 2012; Viner *et al.*, 2012; Gore *et al.*, 2011; Patton & Viner, 2007). Muscle strength development during adolescence is an important component of physical fitness and is a predictor of health in early adulthood (Kawada, 2020; Garcia-Hermoso, Ramirez-Campillo & Izquierdo, 2019). The 2018 Physical Activity Guidelines for Americans recommend teenagers participate in muscle resistance exercises at least three times a week for a better, healthier life (Piercy *et al.*, 2018). Studies have shown that muscle strength in children and adolescents is a predictor of all-cause mortality, chronic cardiovascular disease, and even psychological health (Zhang *et al.*, 2022; Smith *et al.*, 2014; Perez-Bey *et al.*, 2018; Ludyga *et al.*, 2021; Rodriguez *et al.*, 2015). It was also reported that muscle strength in childhood has been shown to track into adulthood (Castillo-Garzon *et al.*, 2007) and is linked to future cardiovascular disease (CVD) risk (Grontved *et al.*, 2015).

Adolescents are prone to a variety of psychological symptoms such as non-suicidal self-harming behaviors, depression, hostility, and anxiety (Schoeps *et al.*, 2018; Kieling *et al.*, 2011; Perou *et al.*, 2013; Resnick *et al.*, 1997). According to relevant studies, about 10–20% of teenagers have at least one psychological symptom (Younger, 2016; WHO, 2020). More than 50% of adults have been diagnosed with some kind of mental illness, and the majority of symptoms reported in adulthood can be traced back to before the age of 14 years old (Xu *et al.*, 2019).

A study has suggested that muscle strength is associated with mental health outcomes in adults (Hwang & Ahn, 2021). A narrative review summarized that all eight cross-sectional studies included in the review reported significantly lower odds of having depressive symptoms with increased levels of muscular strength. This association persisted even after adjusting for several confounders including the level of physical activity, particularly in older people (Volaklis *et al.*, 2019). A longitudinal cohort study identified the bidirectional associations between handgrip strength and depressive symptoms in Chinese adults (Lian *et al.*, 2021). Low handgrip strength has also been found to be associated with poor mental health among Korean males (Hwang, Ahn & Choi, 2021). However, it remains unclear whether muscle strength is directly linked to psychological symptoms in Chinese adolescents.

Given the declining muscle strength (Dong *et al.*, 2021; Department of Physical Health & Arts Education Ministry of Education, 2021) and mental health status of Chinese adolescents (Xin, Niu & Chi, 2012; Zhang *et al.*, 2020a), the present study aimed to explore the correlation between muscle strength and psychological symptoms and explore the gender differences of those correlations in Chinese adolescents. We hypothesize that muscle strength is negatively correlated with the presence of psychological symptoms in

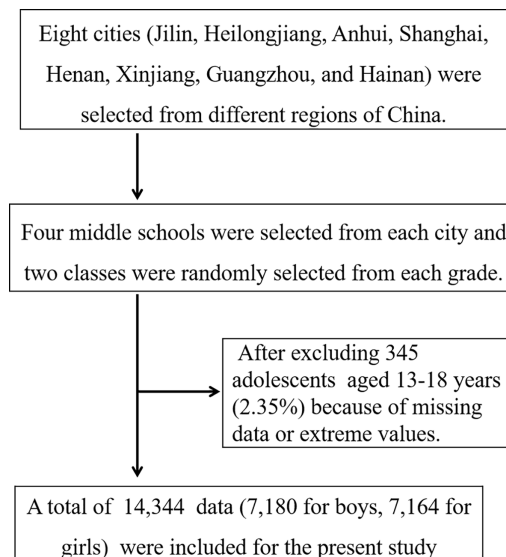

Figure 1 The flow of the participants in the trial.

Chinese adolescents and that psychological symptoms in males were more correlated to muscle strength than in females.

MATERIALS AND METHODS

Data source and participants

The study was conducted from April to July 2018. All students included in this study met the following conditions: (1) current student enrolled in school; (2) students of average intelligence as judged by the class teacher, and physically able to participate in the muscle strength test; (3) and voluntarily willing to participate in this study. Eight cities (Jilin, Heilongjiang, Anhui, Shanghai, Henan, Xinjiang, Guangzhou, and Hainan) were selected from different regions of China and four middle schools were selected from each region. Two classes were randomly selected from each grade and the eligible students in the selected class were recruited as participants. In total, 14,689 Chinese adolescents were surveyed by questionnaire and 14,344 valid responses were collected. The valid response rate was 97.65%, with a total of 7,180 male students and 7,164 female students submitting valid responses (Fig. 1). The age range of the surveyed students was between 13–18 years old and the average age was 15.51 ± 1.72 years old. The survey was approved by the Ethics Committee of the School of Physical Education, Shangrao Normal University, and was carried out after approval (2018R-0219). The study was conducted following the requirements of the World Medical Association Declaration of Helsinki. Written consent was obtained from the student participants and the schools and parents of the participating students.

Demographic information and general household survey

The questionnaire was compiled by experts after a thorough literature review, followed by a discussion and analysis of the results (Tao, 2017). Demographic information obtained

from the general household survey included: age, gender, grade level, the region and city (town) of the surveyed participants, the vocations and educational backgrounds of their parents, and annual family income.

Muscle strength test

The muscle strength test included three items: a grip test to measure upper limb strength, sit-ups to measure torso strength, and a standing long jump to measure lower limb strength. The tests were administered following the methods required by the National Student Physical Health Survey (*CNSSCH Association, 2007*). The instruments were calibrated before use every day by the PE teachers. These teachers filled in the test results on the test cards of the students. Grip strength was tested by an electronic grip dynamometer (CAMRY EH101, Guangdong, China) to 0.1 kg, the students were required to stand relaxed with arms naturally drooping, and hold the grip dynamometer in one hand with full force for at least 2 s. The test was conducted twice and the larger value was recorded as the result. Standing long jump was tested after preparing for the ankle joint and knee joint. The students stand on the starting line with two-foot shoulders-with apart and jump out from the starting line as best as they can. The distance between the starting line with the heel of the foot closest to the starting line was recorded as 0.1 cm. Each student tried three times and the larger value was recorded as the result. Sit-up was tested on a yoga mat. Students lie on their back with their legs naturally bent, hands by their ears. After receiving the start signal, they sat up with their forehead touching their knees and went back to the start position repeatedly for 60 s. The number of times the hands touched the knees was recorded as the result. The result was standardized to obtain the Z value for the three muscle strength tests. For example, $Z_{\text{grip strength}} = (\text{actual test score} - \text{national average score of the age}) / \text{national standard deviation of the age}$. The average score by age and the national standard deviation by age were obtained from the Chinese National Survey on Students' Constitution and Health in 2014 (*CNSSCH Association, 2007*). The muscle strength index was calculated by adding the three test Z scores together: $\text{Muscle strength index} = Z_{\text{grip strength}} + Z_{\text{sit-ups}} + Z_{\text{standing long jump}}$. The muscle strength level was then used to divide the study participants into four groups by quartile ($\leq P25$, $P26-50$, $P51-75$, $>P75$) and the presence of psychological symptoms within each group was then compared.

Survey of psychological symptoms

The Multidimensional Sub-health Questionnaire of Adolescents (MSQA) by *Tao et al. (2008)* was used to measure the psychological symptoms of Chinese teenagers in this study. This questionnaire has 39 entries grouped into three topic areas: emotional symptoms (eight entries), behavioral symptoms (eight entries), and social adaptation difficulties (13 entries). Each entry has six options to describe the duration of psychological symptoms and the participants choose one option that can best reflect their status. Options that described the duration over one month (*e.g.*, more than 2 months) were recorded as 1 score. The remaining options were recorded as 0 scores. If the scores reached 3, 1, and 4 for the three topic areas, the students were defined as having emotional symptoms, behavioral

symptoms, and social adaptation difficulties respectively. The total score was obtained by adding the scores of the three topic areas up. If the total score was ≥ 8 , the students were defined as having psychological symptoms. This scale has been validated by many studies (Zhang *et al.*, 2020b; Tao *et al.*, 2020). The questionnaire has good credibility and the Cronbach α coefficient of the scale is 0.963 (Xing *et al.*, 2008; Qi *et al.*, 2008). The authors also obtained permission to use this instrument from the copyright holders.

Quality control

Trained specialists were asked to survey the students. A total of six to eight specialists were assigned to each of the four groups and the surveys of the students were simultaneously conducted at schools in different cities. The questionnaires were filled out anonymously. The students were asked to fill them out independently after school and the questionnaires were retrieved on site. Any incorrect or missing fields were completed by the students to ensure the validity and completeness of the questionnaire.

Stats and analysis

The χ^2 value was used to compare the detection rates of the psychological symptoms of Chinese adolescents. The presence of psychological symptoms was used as the dependent variable in the logistic regression analysis of the muscle strength of Chinese adolescents and psychological symptoms. The logistic regression analysis was conducted to explore the gender differences between males and females on psychological symptoms influenced by muscle strength. The data were entered twice using EpiData3.1 (EpiData Association, Odense, Denmark) and analyzed with SPSS25.0 (SPSS Inc., Chicago, IL, USA) and $\alpha = 0.05$ was set as the two-sided test level.

RESULTS

Table 1 shows that the psychological symptom incidence among the Chinese adolescents studied was 21.4%. Among the three psychological areas, the detection rate of emotional symptoms (27.7%) and behavioral symptoms (27.5%) was higher than that of social adaptation difficulties (17.1%). Males (22.1%) had a higher detection rate of psychological symptoms than females (20.7%, $\chi^2 = 4.535$, $p = 0.033$). The detection rate of psychological symptoms was 19.3% for adolescents with a muscle strength index $>P75$, which was significantly lower than among those with a muscle strength index $\leq P25$ (23.0%, $\chi^2 = 23.417$, $p < 0.001$).

Table 2 shows the logistic regression analysis of psychological symptoms of Chinese adolescents. The results show that Chinese adolescents with a standing long jump score $<P25$ have a higher risk of psychological symptoms than those with a standing long jump score $>P75$ (OR = 1.14, 95% CI [1.03–1.26], $p = 0.02$). A similar result was found for the overall muscle strength index (OR = 1.18, 95% CI [1.06–1.30], $p < 0.001$).

A logistic regression analysis of psychological symptoms was also conducted after stratification by gender (Table 3). The results show that males with a grip strength $\leq P25$ (OR = 1.23, 95% CI [1.02–1.48], $p = 0.03$) and a muscle strength index $\leq P25$ (OR = 1.30, 95% CI [1.10–1.52], $p < 0.001$), P26–50 (OR = 1.22, 95% CI [1.04–1.44], $p = 0.02$) or

P51–75 (OR = 1.30, 95% CI [1.10–1.55], $p < 0.001$) have a higher risk of psychological symptoms than those with a muscle strength index >P75. Females with a muscle index ≤P25 (OR = 1.21, 95% CI [1.02–1.42], $p = 0.03$) or P26–50 (OR = 1.29, 95% CI [1.10–1.51], $p < 0.001$) have a higher risk of psychological symptoms than those with a muscle strength index >P75. Figure 2 shows a diagram of the OR value (95% CI) for the regression analysis of the psychological symptoms of Chinese adolescents.

Figure 3 shows the diagram of the OR value (95% CI) for the regression analysis of psychological symptoms for Chinese males. Compared with females, the OR values for males in most groups were over one (OR = 1.04–1.43), indicating that males have a higher risk of psychological symptoms than females and that psychological symptoms are more correlated to muscle strength for males than females.

DISCUSSION

The present study used a large sample of Chinese adolescents to explore the correlation between muscle strength and psychological symptoms, concluding that the detection rate of psychological symptoms for Chinese adolescents with a muscle strength index >P75 (19.26%) was significantly lower than among those with a muscle strength index ≤P25 (23.00%) ($\chi^2 = 23.417$, $P < 0.01$). Compared with females, the OR values for males in most groups were over one (OR = 1.04–1.43), indicating that males have a higher risk of psychological symptoms than females.

According to this study, 21.39% of Chinese teenagers had psychological symptoms. These results are higher than those of *Tao et al. (2020)* (11.2%) and lower than those of *Liang et al. (2016)* (22.9%) (*Tao et al., 2020; Liang, 2016*). These differences in results are likely due to differences in survey times and the recall ability of the students surveyed. Otherwise, the high prevalence of psychological symptoms among Chinese adolescents needs to be concerned.

When divided by demographics, male junior high school students had a higher detection rate of psychological symptoms than female students, which is in concordance with the result of *Wu (2019)*. It was reported that male teenagers typically have more bad health habits than female teenagers, such as more time spent playing online games or watching videos (*Zapata-Lamana et al., 2021*), smoking (*Skvortcova & Lushkina, 2018*),

and drinking (Chung *et al.*, 2018), resulting in a higher rate of psychological symptoms (Silva *et al.*, 2021). The detection rate of psychological symptoms of junior high school students was higher than that of senior high students, which can be attributed to the fact that junior high school students are in a rather unstable state of mind at the peak of their puberty, while high school students have better psychological knowledge and can better adjust to their psychological state (Zhang *et al.*, 2020a). Our study also found a higher rate of psychological symptoms among students in the country regions compared with urban students, which can be explained by disparities in educational resources and emphasis on psychological health between rural and urban schools (Chen *et al.*, 2019). Rural students are also more likely to have parents with lower educational levels than urban students and there is likely less emphasis placed on mental health in these homes. This implies that the higher the academic level of the parents, the lower the incidence of psychological symptoms among the students, which is also the conclusion of Kandola *et al.* (2020). The hypothesis is that parents with higher levels of education are more aware of the importance of psychological health and how to get help when their children have psychological symptoms (Ekelund *et al.*, 2016). Another finding of our study is that the higher the family income, the lower the incidence of psychological symptoms among Chinese teenagers. Family income is correlated to the educational attainment of the parents, corresponding with a better emphasis on mental health and more access to resources when help is needed (Tang *et al.*, 2021). These results indicate that more emphasis should be placed on the psychological development and mental health of rural students and on cultivating a better environment for the psychological development of these students.

Our study found that Chinese adolescents with a lower percentile of muscle index (*e.g.*, <P25, or P26–50) have a higher risk of psychological symptoms than those with a higher muscle strength index (*e.g.*, >P75). In one study (Zhang *et al.*, 2020b), the students whose muscle strength levels were higher had better physical activity levels and performed better in teamwork and socializing, both of which play a positive role in lowering psychological symptoms. Another study (Szeremeta, Grzywacz & Czarny, 2020) found that students with higher muscle strength levels spent more time participating in extracurricular sports and they usually communicated better with their partners, two things that also have a positive impact on lowering psychological symptoms.

We also found that compared with females, the muscle strength of males is a more significant factor in the presence of psychological symptoms. Males always perceive several benefits to becoming more muscular and they wanted to be more muscular because they believe that it would make them feel more confident and more attractive to women (*Frederick et al., 2007*). However, masculinities are often associated with poor mental health and well-being outcomes for men (*Clark et al., 2020*) and they are reluctant to seek professional psychological help because of the traditional ideas of masculinity that being stronger and self-reliant (*Staiger et al., 2020*). This vicious cycle implies that more attention should be put on the muscle strength level and psychological symptoms of males.

STRENGTHS AND LIMITATIONS

Using a large national sample, this study is the first to analyze the correlation between the muscle strength of Chinese adolescents and the presence of psychological symptoms. This study also has some limitations. This is a cross-sectional survey, therefore, it was capable of identifying correlation but not causation. Longitudinal studies are needed to explore the causal relationship between psychological symptoms and muscle strength in Chinese adolescents. We also used self-evaluated questionnaires to estimate psychological symptoms, which are inherently limited by the memory recall ability of the participating students.

CONCLUSIONS

Our original study found that the presence of psychological symptoms in Chinese adolescents is correlated with muscle strength. For males, the correlation between psychological symptoms and muscle strength was stronger than for females. The significance of the present study is that it provides insights into the importance of integrated mental and physical fitness intervention strategies that promote muscle strength and psychological symptoms in Chinese adolescents simultaneously. Targeted intervention and guidance for males and females should be separated for better psychological development.

ACKNOWLEDGEMENTS

We thank the students and parents who participated in this study, as well as the staff who participated in the data testing of this study.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

The research is supported by the 2017 national general project of the 13th five-year plan of the National Education Science: Research on Rural School Development (1949-2017) (NO. bha170138). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Grant Disclosures

The following grant information was disclosed by the authors:

National Education Science: Research on Rural School Development (1949-2017): bha170138.

Competing Interests

The authors declare that they have no competing interests.

Author Contributions

- Jinkui Lu conceived and designed the experiments, authored or reviewed drafts of the article, and approved the final draft.
- Hao Sun conceived and designed the experiments, performed the experiments, prepared figures and/or tables, authored or reviewed drafts of the article, and approved the final draft.
- Ningling Liu conceived and designed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the article, and approved the final draft.
- Jianhua Qiu performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the article, and approved the final draft.
- Xiaofei Xia performed the experiments, analyzed the data, prepared figures and/or tables, and approved the final draft.

Human Ethics

The following information was supplied relating to ethical approvals (*i.e.*, approving body and any reference numbers):

The survey was approved by the Ethics Committee of the School of Physical Education, Shangrao Normal University and was carried out after the approval.

Data Availability

The following information was supplied regarding data availability:

The raw measurements are available in the [Supplemental File](#).

Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.14133#supplemental-information>.
