## ABSTRACT

**Background:** Cognitive impairment is a major challenge for elderlies, as it can progress in a rapid manner and effective treatments are limited. Sarcopenic elderlies have a higher risk of dementia. This scoping review aims to reveal whether muscle is a mediator of cognitive function from pre-clinical evidence.

**Methods:** PubMed, Embase, and Web of Science were searched to Feb 2nd, 2022, using the keywords (muscle) AND (cognition OR dementia OR Alzheimer) AND (mouse OR rat OR animal). The PRISMA guideline was used in this study.

**Results:** A total of 17 pre-clinical studies were selected from 7638 studies. 4 studies reported that muscle atrophy and injury harmed memory, functional factors, and neurons in the brain for rodents with or without Alzheimer's disease (AD). 3 studies observed exercise induced muscle to secrete factors, including lactate, fibronectin type III domain-containing protein 5 (FNDC5), and cathepsin B, which plays essential roles in the elevation of cognitive functions and brain-derived neurotrophic factor (BDNF) levels. Muscle-targeted treatments including electrical stimulation and intramuscular injections had effective remote effects on the hippocampus. 6 studies showed that muscle-specific overexpression of scFv59 and Neprilysin, or myostatin knockdown alleviated AD symptoms. 1 study showed that muscle insulin resistance also led to deficient hippocampal neurogenesis in MKR mice.

**Conclusions:** The skeletal muscle is involved in the mediation of cognitive function. The evidence was established by the response in the brain (altered number of neurons, functional factors, and other AD pathological characteristics) with muscle atrophy or injury, muscle secretory factors, and muscle-targeted treatments.

**The translational potential of this paper:** This study summarizes the current evidence in how muscle affects cognition in molecular levels, which supports muscle-specific treatments as potential clinical strategies to prevent cognitive dysfunction.

## 1. Introduction

The brain is a vital part of the central nervous system (CNS), dominating our cognitive function and movements. On the other hand, the skeletal muscle is the largest organ of peripheral tissues, and responds to instructions from the brain via signal transductions by motor neurons. With the ageing population, patients suffering from dementia and sarcopenia has risen significantly [1,2]. The estimated global prevalence of dementia has been projected to 152.8 million by 2050, which is almost 3-fold higher than in 2019 [2]. The healthcare cost for Alzheimer's disease (AD) was also estimated to be \$305 billion in 2020 [3]. Sarcopenia is as an age-related muscle disorder, characterized by progressive loss of

muscle mass and function [4]. The prevalence of sarcopenia is approximately 27% in the elderly [1]. Similar to dementia and AD, sarcopenia is also strongly associated with higher mortality, disability and poor quality of life [5–8]. Interestingly, cross-sectional studies have shown that muscle strength and functional performance were inversely related to cognitive function in the older population [9,10]. Recent literature has reported that sarcopenia was independently associated with cognitive impairment [11], with odds ratio 2.85 times higher compared to control subjects [12]. Brain disorders contribute to malnutrition and muscle disuse, and may ultimately lead to sarcopenia [13,14]. A cohort study also reported that sarcopenic individuals had a faster rate of cognitive decline and higher risks of incident AD (hazard ratio 1.50, 95% CI 1.20

Received 11 August 2022; Received in revised form 25 September 2022; Accepted 5 October 2022

to 1.86) after following an average of 5.6 years [15]. Recently, a larger cohort involving over 8000 elderly demonstrated that the 3-year cognitive decline was faster in old people with lower lean mass [16]. This had led to postulations of the mediating role of muscle in cognitive function.

Irreversible memory loss and brain dysfunctions brought by AD has led to substantial research. Unfortunately, there are still limited efficient strategies to suspend the progression of AD. Similar to the brain, the skeletal muscle has an abundant amount of nerves, and degenerate together with the CNS with age [17]. Recent evidence from pre-clinical studies also showed that muscle loss promoted cognitive dysfunction in mice with AD [18]. As of now, numerous treatments have dual effects on the muscle and brain, especially the function of the hippocampus, including exercise and dietary supplements. For instance, aerobic and resistance training, alpha-ketoglutarate supplements, and ketogenic diets improve both muscle and brain status [19–22]. However, it is still unclear whether muscle is a mediator of cognition remodeling [23]. The alteration of gut microbiota and its metabolites can also influence remote organs under disease states or during interventions [24,25]. In patients with congestive heart failure, those with gut microbiota dysbiosis and less beneficial microbial metabolites (short-chain fatty acids) were associated with lower muscle quality and cognitive function [26]. The gut microbiota may also be a medium between muscle and cognition [27]. Previous reviews lacked a comprehensive summary in how muscle affects cognitive function [11,28–32]. Whether muscle can be a potential target to enhance cognitive function should be proven in pre-clinical studies for further clinical translation. To explore how muscle affects cognitive function, we performed a scoping review to summarize the underlying pathways, and the muscle-targeted interventions that can alter cognitive function.

## 2. Methods

### 2.1. Search strategy

3 databases PubMed, Embase, Web of Science were utilized for study extraction. The latest search access was Feb 22nd, 2022. The keyword search was “(muscle) AND (cognition OR dementia OR Alzheimer) AND (mouse OR rat OR animal)”. Additional studies from other reviews were also manually searched. This review complied with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [33].

### 2.2. Search criteria

The inclusion criteria of this review were: 1) pre-clinical studies, 2) studies in how skeletal muscle affects the brain or cognition, 3) muscle-targeted treatments that alter brain function or structure. The exclusion criteria were: 1) review articles 2) conference and abstract publication, 3) no mechanism on how muscle affects the brain, 4) rare genetic diseases. The screening of studies was conducted by two reviewers (C. Liu, and P.Y. Wong) independently. Briefly, the two reviewers screened the titles and abstracts to include as many potential eligible studies. The full text of these studies were screened, and final eligible studies were included. Any disagreements were decided with a third researcher (R.M.Y. Wong) according to the inclusion and exclusion criteria.

### 2.3. Data extraction and analysis

The data extraction including author, year, animal model, intervention, end-points, assessments, and outcomes (cognitive function, brain, or muscle), as well as key findings were executed. As the heterogeneity was high in the pre-clinical studies, a qualitative review was performed. SYRCL's risk of bias was performed to evaluate the risk of bias in the included animal studies [34]. The indicators with  $p < 0.05$  were shown by arrows in Supplemental Table 1, while those without significant

differences were described.

## 3. Results

A total of 7638 records were identified through the database search (Fig. 1). After removal of duplicates, 6323 studies were selected for further screening. 77 studies with full texts were reviewed. 17 pre-clinical studies meeting the inclusion and exclusion criteria were finally included. Details of selected studies were shown in Supplemental Table 1. The overview of bias assessment was displayed as percentages (Fig. 2) and details of each study were shown in Supplemental Table 2. Most types of bias had relatively low risks except for blinded group allocation and intervention with more than 50% studies judged as high risks.

### 3.1. Animal models

Amongst the 17 studies, 8 studies used non-transgenic mice and rats, including C57BL/6 mice in 5 studies [22,35–38], BALB/C mice in 2 studies [38,39], Wistar rats in 1 study [40], and Sprague Dawley rats in 1 study [41]. AD animal models were shown in 5 studies. 3 studies used amyloid precursor protein/presenilin-1 (APP/PS1) mice [42–44], 1 study used 5 × FAD mice [18], and 1 study used 3xTg-AD mice [45]. Muscle-specific gene knockout mice were also utilized in 3 studies. 2 studies used MCK-peroxisome proliferator-activated receptor co-activator-1 $\alpha$  (PGC1 $\alpha$ ) mice with the overexpression of PGC1 $\alpha$  in skeletal muscle [46,47], whilst 1 study used MKR transgenic mice with impaired insulin-like growth factor 1 (IGF-1) and insulin signaling in skeletal muscle [48]. The total body gene knockout CX3CR1<sup>GFP/+</sup> (green fluorescent microglial cells) and cathepsin B (CTSB)<sup>-/-</sup> mice were used in 2 studies [22,49]. 1 study utilized Rhesus monkeys to verify the findings from mouse studies [22].

### 3.2. Study designs to explore how muscle affects cognitive function

There were 3 main strategies to investigate how muscle affects the cognitive function. Firstly, brain function changes after muscle atrophy and injury interventions can be considered as affected by skeletal muscle, which were performed in 4 animal studies. The outcomes of brain included the composition of neurons, brain functional factors, behavioral performances, signaling pathways, and other AD symptoms, such as amyloid beta (A $\beta$ ) deposits. 3 studies conducted tail suspension or hindlimb cast-immobilization to induce muscle atrophy [18,40,41], and 1 study used the muscle injury animal model by freezing the tibialis anterior [49]. Nagase et al. detected that muscle secreted hemopexin demonstrated the potential molecular pathways of factors delivery from muscle to brain [18].

Secondly, 3 studies discovered muscle-secreted factors after exercises, which play significant roles in brain function [22,36,38]. Amongst the secreted factors, two were found from the preconditioned muscle cell culture conditional mediums. Through confirmation by exogenous or endogenous periphery supplements, inhibitors, and gene knockout, the effects of the muscle secretions after exercise or immobilization on the brain could be established.

Thirdly, muscle-targeted treatments also aid in the exploration of mechanisms, which were shown in 11 studies. 2 studies used electrical stimulation to induce muscle contraction [35,40]. 1 study treated the muscle of older mice with mechanical strained muscle-resident mesenchymal stem/stromal cells (mMSCs) from young mice [37]. 1 study injected the muscle with BOTOX® [39]. 4 studies utilized adeno-associated viruses (AAV), plasmid, and short hairpin RNA (shRNA) to interfere gene expressions of muscle [42–45], whilst 3 studies directly used muscle-specific transgenic mice [46–48]. After the alterations of skeletal muscle, the corresponding changes of brain were the primary outcomes to show if there was a related pathway from the muscle to cognitive change.

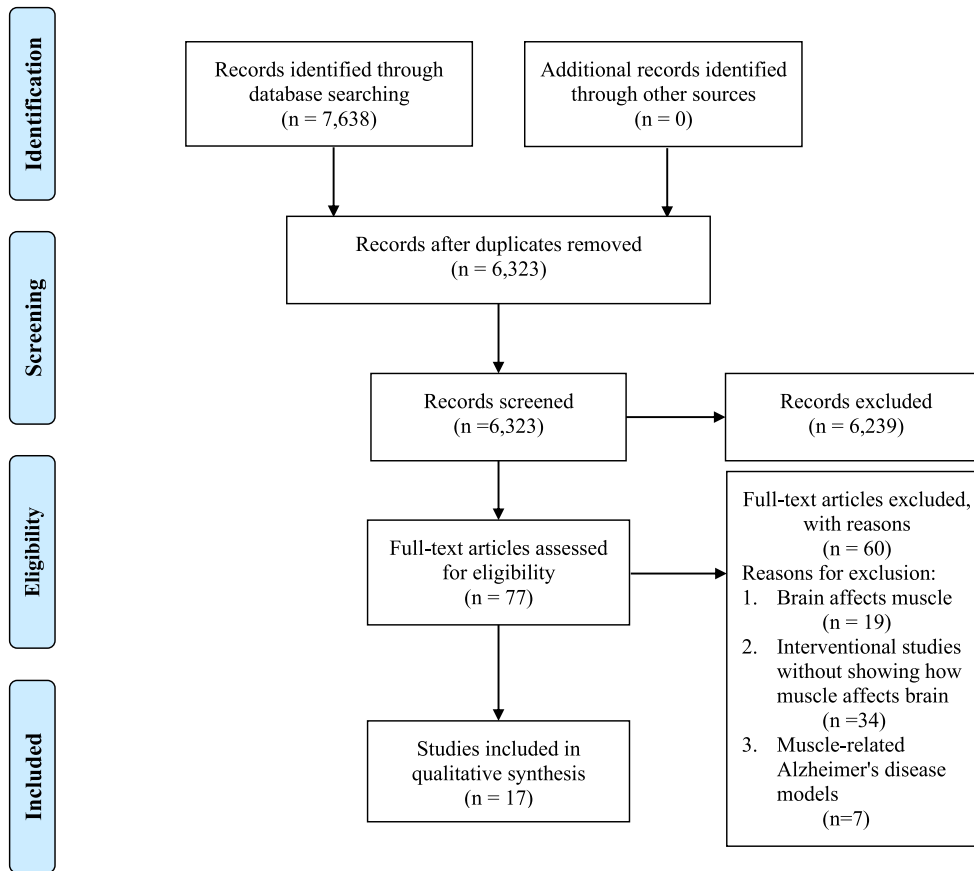

Fig. 1. PRISMA flow diagram.

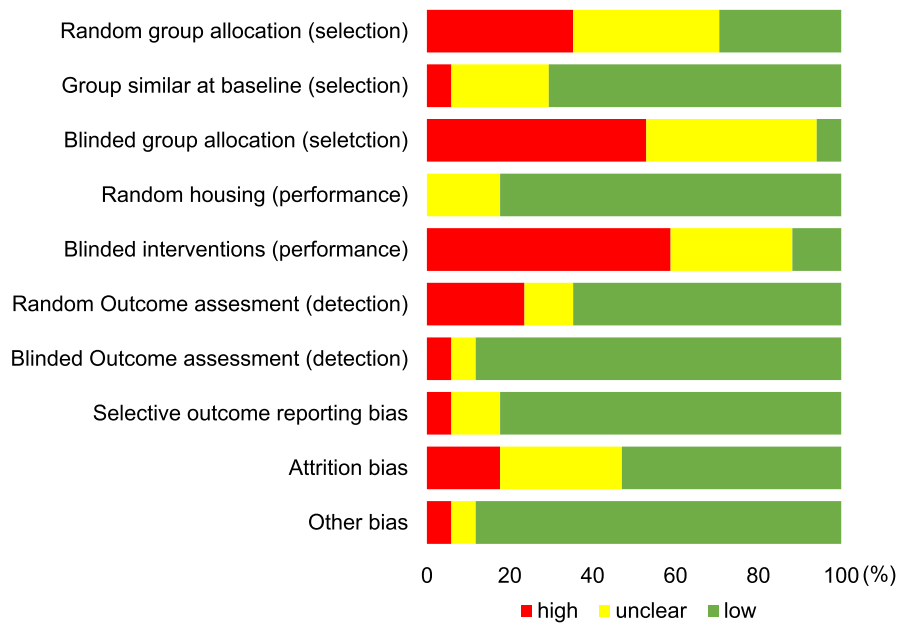

Fig. 2. Results of SYRCLE's tool for assessing the risk of bias.

### 3.3. Outcome assessments of cognition

All 17 studies assessed cognitive indicators, such as cognitive functional tests, brain histology, as well as the expression of mRNA and

protein levels. Cognitive functional tests were performed in 10 studies. Morris water maze test, fear conditioning test, open field test, and object recognition test were most widely used. Brain tissue staining were shown in 13 studies to recognize different cells in brain regions by staining with

Nissl, or antibodies against Ki67, doublecortin (DCX), neuronal nuclear protein (NeuN), bromodeoxyuridine (BrdU), glial fibrillary acidic protein (GFAP), cFos, S100, Nestin, ionized calcium binding adaptor molecule 1 (Iba1) and CD11b. Table 1 shows the cell types corresponding to staining results. To detect the small molecules, 10 studies evaluated the brain levels of brain derived neurotrophic factor (BDNF), nerve growth factor ( $\beta$ -NGF), hemopexin, A $\beta$ , lactate, CTSB, or fibronectin type III domain-containing protein 5 (FNDC5). 8 studies executed polymerase chain reaction (PCR) or western blot analysis of brain tissue. As the amount of the extracted protein from brain tissue, especially in the hippocampus was lower, enzyme-linked immunosorbent assay (ELISA) was used in 6 studies to accurately measure protein contents. Please refer to Supplemental Table 1.

### 3.4. Key findings of underlying pathways and muscle-targeted interventions affecting cognitive function

4 studies revealed that muscle atrophy or injury induced memory decline, learning capacity reduction, decreased immature neurons and normal microglial, increased A $\beta$  deposit, and lower levels of  $\beta$ -NGF in brain [18,40,41,49]. In contrast to muscle atrophy, muscle injury enhanced BDNF concentrations in brain [49]. Muscle secreted hemopexin after immobilization, and the cerebrospinal fluid injection of hemopexin reproduced the accelerated cognitive dysfunction [18]. The regulations of brain lipocalin-2 (Lcn2), ERK1/2, BDNF,  $\beta$ -NGF, hemopexin, and A $\beta$  levels were potential pathways when muscle was under an unfavorable status.

The effects of exercise on the brain with muscle as a mediator was shown in 3 studies. The well-known lactate was released by muscle, and raised in the plasma and hippocampus after exercise [36]. Mice with exercise or lactate injection had activation of Sirt1, enhanced levels of PGC1 $\alpha$  and FNDC5 expression, as well as hippocampal BDNF levels and cognitive functions. The injection of lactate transporter inhibitor weakened the benefits of exercise. The lactate-induced BDNF improvement were Sirt1-dependent proven by *in vitro* studies. Running also related to the increased CTSB in the muscle of mice, and CTSB could cross the blood–brain barrier [22]. CTSB<sup>-/-</sup> mice showed depression-like behavior, decreased hippocampal P11, and attenuated exercise-induced DCX + cells increment. The recombinant CTSB administration of

**Table 1**

Brain tissue staining: reagent, results, and corresponding cells.

Staining reagent	Results and corresponding cells
Immunohistochemistry (IHC) staining with anti-Ki67, and anti-DCX antibodies	DAPI+/Ki67+ cells = cells in mitotic phase DCX + cells = immature neurons DAPI+/Ki67+/DCX + cells = mitotic immature neurons
IHC staining with anti-Nestin, anti-DCX, and anti-GFAP antibodies	Nestin+/DCX- cells = neural progenitor cells Nestin+/DCX + cells = proliferating neuroblasts Nestin-/DCX + cells = immature neurons Nestin+/GFAP + cells = neural stem cell Nestin-/GFAP + cells = mature astrocytes GFAP + cells = astrocytes
IHC staining with anti-BrdU, and anti-NeuN antibodies	BrdU + cells = newly generated cells NeuN + cells = neuronal cell bodies NeuN+/BrdU + cells = new mature neurons
IHC staining with anti-BrdU, and anti-S100 $\beta$ /S100 antibodies	BrdU+/S100 $\beta$ + cells = new astrocytes S100 + cells = astrocytes
IHC staining with anti-Iba1 or anti-CD11b antibodies	Iba1 + or CD11b + cells = activated microglia
IHC staining with anti-cFos antibody	cFos + cells = cells with neuronal activation
Cresyl Violet	Nissl substance in neurons

neural cells facilitated the *Dcx* and *Bdnf* expression. In monkey and human, the plasma concentration of CTSB also elevated after exercise. Exercised mice had higher expressions of *Fndc5* and *Pgc1 $\alpha$*  in muscle, as well as *Fndc5* and *Bdnf* in hippocampus compared to sedentary mice [38]. FNDC5 is known to secrete irisin after proteolysis, and plays positive roles in hippocampal functions. The expression of peripheral FNDC5 increased the plasma irisin levels, and the hippocampal gene expressions of *Bdnf*, *Npas4*, *cFos*, *Arc*, and *Zif268*. Therefore, the increments of brain BDNF and other functions by exercise were associated with muscle secretory factors.

Additionally, 2 studies showed that common methods of promoting muscle contraction by dynamic foot stimulation (DFS) and sciatic nerve electrical stimulation could benefit immature migrating neurons and astroglialogenesis in the brain [35,40]. The intramuscular injection of BOTOX<sup>®</sup> and preconditioned mMSCs benefited memory and hippocampal neurons of mice [37,39]. Genetic interventions were performed in 7 studies. Skeletal muscle Nepriylsin (an A $\beta$  peptide-degrading enzyme) overexpression ameliorated the A $\beta$  load and memory decline of AD mouse models [42,45]. The inhibition of myokine myostatin enhanced the contextual freezing time of APP/PS1 mice [43]. The muscle delivery of scFv59 (an anti-A $\beta$  antibody) to the AD mice increased muscle scFv59 expression, and alleviated A $\beta$  deposits in hippocampus and neocortex [44]. 2 studies reported that overexpressed PGC1 $\alpha$  in skeletal muscle could not promote the neurogenesis and brain *Bdnf* expression in older mice as exercise did [46,47]. MKR mice as the obesity-independent type-2 diabetes mellitus model, displayed insulin resistance of skeletal muscle and a lower number of new neurons in the hippocampus [48]. Numerous muscle-related treatments improved the brain function and neurogenesis, although some failed.

## 4. Discussion

Although skeletal muscle and brain are physically distant, there is increasing evidence showing that there is a bi-directional interaction [50]. The CNS controls muscle movement via neural and chemical signal transduction. Specifically, motor neuron endings and motor endplates of muscle fibers form the neuromuscular junction (NMJ). Electrical signals from lower motor neurons stimulate the release of neurotransmitters which bind with the receptor of endplates to induce muscle contraction [51]. In addition to the well-known muscle regulation by motor neurons, cognitive dysfunction induces physical inactivity and appetite loss, leading to a higher risk of sarcopenia [52,53]. The sensory nerve is also a bridge between muscle and brain. For instance, muscle spindle and Golgi tendon organ as proprioceptors can inform muscle activity to the CNS via sensory feedback [54]. Clinical studies have recently presented that muscle also affects cognitive function, but the underlying mechanisms are unclear [15]. In this review, we comprehensively reviewed how muscle affects cognition from the evidence of pre-clinical studies. Mice and rats were mainly used to study the relationship between muscle and brain. AD animal models were specifically used in 5 studies. With the development of gene editing technology, muscle-specific gene knock-down, knockout, or overexpression is favorable for investigations in this field. Therefore, AD animal models and muscle-specific gene alteration models can be considered in future relevant studies.

There are various studies that focused on both muscle and brain, however, only few can explain the effects of muscle on cognition due to the study design. Despite the obvious association of muscle loss and cognitive dysfunction in clinical findings, the causality and underlying mechanisms should be conducted by interventional studies [11]. 3 main interventional methods were conducted. The simplest approach is to alter muscle status, such as atrophy and injury inductions. Considering ethical issues, utilizing muscle atrophy or injury animal models appears to be more appropriate. Diverse whole-body treatments have been raised to promote both muscle and brain functions, and exercise is one of the hotspots [21,50]. As muscle is an endocrine organ, the key points in observing the role of muscle in these kinds of treatments is to discover the

muscle-derived molecules, which can be assisted by modern sequencing analysis [28]. In addition to muscle, exercise can also benefit other organs, such as liver and adipose tissue [50]. Fibroblast growth factor 21 (FGF21) and insulin-like growth factor 1 (IGF1) as exercise factors instead of muscle factors contributed to cognitive enhancements, since they are not mainly secreted by muscle [50]. Therefore, it is essential to ensure the interested factors are secreted by skeletal muscle in order to confirm the mediator role of muscle. Another approach is to use muscle-specific interventions, including gene editing, injections of AAV, small interfering RNA (siRNA), shRNA, MSCs, plasmid DNA vector, or special biomaterials. It should be noticed that muscle is also a medium of drug injection, called intramuscular injection [55]. If treatments do not change muscle characteristics, the skeletal muscle would not be able to mediate the brain or cognition. Although neuroscience advances rapidly, and novel techniques including neural tracing are proposed, there is little evidence indicating that muscle can regulate cognitive function in turn via the neural connection [56]. In addition to humoral and circulatory systems, the underlying neural pathways of muscle and brain are necessary in future investigations. The gut microbiota is also an important regulator of various systems including musculoskeletal system and nervous system. Germ-free AD mice had reduced AD-like pathologies and microbiota transplantation of AD patients aggravated the symptoms of AD mice [57], whilst germ-free mice had lower muscle mass, and could be improved after the microbial transplantation from pathogen-free mice [58]. Therefore, the gut microbiota, muscle, and brain might interact with each other [27]. In summary, current evidence shows that muscle atrophy models, muscle-derived factors, and muscle-specific treatments are the important components to build the relationship between muscle and cognitive function.

The skeletal muscle plays an important role in different subregions of the brain (cerebrum, hippocampus, neocortex, dentata gyrus, entorhinal cortex, subgranular zone) by regulating learning capacity and memory, numbers of immature neurons, astrocytes and pyramidal neurons, neuronal activity, synaptic plasticity (ARC, ZIF268), BDNF and  $\beta$ -NGF levels, A $\beta$  deposit, as well as the brain expression of ERK1/2, SIRT1,

PGC1 $\alpha$  and P11 (Fig. 3). Postoperative muscle disuse and cognitive dysfunction are prevalent in old patients [59,60]. Rodents with preoperative or perioperative muscle atrophy or injury suffered poor memory, decreased brain functional factor levels and cRaf/ERK1/2 pathway activation indicating that muscle may be a regulator of neuronal differentiation and cognitive function [41,49]. However, tail suspension method to induce muscle atrophy in animals also increases the cerebral vascular resistance, which may be a confounding factor of relationship between muscle and brain [61]. Hence, the immobilization of muscle may be a superior approach to induce atrophy [18]. Up to now, only muscle-secreted hemopexin was observed to be involved in this crosstalk [18]. This secretion was detected as the most differential protein between non-cast and cast-immobilized muscle-derived conditioned media [18]. After the intracerebroventricular infusion of hemopexin, *Lcn2* mRNA expression was upregulated in the hippocampus and induced memory impairment of young 5XFAD mice. However, hemopexin as a plasma protein, is primarily synthesized in the liver. Whether the changes of hemopexin expression in liver during muscle immobilization is unclear, warranting further studies. Although muscle atrophy and injury mainly led to regional inflammatory response, the exudation of inflammatory cells to the circulatory system and peripheral blood flow changes may also influence brain function [62]. One recent research reported that proteasome stress in skeletal muscle induced muscle-secreted amylase Amyrel, which could delay brain aging via disaccharide transport pathways [63]. This confirms the relationship between muscle status and brain neurodegeneration. Exercise-linked muscle-derived FNDc5/irisin and CTSB were noted as the potential treatments of AD in pre-clinical studies [22,38,64–66]. *Fndc5* knock-out had impaired neurotrophin signaling pathway and dendrite development, as well as cognitive function, which could be rescued via the delivery of irisin into the dentate gyrus [66]. Although exercise-induced higher CTSB and irisin are associated with cognition improvement, the muscle expression of *Ctsb* and *Fndc5* upregulated in muscle-specific PGC1 $\alpha$  overexpression mice did not affect hippocampal neurogenesis in aging [47]. The elevation of beneficial muscle secretions might be dose-dependent and with discrepant

**Fig. 3.** Pre-clinical evidences of the highway from muscle to brain. Muscle atrophy/injury animal models and diabetic MKR mouse (muscle insulin resistance) showed cognitive dysfunction and abnormal neurogenesis. Exercise, electronic stimulation, intramuscular injection of muscle-targeted agents attenuated symptoms of Alzheimer's disease and enhanced the neurogenesis, especially in hippocampus. The transport of muscle-secreted hemopexin after atrophy and FNDc5/Irisin, Cathepsin B, as well as lactate after exercise played roles in the brain.

effects in different population. The discovery of lactate receptor G-protein-coupled receptor 81 (GPR81) in brain also provided evidence of how muscle-derived lactate activated brain cells [67]. The inhibition of lactate transporter reduced BDNF, Sirt1, PGC1 $\alpha$  and FNDC5 levels in the hippocampus of exercised mice [36]. Unfortunately, a randomized controlled trial revealed that a 12-month moderate to high intensity aerobic and strength exercise program failed to improve the cognitive function in patients with mild to moderate dementia [68]. Since low levels of physical activity are risk factors of dementia, exercise may mainly prevent against the occurrence of cognitive impairment [69,70]. The effects of myokines on brain were shown by performing exercise, activity restriction, extrinsic supplement, or conditional knockout in animal studies. However, to increase the value of clinical translation, the dose-dependent effects of muscle secretory supplements on cognitive function should be further investigated, especially in older adults. In addition to AD, patients with Parkinson's disease (PD) can also suffer from cognitive impairment and sarcopenia [71,72]. Although the cognitive abilities of PD mice could be elevated by exercise, the role of muscle has not been reported or well-validated in this disease [73,74]. This field should be explored in the future.

Other muscle treatments also enhanced brain function, such as electronic stimulation and BOTOX®. Pre-clinical studies demonstrated that electronic stimulation increased the immature neurons and astrocytes of hippocampus, but not changed the behavior performance of rodents [35, 40]. Recent clinical evidence showed neuromuscular electrical stimulation improved clinical outcomes except for cognitive functions in dementia patients [75,76]. People with vascular dementia may suffer paratonia [77]. The intramuscular injection of botulinum toxin relieved muscle tone abnormalities shown in patients [78], and enhanced hippocampal plasticity shown in mice via the proper inhibition of cholinergic neurotransmission [39]. The peripheral nerves that exist in muscle might be the essential bridge between muscle treatments and brain changes [79,80]. The enhanced physical activity in patients with paratonia by botulinum toxin injection may increase BDNF levels and lead to stronger brain neuroplasticity [39]. Novel cell and gene therapies could also benefit brain at the pre-clinical exploratory stage. The brain is not easily intervened as the muscle, especially in invasive ways. Intramuscular injection of mechanical strained mMSCs produced various regenerative growth factors, such as hepatocyte growth factor (HGF) and epidermal growth factor (EGF) to promote neurogenesis and astrogliogenesis in the hippocampus of aged mice [37]. The muscle-specific overexpressed Nprilysin and scFv59, myostatin knockdown, as well as normalizing insulin sensitivity were all beneficial to the brain in mouse studies. Skeletal muscle increased the expression of hNEP which could cross the blood–brain barrier to reduce A $\beta$  deposits in brain [42]. rAAV1-mediated scFv59 increased muscle scFv59 expression and reduced A $\beta$  levels in cerebrospinal fluid [44]. Muscle dysfunction may induce abnormal insulin and glucose metabolism, which negatively regulates cognitive function [81]. The reduction of muscle myostatin and insulin resistance might enhance cognitive functions [43,48]. These muscle-targeted strategies have clinical translation values to treat cognitive impairment. Nevertheless, muscle-specific PGC1 $\alpha$  overexpression fails to increase brain functions as exercise and peroxisome proliferator-activated receptor  $\delta$  agonist did [46,47,82]. This phenomenon reminds us that some effects of whole-body treatment did not come from the altered expression of a single muscle gene. Although various pre-clinical evidence revealed direct and indirect effects of muscle on cognitive function and related pathways, there is no favorable result shown in clinical interventional trials based on old population [83]. It is important for elderly people to maintain muscle mass and strength, which can not only prevent against sarcopenia, but also have the potential to slow down cognitive impairment via the above pathways. The combination of cognition and muscle therapeutic approaches may play a greater role in cognition improvement. Pilot studies of other novel muscle treatments should be conducted to observe the effects on brain in the future [84].

To our knowledge, this is the first scoping review to summarize the current pre-clinical evidence that shows how skeletal muscle affects cognitive function (mainly AD-related) with our search criteria. We classified the study designs into three main types to provide a reference for future research. The muscle-targeted strategies as potential brain function enhancers were proposed. There are several limitations of this study. The pre-clinical studies had high heterogeneity so that only qualitative analysis has been done. Although the risk bias of included animal studies was not high, some studies only showed the phenotype changes of the brain or behaviors without in-depth mechanism exploration. Furthermore, publication bias may exist, with only publication of the positive roles played by muscle. The evidence were all from animal models, and the feasibility in human remains unclear. As *in-vitro* studies hardly illustrate the relationship across organs, we did not include simple cell studies. Furthermore, we did not include studies that reported muscle-brain connection of other conditions, such as anxiety, fear, and depression, which should be summarized in the future.

In conclusion, current pre-clinical evidence shows that skeletal muscle is an important mediator of cognitive function. Interventions that induce muscle atrophy, hypertrophy, or regulate muscle gene expression have aided in the discovery of the remote effects of muscle on brain (cognitive behaviors, brain functional factors, hippocampal neurogenesis, and A $\beta$  load) through the transportation of muscle-secreted lactate, FNDC5/irisin, hemopexin, and CTSB. In addition to humoral and circulatory systems, whether muscle can affect cognition via neural connection should be investigated in the future.
