Abstract

Background and Aims: Carpal tunnel syndrome (CTS) is the most common peripheral nerve entrapment syndrome with a high prevalence among workers. Insights on the physical work-related risk factors is necessary to develop appropriate preventative methods. The objective of this systematic review, including meta-analyses, is to assess which physical work-related risk factors are associated with carpal tunnel syndrome.

Methods: Systematic literature searches were carried out using PubMed and Embase until September 6, 2021. Studies were included if: (1) CTS was clinically assessed, (2) the studies were prospective cohort studies, and (3) the exposure was reported using terms of exposed/less or nonexposed. Risk of bias was assessed using the Quality in Prognosis Studies (QUIPS) tool. Quality of evidence was assessed using the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE).

Results: In total, 9270 patients with CTS from a population of 1,051,707 workers were included from 17 studies. Meta-analyses revealed high-quality evidence for associations between CTS and high exposures to repetition (hazard ratio [HR] 1.87, 95% CI 1.42–2.46), force intensity (HR 1.84, 95%CI 1.22–2.79), exposures above hand activity level of ACGIH (HR 1.75, 95%CI 1.40–2.17), and the Strain Index >10 (HR 1.58, 95% CI 1.09–2.30). No significant associations were found for pinch gripping, hand-arm vibration or force duration. High computer-use exposure was significantly associated with a decreased rate of work-related CTS (HR 0.28, 95% CI 0.12–0.64).

Conclusion: This systematic review of prospective cohort studies found high certainty for an increased rate of CTS due to a high Strain Index, exposures exceeding the Activity Level of ACGIH, and high force intensity and high repetition. Workers performing tasks requiring both high force and high repetition even have a higher rate of developing CTS.

KEYWORDS
carpal tunnel syndrome, occupational exposures, physical risk factors, prevention

1 | INTRODUCTION

Carpal tunnel syndrome (CTS) is the most common peripheral nerve entrapment syndrome and is caused by pressure on or around the median nerve. The carpal tunnel is a narrow passageway located at the palm side of the hand and is defined by the carpal ligament at the volar side where some tendons of the fingers (flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus) and the median nerve run through. Compression of the median nerve causes tingling, weakness, and numbness in the thumb, index finger, middle finger, and on the radial side of the ring finger.[1,2]

In de past two decades several studies have been performed to identify personal and psychosocial risk factors for CTS, but not often with a prospective study design to assess causal associations between risk factors and CTS. Examples of reported personal risk factors are sex, age, pregnancy, obesity, square wrists, and comorbid diseases such as rheumatoid arthritis, diabetes, and thyroid diseases.[3–5] Studies have also shown that CTS might affect postmenopausal women and women taking oral contraception.[6,7] More recently, studies have described an association between psychosocial factors and carpal tunnel syndrome such as job strain and dissatisfaction.[8,9]

Although personal and psychosocial factors have been associated with CTS, CTS is still seen as a frequently occurring occupational disease probably caused by work/related.[10] Luckhaupt et al concluded that the overall lifetime prevalence of clinician-diagnosed CTS among current workers was 6.7% and the 12-month prevalence was 3.1%, representing approximately 4.8 million workers with current CTS.[11] This high prevalence also leads to high sickness absence rates after carpal tunnel release and the average return to work ranges from 21 days for nonmanual to 39 days for manual work.[12] We do know that the problem is not only a financial issue, as some workers can't fulfill their jobs anymore and may need to find another job, also employers may suffer indirect costs such as loss of productivity and time spent on hiring new employees.[13]

Since CTS is associated with many risk factors, it is important to look into the work-related population attributive fraction (PAF) of CTS. This indicates the proportion of incidents of CTS in the population that are attributable to work. Roquelaure et al.,[14] a study regarding the attributable risk of CTS in the general population, showed a PAF of 50% for males performing manual work and 19% for females. This suggests that the incidence of CTS caused by work might decrease by introducing changes in the workplace. Given the association with manual work, it is important to determine the work-related physical risk factors of CTS to lower the incidence. Therefore, we decided to include only work-related physical risk factors in this review. Moreover, we presume that physical risk factors are likely to be explained by the pathophysiologic mechanisms in CTS.[15,16] Therefore, these physical risk factors are more likely to be causative for CTS and

coherent preventive measures probably more effective to reduce the risk of manual work.

The American Academy of Orthopaedic Surgeon (AAOS) published a guideline in 2016 for the management of CTS, in which they described risk factors of CTS sorted into limited, moderate and strong evidence. They found an increased risk of CTS due to repetition with strong evidence. Moderate evidence was found for the following risk factors are: vibration, computer use and force.[17]

Complementary to that, a number of reviews have been published over the past two decades, for example, van Rijn et al.,[18] Barcenilla et al.,[19] and Kozak et al.[20] These reviews assessed cross-sectional, case-control and cohort studies to determine the occupational risk factors concluded that repetition, force, vibration and wrist bending are risk factors for carpal tunnel syndrome. To properly infer causality between work-related risk factors and CTS, it is preferred to use longitudinal studies preferably also adjusting for confounding factors.

Hence, we conducted a systematic review, including meta-analyses with evidence synthesis using the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework, using only prospective cohort studies to determine the association between physical work-related risk factors and clinically assessed CTS. The aim of this systematic review is to investigate which work-related physical risk factors are associated with clinically diagnosed CTS.

2 | METHODS

This systematic review, including a meta-analysis, was conducted according to the criteria of the PRISMA statement.[21]

2.1 | Eligibility criteria

Only cohort studies published in peer-reviewed journals fulfilling the following criteria were used: the study was written in English, German, French, Italian or Dutch; CTS was clinically assessed; the association between CTS and the work-related physical risk factors was described using the effect measures, hazard ratio (HR), relative risk (RR) or could be calculated with the provided data; exposure data were provided for CTS and at least two levels of exposures were reported to retrieve a risk estimate. The clinical examination should report at least symptoms and signs as tingling, weakness, and numbness in the thumb, index finger, middle finger and on the radial side of the ring finger. Physical work-related risk factors had to be described in terms of physical workload or specific occupational activities such as repetitive hand movements or postures. No studies were excluded on the basis of the year of publication.

2.2 | Literature search

Systematic literature searches were carried out using PubMed and Embase from 1954 to December 2, 2021. We combined several CTS terminologies and work-related physical risk factors to generate the search strategy. The search strategies used in both databases are shown in Appendix 1.

2.3 | Study selection

After duplicates from PubMed and Embase had been removed, all studies were checked independently and blinded for each other by at least two of the authors. First, titles and abstracts were screened to identify relevant studies and to exclude studies that did not fulfill the inclusion criteria. Secondly, we obtained the full texts of the remaining studies and assessed those for eligibility. Disagreement was resolved by discussion between the two authors, and if needed a third author was asked. Endnote X9 and Rayyan were used to manage the screening and selection.

2.4 | Data extraction

The following data were extracted from each article: author; year of publication; country; study design; case definition of CTS; length of follow-up; definition of work-related physical risk factors; method of assessment of work-related risk factors; number and characteristics of participants such as sex and age; risk estimate and confidence interval; and adjustment for confounding.

2.5 | Quality assessment

The methodological quality of the study was rated independently by two authors. Since we only included prospective cohort studies, we used the Quality in Prognosis Studies (QUIPS) tool. The checklist covers six domains: (1) study population (e.g., the study sample represents the population of interest), (2) study attrition (e.g., the response rate was >80%), (3) prognostic factor measurement (e.g., the exposure was assessed by professionals), (4) outcome measurement (e.g., CTS was clinically assessed), (5) study confounding (e.g., the risk-estimate was adjusted for age, sex, BMI and diabetes mellitus), (6) statistical analysis and reporting (e.g., a risk-estimate was calculated). Every domain was scored as having a low, moderate or high risk of bias.[22] The overall quality of the studies was classified as having a high risk of bias if one domain was scored as having a high risk of bias or two domains were scored as having a moderate risk of bias.

2.6 | Data analysis

A meta-analysis was performed if there were at least two studies to determine whether work-related physical risk factors were associated

with CTS. For each risk factor, we used the highest versus the lowest exposures as reported in the studies. If the exposure was trichotomized, we used the reported medium exposed group as exposed category and the reported low exposure as reference category. A pooled HR and 95% confidence interval (CI) were calculated for each risk factor using a random effects model in Cochrane's RevMan 5.4. Heterogeneity was assessed using the I^2 test, which describes the dispersion of effect sizes and the relative heterogeneity in the studies as compared to random chance. Heterogeneity was considered high if $I^2 > 70\%$. Forest plots were made for each risk factor to visualize the pooled results.

2.7 | GRADE

To assess the certainty of evidence for the association between physical work-related risk factors and CTS of risk factors that were included in the meta-analyses we used the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework.[23] GRADE uses four levels to judge the certainty of evidence: very low, low, moderate, and high. Since we included only prospective cohort studies that studied an association between specific risk factors and CTS, the starting qualification of certainty of evidence for each risk factor was high. The quality of evidence was downgraded on the basis of the following five factors: (1) study limitation (high risk of bias present in the majority of the studies), (2) inconsistency ($I^2 > 70\%$), (3) indirectness (CTS not clinically assessed), (4) imprecision (range of the 95% CI > 2.0), and (5) presence of publication bias. If the quality of evidence was not downgraded on the basis of these five criteria, it could be upgraded on the basis of two factors: (1) large effect size (the risk estimate of a risk factor >2.5), and (2) presence of a dose-effect relationship in the reported study. Two authors independently assessed the quality criteria and the level of agreement was discussed in the whole author group.

3 | RESULTS

3.1 | Study selection

Our search strategy resulted in 3846 studies of which 1202 were duplicates. After our first screening of the titles and abstracts we excluded 2551 articles that did not meet our inclusion criteria's. The remaining 97 articles were assessed in our full-text screening. In total, 17 studies[9,24-39] were included and 12 of these studies were enrolled in our meta-analysis. Three studies[26,28,29] used the same pooled cohorts with the same participants and because of that we chose study[27] with the most participants in the meta-analysis. The study selection process is shown in a PRISMA flowchart in Figure 1.

3.2 | Study characteristics

All the studies are prospective cohort studies and were published between 2001 and 2021. The included studies were conducted worldwide with eight studies in the United States,[25-29,31,32,36] two in
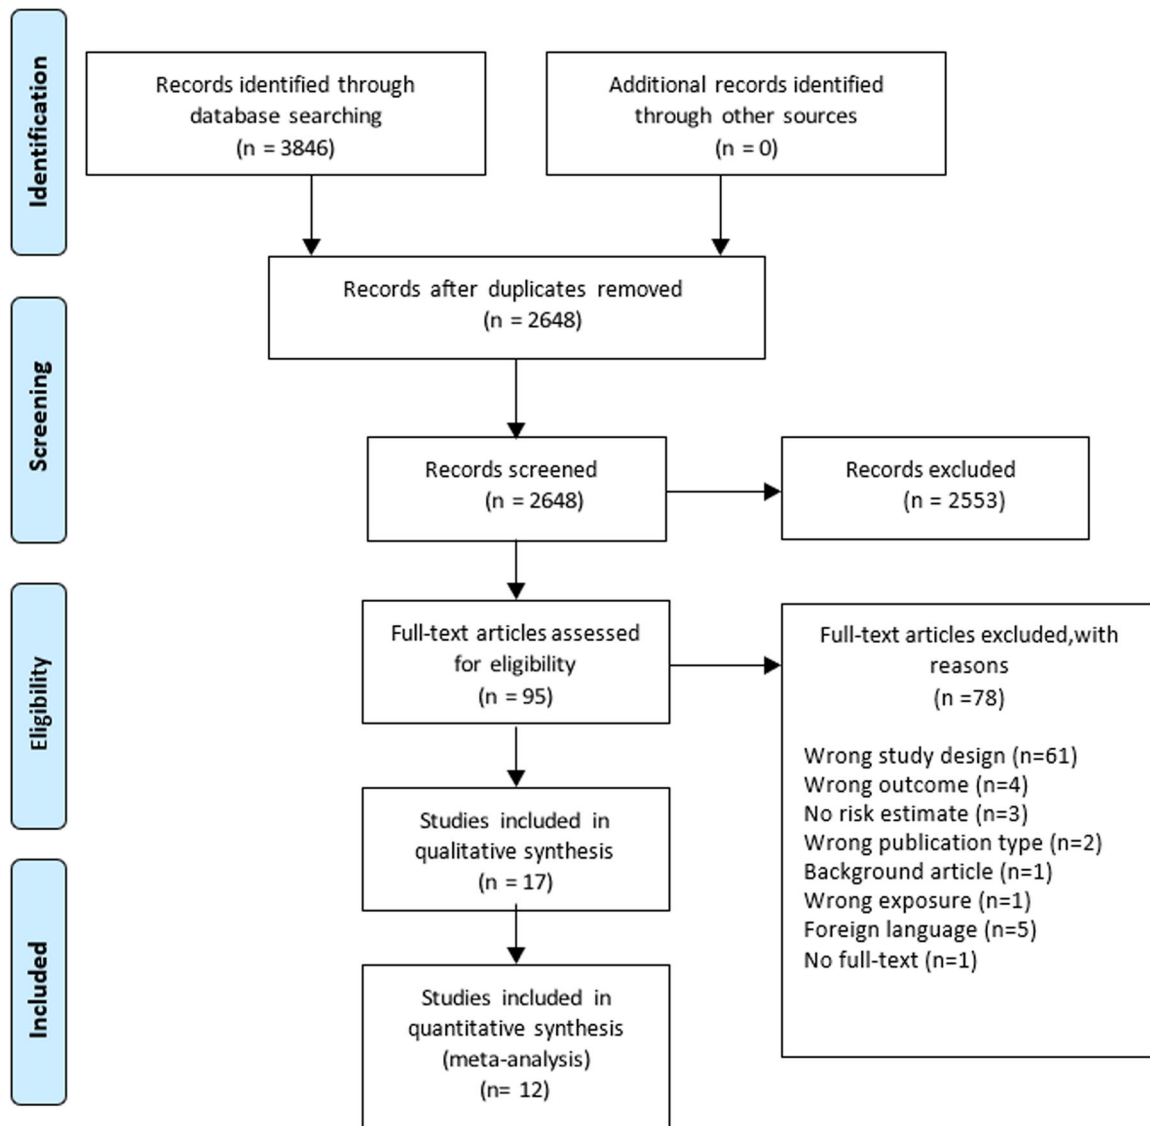

FIGURE 1 Flow chart of the included studies.

France,[9,33] three in Italy,[24,38,39] two in Finland,[30,37] one in Denmark,[34] and one in both the United States and France.[35] The total number of included workers was 1,051,707 and were all 18 years of age or older. In total, 9270 cases of CTS were clinically assessed but two studies did not mention the cases of CTS in their articles. CTS was clinically assessed in all the studies by symptoms with or without nerve conduction studies (NCS). Symptoms were tingling, numbness, pain and/or burning in two or more of the first four digits. Leclerc et al.,[33] Lund et al.[34] and Roquelaure et al.[9] assessed CTS if these symptoms were present. Hulkkonen et al.[30] and Pourmemarie et al.[37] obtained data on hospitalizations due to CTS. The remaining studies assessed CTS by both the presence of the above-mentioned symptoms and NCS. Six studies studied the association between the ACGIH Threshold Limit Values (TLV) and the incidence of CTS[24,25,27,32,38,39]; four studies assessed the association between repetition and the incidence of CTS[26,28,29,39]; Four studies studied the association between force duration and the incidence of CTS[25,26,28,29]; Four studies assessed the

association between vibration and the incidence of CTS[28,30,36,37]; six studies assessed the association between force intensity and the incidence of CTS[26,28,29,33,34,39]; two studies assessed the association between wrist bending posture and the incidence of CTS[9,28]; three studies assessed the association between pinch gripping and the incidence of CTS[9,33,37]; two studies assessed the association between computer/keyboard use and the incidence of CTS[35,36] and finally, two studies studied the association between a high Strain Index (SI) and the incidence of CTS.[27,31] The characteristics of the studies are described in Appendix 2.

3.3 | Quality of the studies

Bonfiglioli et al.[24] and Violante et al.[38] had the best quality and had a low risk of bias on all six domains. Seven studies[9,26,30,33–37,39] had a moderate risk of bias on the first domain because they did not provide a table with

the baseline characteristics or did not have a sufficient number of participants in their study (<500 participants). All of our included studies, except two studies,[24,39] did not provide a table with the baseline characteristics of the participants lost to follow up and on top of those five studies also had a low response rate (<70%). Studies[9,30,33,35] that measured the exposure by a self-administered questionnaire had a high risk of bias on the third domain and one study[37] that measured the exposure by interviews had a moderate risk of bias on the third domain. Lastly, five studies[9,25,26,33,36] did not measure all the confounders and had a moderate/high risk of bias on the fifth domain. The complete assessment of the studies is shown in Table 1.

3.4 | Risk factors and CTS

3.4.1 | Meta-analysis and GRADE

We performed a meta-analysis for the following risk factors: repetition, force duration, force intensity, ACGIH Threshold Limit Values (TLV), vibration, pinch gripping computer use, the Strain Index (SI). We could not perform a meta-analysis for the following risk factor: wrist bending posture because there were not enough studies to include in the meta-analysis. Details of the assessment of the GRADE framework are presented in Table 2.

3.4.2 | Repetition and CTS

Repetition was measured using the HAL-scale, which is a 10-point scale that rates the repetitiveness of hand use and also accounts for pauses and efforts.[40] The meta-analysis showed, based on two studies,[28,39] that there was high-quality evidence that high exposure of repetition is significantly associated with an increased rate of the onset of CTS (HR 1.87, 95%CI 1.42–2.46) (Figure 2C).

3.4.3 | Force and CTS

Force was measured using two methods. We made a distinction between force intensity, which measures the actual perceived force, and force duration, which measures the duration of time in forceful exertion. This resulted in two forest plots regarding force and CTS.

Force intensity was measured using the Borg-10 scale, which estimates an individual's effort, exertion, and breathlessness during physical tasks.[41] The meta-analysis showed, based on three studies,[28,33,39] that there was high-quality evidence that high exposure of force is significantly associated with an increased rate of the onset of CTS (HR 1.84, 95%CI 1.22–2.79) (Figure 2D).

Force duration was measured in percentage of time in forceful exertion. The meta-analysis showed, based on two studies,[25,28] that there was very low-quality evidence that high exposure of forceful exertion is not significantly associated with an increased rate of the onset of CTS (HR 1.80, 95%CI 0.98–3.31) (Figure 2E).

3.4.4 | ACGIH threshold limit values (TLV) and CTS

The ACGIH Threshold Limit Values (TLV) is a method to assess the risk on the overload of the wrists and hands of workers. It combines two parameters: the Hand Activity Level (HAL) and normalized Peak Force (nPF). ACGIH differentiates between three levels of exposure. Below Activity Level (AL) is the lowest level, AL to Threshold Limit Value (TLV) is the intermediate level and above TLV is the highest level.[42] In our meta-analyse we used <AL as the low exposure and ≥AL + < TLV (intermediate) as the high exposure. The meta-analysis showed, based on four studies,[27,32,38,39] that there was high-quality evidence that the high exposure is significantly associated with an increased rate of the onset of CTS (HR 1.75, 95%CI 1.40–2.17) (Figure 2A).

3.4.5 | Vibration and CTS

Low exposure was defined as not/lightly using a vibration tool and high exposure was defined as using a vibration tool. The meta-analysis showed, based on three studies,[28,30,37] that there was very low-quality evidence that high exposure of vibration is not significantly associated with an increased rate of the onset of CTS (HR 1.47, 95%CI 0.63–3.42) (Figure 2B).

3.4.6 | Pinch gripping and CTS

High exposure was defined as gripping for more than 4 h a day or any pinch grip force. The meta-analysis showed, based on three studies,[9,33,37] that there was very low-quality evidence that high exposure of pinch gripping is not significantly associated with an increased rate of the onset of CTS (HR 1.84, 95%CI 0.96–3.52) (Figure 2F).

3.4.7 | Computer/keyboard use and CTS

Low exposure was defined as never or almost never using a computer and high exposure was defined as using a computer all or almost all day. The meta-analysis showed, based on one study with two cohorts,[35] that there was moderate-quality evidence that high exposure of computer use is significantly associated with a decreased rate of the onset of CTS (HR 0.28, 95%CI 0.12–0.64) (Figure 2G).

3.4.8 | The Strain Index (SI) and CTS

The SI is an index that assesses the physical exposure of the distal upper extremities based on frequency, duration, intensity and hand/wrist posture.[43] Kappellusch et al.[31] defined the high exposure as SI > 10 and Garg et al.[27] defined the high exposure as SI > 6.1 This meta-analysis showed that there was high-quality evidence that high exposure of SI is significantly associated with an increased rate of the onset of CTS (HR 1.58, 95% CI 1.09–2.30) (Figure 2H).

3.4.9 | Wrist bending posture and CTS

Roquelaure et al. measured the wrist bending posture as time spent in wrist bending. They differentiated three levels of exposure: low (0 h a day), moderate (2–4 h a day) and high (more than 4 h a day).[9] The moderate exposure had an HR of 1.61 with 95% CI of 0.79–3.29 and the high exposure had an HR of 1.63 with 95% CI of 0.70–3.78 (Table 1). Harris-Adamson et al.[28] measured the wrist bending posture as percentage of time spent in ≥30°wrist flexion or extension. The high exposure of flexion (>1%) had an HR of 0.87 with 95% CI of 0.59–1.29 and the high exposure of extension (>5%) had an HR of 0.83 with 95% CI of 0.60–1.15 (Appendix 2).

4 | DISCUSSION

4.1 | Main findings

This systematic review with meta-analyses showed high certainty for a significantly increased rate of CTS due to force duration (71%), force intensity (47%) and repetition (64%). Workers that perform tasks requiring both force and repetition even have an 80% higher rate of developing CTS, as seen in the meta-analysis for the ACGIH Threshold Limit Values, again with high certainty. We found a significantly increased rate of CTS due to the Strain Index (45%). No associations for hand-arm vibration and pinch-gripping with CTS were found, with low-quality certainty. No associations were also found for wrist bending due to contradictory outcomes of the two included studies. Computer use was found to reduce the risk of work-related CTS with 72% with moderate-quality certainty. However, in the current study low exposure was defined as never or almost never using a computer and high exposure as using a computer all or almost all day. Therefore, the reference group might be a high-risk CTS group performing work characterized by high exposure to force and repetition. Future studies on CTS and computer use are needed that compare high versus low exposure to computer use in terms of posture, repetition, and force, for instance comparing all-day data entry jobs with other types of office work having more variability and thereby less exposure to computer use.

Although Barcenilla et al.,[19] reporting about a meta-analysis on CTS and occupation, did find a significant association for vibration, our meta-analysis did not show sufficient evidence for this association. A possible explanation is that we included studies with a lower risk of bias in our meta-analysis. In general, our conclusion is in line with the study of Kozak et al.,[20] which is an overview of systematic reviews. In their meta-analysis they also concluded that in current high-quality primary studies vibration is not an independent risk factor of CTS. In line with our results, Barcenilla et al.[19] also found a significant association between force and repetition and the incidence of CTS. For both risk factors, they reported higher risks estimates than we found: for force OR = 4.23 (95% CI 1.53–11.68) versus our HR = 1.84 (95% CI 1.22–2.79) and for repetition OR = 2.26 (95% CI 1.73–2.94) versus our HR = 1.87 (95% CI 1.42–2.46). This could also be due to the fact that we only used prospective cohort studies, while Barcenilla et al.[19] also included cross-sectional studies. Furthermore, our meta-analysis showed a significant association between the ACGIH Threshold Limit Values and CTS. This finding confirmed and strengthened the evidence as reported in the study of Kozak et al.[20] The RR they reported was 1.54 (95% CI 1.02–2.31), which is lower than our HR of 1.75 (95% CI 1.40–2.17).

Two previous studies[44,45] reviewed the association between computer use and CTS. While those two studies did not find an association between computer use and CTS, our meta-analysis showed a reduced risk of CTS and computer use at work, possibly due to the fact that low-level hand-activity is a protective factor.

Lastly, our systematic review assessed whether pinch gripping and the Strain Index are risk factors for CTS. We did find a significant association between the Strain Index and an increased rate of CTS, and did not for pinch gripping.

4.2 | Methodological considerations

The strength of this review is that we only included prospective cohort studies, as these designs are the preferred evidence for inferring causality. In addition, we performed a meta-analysis and used GRADE for the assessment of the certainty of evidence. Our systematic review solely included prospective cohort studies and used GRADE to determine the certainty of evidence and therefore has high accuracy and precision.

Another strength is that CTS had to be clinically assessed. All the studies used the same set of symptoms (tingling, weakness and numbness in the thumb, index finger, middle finger, and on the radial side of the ring finger) to diagnose CTS. Some studies did also require NCS in the diagnosis of CTS. We did not find a difference in risk estimates for studies using NCS versus those that did not. A proper clinical assessment is important to secure an accurate risk estimation because self-assessment of CTS could lead to an overestimation of the hazard ratios and the risk factors involved.

A limitation of our review is that five studies did not perform a (blinded) observation to assess exposure. Instead, they conducted an

FIGURE 2 Forest plots of the eight work-related physical risk factors for developing carpal tunnel syndrome. (A) Forest plot of comparison <Action Limit versus ≥Action limit +< Threshold Limit Value. (B) Forest plot of comparison low vibration versus high vibration. (C) Forest plot of comparison low repetition versus high repetition. (D) Forest plot of comparison low force intensity versus high force intensity. (E) Forest plot of comparison low force duration versus high force duration. (H) Forest plot of comparison low Strain Index versus high Strain Index. CI, confidence interval; SE, standard error.

interview or collected information on exposure using a questionnaire. This is an important source of recall bias and possibly overestimation of exposure.

4.3 | Awareness and prevention

Despite the available evidence of high certainty about work-related physical risk factors for CTS, there still might be a lack of awareness in clinical care for prevention. The study of Yagev et al.[46] on the recognition of occupational risk factors by clinicians showed that in 60% of the cases the clinician did not ask about the patient's job, and even when the job was mentioned, no further assessment was made regarding the specific tasks and activities in the job. In addition, fewer than 10% of the patients were referred to an occupational physician for further evaluation. The awareness of all clinicians is required for optimal patient care and to help the patient to promote preventative measures at work. Also in teaching, attention should be given to the importance of work as a possible etiological risk factor for the development of CTS and enhance communication among various medical disciplines and active referral of patients who are at risk at work.[46]

5 | CONCLUSION

This systematic review of prospective cohort studies found high certainty for an increased rate of CTS due to a high Strain Index, exposures exceeding the Activity Level of the ACGIH, and high force intensity and high repetition. Workers performing tasks requiring both high force and high repetition even have a higher rate of developing CTS. Therefore, we recommend to develop and implement preventive measures, especially for these two risk factors and to evaluate which measures best reduce the incidence of CTS.
