Acute Impact of Fine Particulate Air Pollution on Cardiac Arrhythmias in a Population-Based Sample of Adolescents: The Penn State Child Cohort

Fan He , PhD; Jeff D. Yanosky, ScD; Julio Fernandez-Mendoza , PhD; Vernon M. Chinchilli, PhD; Laila Al-Shaar, PhD; Alexandros N. Vgontzas, MD; Edward O. Bixler, PhD; Duanping Liao, MD, PhD

BACKGROUND: Fine particulate (fine particles with aerodynamic diameters $\leq 2.5 \mu\text{m}$ [$\text{PM}_{2.5}$]) exposure has been associated with a risk of cardiac arrhythmias in adults. However, the association between $\text{PM}_{2.5}$ exposure and cardiac arrhythmias in adolescents remains unclear.

METHODS AND RESULTS: To investigate the association and time course between $\text{PM}_{2.5}$ exposure with cardiac arrhythmias in adolescents, we analyzed the data collected from 322 adolescents who participated in the PSCC (Penn State Child Cohort) follow-up examination. We obtained individual-level 24-hour $\text{PM}_{2.5}$ concentrations with a nephelometer. Concurrent with the $\text{PM}_{2.5}$ measure, we obtained 24-hour ECG data using a Holter monitor, from which cardiac arrhythmias, including premature atrial contractions and premature ventricular contractions (PVCs), were identified. $\text{PM}_{2.5}$ concentration and numbers of premature atrial contractions/PVCs were summarized into 30-minute-based segments. Polynomial distributed lag models within a framework of a negative binomial model were used to assess the effect of $\text{PM}_{2.5}$ concentration on numbers of premature atrial contractions and PVCs. $\text{PM}_{2.5}$ exposure was associated with an acute increase in number of PVCs. Specifically, a $10 \mu\text{g}/\text{m}^3$ increase in $\text{PM}_{2.5}$ concentration was associated with a 2% (95% CI, 0.4%–3.3%) increase in PVC counts 0.5 to 1.0, 1.0 to 1.5, and 1.5 to 2.0 hours after the exposure. Cumulatively, a $10 \mu\text{g}/\text{m}^3$ increment in $\text{PM}_{2.5}$ was associated with a 5% (95% CI, 1%–10%) increase in PVC counts within 2 hours after exposure. $\text{PM}_{2.5}$ concentration was not associated with premature atrial contraction.

CONCLUSIONS: $\text{PM}_{2.5}$ exposure was associated with an acute increased number of ventricular arrhythmias in a population-based sample of adolescents. The time course of the effect of $\text{PM}_{2.5}$ on ventricular arrhythmia is within 2 hours after exposure.

Key Words: adolescents ■ air pollution ■ cardiac arrhythmia ■ premature ventricular contraction

Sudden cardiac death (SCD) is a major public health threat. It is estimated that SCD accounts for $\approx 50\%$ of cardiovascular-related deaths and 15% to 20% of all-cause mortality in Western countries.^{1–3} Although relatively rare, SCD among otherwise healthy children and youths, including world-class athletes, has a devastating impact on their families. In addition, considering the large number of life-years lost,

the public health burden related to SCD in youth is not trivial. As a result, causes for SCD among children and youth have been studied extensively.^{4–6} Unlike older adults, among whom atherosclerotic coronary artery disease is the predominant cause of SCD, cardiac arrhythmia is one of the most prominent risk factors for SCD in youths.⁴ For example, unexplained SCD (ie, SCD without apparent cause after comprehensive

CLINICAL PERSPECTIVE

What Is New?

- The current study is the first of its kind to show an acute association between air pollution of fine particles with aerodynamic diameters $\leq 2.5\mu\text{m}$ and ventricular arrhythmia in a population-based sample of adolescents.
- The time course of the impact of air pollution on ventricular arrhythmia was within ≈ 2 hours after exposure.

What Are the Clinical Implications?

- Because of the ubiquitous and involuntary nature of air pollution, air pollution control measures may be taken to reduce the risk of cardiac arrhythmia in adolescents.
- Reducing cardiac arrhythmia risk during adolescence may further reduce cardiovascular disease burden in adults because of the importance of early prevention of cardiovascular disease in early life stages.

SCD	sudden cardiac death

autopsy), which can be mostly attributed to cardiac arrhythmias, accounts for one-third of SCD among children and young adults.⁵ Therefore, it is of great public health importance to identify modifiable risk factors for cardiac arrhythmias among children and adolescents.

The occurrence of cardiac arrhythmias may be attributed to impaired cardiac autonomic balance,^{7,8} systemic inflammation,^{9,10} and oxidative stress.¹¹ Because ambient air pollution from fine particles with an aerodynamic diameter $\leq 2.5\mu\text{m}$ (PM_{2.5}) has been associated with these biological processes,¹² it is plausible that PM_{2.5} exposure may also relate to an increased risk of cardiac arrhythmias. In fact, the association between PM_{2.5} and cardiac arrhythmias has been observed in adult epidemiological studies based on mortality data,^{13,14} arrhythmia episodes captured by implantable cardioverter defibrillator,^{15–20} and ECG monitoring.^{21–26} For example, long-term PM_{2.5} exposure has been associated with increased mortality from arrhythmias, especially among smokers.¹³ Moreover, acute exposure to PM_{2.5} has been associated with increased odds of atrial fibrillation recorded by implantable cardioverter defibrillator within hours of exposure.¹⁶ In both the

general adult population^{22,23,26} and patients with cardiovascular disease,^{21,25} exposure to ambient particles has also been associated with ventricular arrhythmias from ECG monitoring. Although these studies have provided convincing evidence to support that PM_{2.5} exposure is a risk factor for cardiac arrhythmias, nearly all of them were conducted in adults, including patients with preexisting cardiovascular diseases. Therefore, the findings cannot be generalized to low-risk populations, such as adolescents who are free of underlying cardiovascular conditions. Given the paramount importance of arrhythmias in the cause of SCD among youths, there is an urgent need to understand whether PM_{2.5} exposure triggers cardiac arrhythmias in youth.

Therefore, we conducted this study to evaluate the association between ambient PM_{2.5} concentration and cardiac arrhythmias in a population-based sample of adolescents. We hypothesize that elevated PM_{2.5} is associated with an acute increased number of cardiac arrhythmias within hours of exposure.

METHODS

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Study Population

In this study, we analyzed data collected from a population-based sample of adolescents who completed the follow-up examination of the PSCC (Penn State Child Cohort) study. Detailed descriptions of the PSCC baseline and follow-up examinations have been published elsewhere.^{27–30} Briefly, 700 children aged 6 to 12 years who were in 3 school districts in the Harrisburg metropolitan area were recruited for the baseline examination from 2002 to 2006. After an average of 7.4 years, 421 of them returned and completed the follow-up examination from 2010 to 2013. No major differences in the demographic characteristics were observed between these participants and the 279 who did not return for the follow-up examination.^{28,30}

During the follow-up examination, the participants were given a personal PM_{2.5} monitor and connected with a Holter ECG to proceed with their daily routines. The PM_{2.5} monitor and holter ECG were collected from the participants after 24 hours of recording. All participants started the recording period at 8:00 AM on day 1 and ended at 8:00 AM on day 2.

The study protocol was approved by the Pennsylvania State University College of Medicine Institutional Review Board. Written informed consents were obtained from the participants and their parents/legal guardians if participants were aged <18 years.

Personal PM_{2.5} Exposure

In the PSCC follow-up examination, we fitted a personal PM_{2.5} DataRam (pDR, model 1200; Thermo Scientific, Boston, MA) in combination with a PM_{2.5} size-selection cyclone (KTL SCC1.062; BGI, Inc., Winchester, NH), an air pump (BGI Inc.), and a battery pack in a backpack. A similar device has been used in our previous study to measure individual-level acute exposure to PM_{2.5}.²² The entire PM_{2.5} monitoring system was cleaned and calibrated before it was dispatched to each participant. The participants were instructed to bring the monitor with them when performing outdoor activities and kept the monitor in the same room when they were indoors for 24 hours.

The real-time PM_{2.5} concentration was originally recorded continuously at 1-minute intervals by the pDR. In the statistical analysis phase, the recording was averaged for 30-minute segments at the top and bottom of the whole hours (eg, 8:01–8:30 and 8:31–9:00 AM). The segment-specific PM_{2.5} concentrations were treated as repeated time-varying measurements in the analysis, such that each participant contributed up to 48 data points during the 24-hour period.

ECG and Cardiac Arrhythmias

Concurrent with the 24-hour PM_{2.5} monitoring, a high-fidelity (1000 Hz sampling rate) 12-lead Holter (Mortara H12+; Mortara Instrument, Inc., Milwaukee, WI) was used to record the ECG data. The ECG recordings were subjected to automatic analyses by using the HSCRIBE System software (version 4.21; Mortara Instrument, Inc.), which identifies various forms of cardiac arrhythmias. After which an experienced technician visually inspected the entire recording to remove recording artifacts, verified software-identified arrhythmic heartbeats, and identified additional arrhythmias in the ECG data. Because our study population is a population-based sample of adolescents, none of them presented with malignant cardiac arrhythmias (eg, atrial fibrillation or ventricular tachycardia) or reported having structural heart diseases. Therefore, we chose to focus on the most prevalent forms of arrhythmias in the general population, including premature atrial contractions³¹ (PACs) and premature ventricular contractions³² (PVCs). Specifically, a PAC is defined as a premature heartbeat with $\geq 25\%$ reduction in the R-R interval compared with the immediate prior R-R interval; a PVC is a heartbeat characterized by an absence of P wave and a premature QRS complex with an abnormally large width and amplitude on ECG. The ECG characteristics of normal heartbeat, PAC, and PVC are presented in Figure S1. After labeling all arrhythmic heartbeats in the ECG recording, we calculated the numbers of PACs and PVCs every 30 minutes based on the top and bottom of the whole hour (eg,

8:01–8:30 and 8:31–9:00 AM). As a result, each participant also contributed up to 48 repeated time-varying PAC/PVC count data points.

Meteorological Covariates

In addition to the PM_{2.5} and ECG measurements, we obtained 24-hour, real-time, individual-level temperature and relative humidity with a HOBO H8 logger (Onset Computer Corp., Bourne, MA) fixed to the backpack housing the PM_{2.5} monitoring system. Similar to the PM_{2.5} data, the logger recorded real-time temperature and relative humidity on a 1-minute basis and averaged into 30-minute-based segments corresponding to the time segments used in PM_{2.5} and arrhythmia data. Hence, these meteorological covariates were treated as repeated time-varying measurements, such that each participant contributed up to 48 segments.

Other Covariates

In the PSCC follow-up examination, a self-administered demographic questionnaire was used to obtain participant age, race and ethnicity, and sex. As our study population consisted of 79.3% non-Hispanic White participants,³⁰ race and ethnicity were treated as binary covariates (ie, non-Hispanic White populations versus racial and ethnic minorities) in the analyses. In addition, each participant underwent a detailed physical examination, from which their body mass index was calculated as weight/height² (kg/m²). Based on the body mass index, the age- and sex-adjusted body mass index percentiles were calculated based on the algorithm provided in the 2000 US Centers for Disease Control and Prevention growth charts.³³

Statistical Analysis

Because of the limited availability of the PM_{2.5} monitoring system, PM_{2.5} data were available from 322 (76.5%) of the 421 adolescents. As a result, the effective sample size for the current report is 322. As shown in Table S1, there were no significant differences in demographic characteristics or arrhythmia measures between those with and without PM_{2.5} data.

As the independent variable, PM_{2.5} concentrations were continuously measured for 24 hours and partitioned into repeated time-varying measurements. Therefore, a high-level collinearity is expected between PM_{2.5} segments (ie, lag terms), especially when they are temporally close. Therefore, we chose polynomial distributed lag models^{34–36} to reduce the potential collinearity of PM_{2.5} exposure metrics across the 30-minute segments. We decided, a priori, to include second-degree polynomials in all of our models. To compare the performance of models with different polynomial

terms, we conducted sensitivity analyses by using distributed lag models that include first-degree terms (ie, only include zero- and first-degree terms) or third-degree terms (ie, include zero-, first-, second-, and third-degree terms). Because the dependent variables (ie, PAC/PVC counts) were repeated count measurements, we nested the distributed lag model within the framework of a negative binomial model³⁷ with generalized estimating equation.³⁸ Because the outcome measurements were equally spaced (ie, 30 minutes apart), autoregressive order 1 was used to account for the potential autocorrelation in the arrhythmia counts.

Taken together, we performed repeated-measurement analyses using distributed lag models under a negative binomial model framework²² to assess the acute association between PM_{2.5} exposure and arrhythmia counts. In these models, 1 lag period indicates a 30-minute separation between the exposure and outcome. In other words, a lag-0 effect indicates the instantaneous impact of PM_{2.5} on cardiac arrhythmias, and a lag-1 effect indicates the impact of PM_{2.5} on the arrhythmia counts measured 30 minutes later, and so on. The cumulative effects of multiple lags of PM_{2.5} concentrations on arrhythmia counts may be considered as the sum of multiple individual-lag effects. To determine the number of lag terms included in our final model, we decided, a priori, to start from the model with the smallest number of lags (ie, lag 0 only) and incrementally increase the number of lags included (ie, lag 0; lag 0, 1; lag 0, 1, 2; etc), until the largest cumulative effect was obtained, conditional on the significance of individual lag terms not changing (ie, such that including additional lag terms did not attenuate to null terms of the earlier lags). Moreover, because the ECG and air pollution data were obtained concurrently, arrhythmia data obtained during the first 6 hours of the recording period (ie, segments 0–12) would not have a corresponding PM_{2.5} concentration measured at 6.5 hours before them (ie, lag-13 PM_{2.5}). Consequently,

the first 6 hours of data would be excluded from analysis in the model of lags 0 to 13. To preserve the validity of the statistical analyses, it is commonly accepted that ≥75% of the nominally available data (ie, 18 hours of the 24-hour recording) need to be nonmissing in regression models. Therefore, the largest number of lag terms included in our model was 13 (ie, lags 0–12).

In the regression models, we adjusted for major meteorological and demographic covariates. The meteorological covariates, including temperature and relative humidity, were treated as time-varying covariates, whereas demographics, including age, race, sex, and body mass index percentile, were treated as time-invariant covariates. To ensure the results were not impacted by segments with an excessive number of arrhythmias, we conducted further sensitivity analyses by excluding segments with >60 (or >30) of PACs and PVCs or truncating extremely high levels of environmental exposure (eg, >95th percentile of PM_{2.5} concentration). All results were expressed as the rate ratios (RRs) in cardiac arrhythmia counts for a 10 μg/m³ increase in PM_{2.5}. SAS 9.4 (SAS Institute, Inc., Cary, NC) was used to perform all analysis. A *P*≤0.05 was used to determine statistical significance.

RESULTS

Participant Characteristics

The demographic characteristics, arrhythmia counts, and environmental exposures with related variables in the study sample are summarized in Table 1. The study sample had a mean age of 16.95±2.25 years and consisted of 79.19% non-Hispanic White participants, and 55.90% were boys. The average 30-minute-based PM_{2.5} concentration was 17.13±38.55 μg/m³. Overall, the mean±SD 30-minute-based PAC and PVC counts were 0.47±3.00 and 0.36±3.09, respectively. Among the 322 participants, 254 (78.88%) had at least 1

Relative humidity, %	43.71±11.75	43.96±11.57	42.29±12.05	<0.01

Data are presented as mean±SD for continuous variables and number (percentage) for binary variables. BMI indicates body mass index; N/A, not applicable; PAC, premature atrial contraction; PM_{2.5}, fine particles with aerodynamic diameters ≤2.5 μm; and PVC, premature ventricular contraction.

*The *t* tests and χ^2 tests were used to obtain *P* values for continuous and categorical variables, respectively.

arrhythmic beat during the 24-hour study period. Of these 254 adolescents, 102 (40.2%) had only PAC, 30 (11.8%) had only PVC, and 122 (48.0%) had both PAC and PVC. Although not significantly different in any of the demographic characteristics, the univariable analyses showed that adolescents who had arrhythmias, compared with those who were free of cardiac arrhythmias, were exposed to significantly higher levels of PM_{2.5} concentration, temperature, and relative humidity.

Distributions of PM_{2.5} and Cardiac Arrhythmias

Detailed distribution of PM_{2.5} concentrations, related environmental variables, and cardiac arrhythmia counts are presented in Table 2. As shown in the table, there was a substantial amount of variation in the environmental exposure during the study period. Although the average PM_{2.5} concentration was relatively low, the concentration was extremely high in some of the segments. Specifically, 5% of the segments had a concentration >62.83 µg/m³, and ≈1% of them were >250 µg/m³. The time-specific distribution of PM_{2.5} is shown in Figure 1, which depicts that PM_{2.5} concentrations increased in the morning (ie, at 6:30 AM) and started to decrease late at night (ie, at 11:00 PM) into the early morning. Such a pattern is consistent with ordinary human time-activity patterns. The figure further illustrates that the PM_{2.5} concentrations in each time segment were highly variable.

As expected in otherwise healthy adolescents, the numbers of PACs and PVCs in 30-minute-based segments were small. Of the segments, >50% had ≤2 PACs and ≤1 PVC, respectively. We further illustrate the time-specific distributions of PAC and PVC counts in Figure 2, which indicate a large amount of variation in the arrhythmia counts in each of the segment. Overall, the arrhythmia counts were relatively high in the early morning (ie, at 4:00–4:30 AM) and around noon (ie, 11:00–11:30 AM), but low in the afternoon (ie, 4:30–5:00 PM).

Associations Between PM_{2.5} and Cardiac Arrhythmias

Individual lag effects and cumulative effects in the association between PM_{2.5} and arrhythmias from all models are summarized in Table S2. The cumulative effect of PM_{2.5} on PVC was significant in all models except the lag-0 model. Also, the cumulative effects gradually increased as the number of lag terms increases. However, we observed a pattern that the significance of the closer lag terms changed when the further lag terms were included in the model. For example, lags 1, 2, and 3 were significant in the model of lags 0 to 3, whereas they were no longer significant in the model of lags 0 to 12. This phenomenon may be attributed to the following 2 potential reasons: (1) the large number of lag terms were competing for the limited amount of variance in the PVC count that may be explained by PM_{2.5} air pollution, and (2) the PVC count was, indeed, impacted by the PM_{2.5} exposure that occurred 3 to 6 hours (ie, lags 6–12) before the ECG measure instead of within 2 hours (ie, lags 0–3). Because there is little prior knowledge of the actual time course of this association, we followed the aforementioned model selection strategy, that is, adding additional lag term (eg, lag 5) into the model should not attenuate the association between earlier terms (eg, lags 0–4) and cardiac arrhythmia to null. Therefore, the model of lags 0 to 3 was selected as our final model.

The multivariable-adjusted RRs and the corresponding 95% CIs from the final model are presented in Table 3. As shown in the table, every 10 µg/m³ increase in PM_{2.5} concentration was associated with a 5% increase in PVC count within 2 hours after exposure. Given that the mean PVC count was 0.36, the effect size was approximately equivalent to an additional 0.02 PVCs every 30 minutes. In contrast, increased PM_{2.5} was not significantly associated with PAC counts.

The individual lag effects further showed that a 10 µg/m³ increase in PM_{2.5} in lags 1, 2, and 3 were each significantly associated with an ≈2% increase in PVC counts, but lag 0 was not significantly related to PVC

Table 2. Distribution of the 30-Minute-Based Environmental Factors and Cardiac Arrhythmias

	Mean	SD	Median	IQR	Minimum	Maximum	Fifth percentile	95th percentile
Environmental factors

count. This suggests that the most significant impact of PM_{2.5} on PVC occurred between 0.5 and 2.0 hours after exposure. Because the second-degree polynomial term was statistically significant ($P < 0.01$), the individual lag effects exhibited nonlinearity and followed a quadratic form. That is, the effect sizes gradually increased from lag 0 to lag 2 and slightly decreased in lag 3. Similar to the cumulative effects, PM_{2.5} was not associated with PAC counts in any of the lags.

Sensitivity Analyses

To compare the results from distributed lag models with different polynomial terms, we replicated the analyses by using first-degree polynomial and third-degree polynomial models. As summarized in Table 4, the RRs for lags 0 to 3 cumulative effects from both models were 1.05, which is identical to the second-degree polynomial model. However, the lag-1 PM_{2.5} concentration was no longer significantly related to PVC counts in the first-degree model. On the other hand, the third-degree polynomial term was not significant ($P = 0.17$) in

the third-degree polynomial model, although including it did not substantially change the estimates. Taken together, the second-degree polynomial model was the best-fitted model for our data. Nevertheless, all models showed a consistent positive association between PM_{2.5} and PVC counts.

To eliminate the potential impact of segments with extremely high PVC counts, we further performed the regression analysis by excluding the 30-minute-based segments with >60 (ie, 2 PVC/min) or >30 (ie, 1 PVC/min) PVCs. As suggested in Table 5, the results did not change from our estimates obtained from the primary analysis as presented in Table 3. Therefore, the significant association between PM_{2.5} exposure and PVC cannot be attributed to the few segments with extremely high arrhythmia counts.

Given the extremely high maximum PM_{2.5} concentration (ie, 3849.0 µg/m³) and temperature (49.9 °C) in our data, we conducted further sensitivity analyses by truncating these 2 variables to their respective 95th percentiles (62.8 µg/m³ and 27.7 °C). As summarized

Figure 2. Time-specific distributions of PAC and PVC counts during the study period.

A, Time-specific distributions of PAC counts. **B,** Time-specific distributions of PVC counts. PAC indicates premature atrial contraction; and PVC, premature ventricular contraction.

in Table S3, every 10 µg/m³ increase in PM_{2.5} was associated with a 6.2% (95% CI, 0.1%–14.6%) increase in the PVC count in the model of lags 0 to 3. The association remained with the further adjustment of key lifestyle factors, including physical activity and self-reported cigarette smoking or exposure to second-hand smoking.

DISCUSSION

The present study found that higher ambient PM_{2.5} concentration is associated with an acute increase in ventricular arrhythmias in a population-based sample of adolescents. Specifically, our results revealed that elevated PM_{2.5} concentration triggers the onset of PVCs within 2 hours after exposure. Such a significant effect was supported by multiple sensitivity analyses. In addition, the most significant impact of PM_{2.5}

on ventricular arrhythmias occurred between 0.5 and 2.0 hours after exposure, and the strongest effect occurred at 1.0 hour after exposure. To the best of our knowledge, this is the first study that reports the association between PM_{2.5} air pollution and cardiac arrhythmias among otherwise healthy adolescents.

PM_{2.5} air pollution has been established as a risk factor for cardiovascular morbidity and mortality.¹² Although the association between air pollution, especially gaseous pollutants, and cardiac arrhythmias is not conclusive,³⁹ it is generally accepted that cardiac arrhythmias induced by PM_{2.5} is 1 of the major pathogenesis pathways linking air pollution and cardiovascular diseases. For example, it has been shown that short-term PM_{2.5} from traffic is associated with hospital admissions for arrhythmia in elderly individuals.⁴⁰ In a study conducted in 176 patients with implantable cardioverter defibrillators, Link et al¹⁶ also found that 2-hour average PM_{2.5} concentration was significantly

Table 3. RRs (95% CI) and P Values in Associations Between 10 µg/m³ Increments of PM_{2.5} Concentrations and Cardiac Arrhythmia Counts*

	PAC		PVC	
	RR (95% CI)	P value	RR (95% CI)	P value
Lag 0, instantaneous	0.995 (0.989, 1.002)	0.17	0.998 (0.983, 1.013)	0.76
Lag 1, 0.5–1.0h prior	0.998 (0.990, 1.003)	0.25	1.015 (1.004, 1.027)	<0.01
Lag 2, 1.0–1.5h prior	1.000 (0.995, 1.006)	0.88	1.022 (1.011, 1.033)	<0.01
Lag 3, 1.5–2.0h prior	1.003 (0.998, 1.009)	0.24	1.016 (1.002, 1.029)	0.02
Cumulative, within 2.0h	0.989 (0.970, 1.009)	0.27	1.051 (1.002, 1.102)	0.04

All models were adjusted for age, race, sex, body mass index percentile, temperature, and relative humidity. P values for zero-, first-, and second-degree polynomial terms were 0.76, <0.01, and <0.01, respectively. PAC indicates premature atrial contraction; PM_{2.5}, fine particles with aerodynamic diameters ≤2.5 µm; PVC, premature ventricular contraction; and RR, rate ratio.

*RRs were calculated by exponentiating the regression coefficients from distributed lag-negative binomial models. An RR of 1.05 indicates a 5% increase in arrhythmia counts/30min in association with a 10 µg/m³ increase in PM_{2.5} concentration.

Table 4. RRs (95% CI) and P Values in Associations Between 10 µg/m³ Increments of PM_{2.5} Concentrations and PVC Counts in First-Degree and Third-Degree Polynomial Distributed Lag Models

	First-degree model*		Third-degree model†	
	RR (95% CI)	P value	RR (95% CI)	P value

All models were adjusted for age, race, sex, body mass index percentile, temperature, and relative humidity. PM_{2.5} indicates fine particles with aerodynamic diameters ≤2.5 µm; PVC, premature ventricular contraction; and RR, rate ratio.

*In the first-degree model, P values for zero- and first-degree polynomials were 0.68 and <0.01, respectively.

†In the third-degree model, P values for zero-, first-, second-, and third-degree polynomials were 0.42, <0.01, 0.04, and 0.17, respectively.

associated with an increased odds of atrial fibrillation. In addition to acute exposure, short-term²³ and long-term²⁶ PM_{2.5} exposure have also been associated with higher odds of having arrhythmias in population-based adults. The consistent association between air pollution and arrhythmias from these observational studies have been further replicated in experimental studies in both human^{41,42} and animal models.^{43,44} Our current study results are consistent with these previous findings that PM_{2.5} is related to an increased risk of cardiac arrhythmias. However, as cardiac arrhythmias are less prevalent in adolescents, it is expected that the strength of their association with air pollution would be weaker than that in adults. Indeed, we found a 5% increase in PVC counts within 2 hours in adolescents and a 10% increase in PVC counts within 1 hour in adults.²² However, it should be noted that the number of arrhythmic events that occur in the early morning (eg, 4:00–6:00 AM) are relatively high, whereas the PM_{2.5} concentration is low in the early morning. Such a misalignment may attenuate the association between PM_{2.5} and cardiac arrhythmias toward null. Therefore, our estimation with regard to the strength of the association was conservative.

Our study is unique in its study population and should not be considered as a simple replication of previous studies. As summarized previously, prior reports,

including our own, were based on data collected from adults, including patients with preexisting cardiovascular diseases and those with implanted pacemakers. There is clear evidence that adults, especially elderly individuals with underlying cardiopulmonary diseases, are particularly vulnerable to the adverse effects of air pollution.¹² Hence, it is not surprising that particulate air pollution may associated with an increased risk of cardiac arrhythmia in adults who have high cardiometabolic burdens. On the contrary, our current study was performed in a sample of population-based adolescents who were, on average, aged 17 years and free of any major cardiovascular conditions. With a relatively mature circulatory system and low cardiometabolic burden, our sample of adolescents may be considered as a low-risk group with respect to their vulnerability to the adverse impact of air pollution. In addition, the arrhythmic burden in our study population was low (ie, <1 PVC/h). Therefore, it is extremely alarming that such a significant adverse impact of air pollution on PVC was observed in these otherwise healthy adolescents. This is the first time that the arrhythmogenesis effect of PM_{2.5} has been reported in such a low-risk population. When considering the level of PM_{2.5} exposure in our study, our findings are even more concerning as the increased risk of PVC was observed at a PM_{2.5} concentration (ie, 17 µg/m³) well under the primary (ie,

health-based) standard of 35 µg/m³ established by the US Environmental Protection Agency.⁴⁵ These novel findings suggests that the adverse impact of air pollution on cardiac arrhythmias may be even larger in regions with high levels of PM_{2.5} (eg, highly populated inner cities).

PACs and PVCs are the most common forms of cardiac arrhythmias. Although highly prevalent and generally considered benign,³¹ large numbers of PACs are responsible for the initiation of atrial fibrillation and increased risks of stroke, pacemaker implantation, and mortality.^{46–49} Similarly, although isolated PVC is common and usually not harmful,³² excessive amounts and severe forms of PVCs (eg, ventricular tachycardia) are independent risk factors for major cardiovascular events, including acute myocardial infarction, stroke, and SCD.^{50–52} Because cardiac arrhythmias, especially ventricular tachycardia, is a predominate cause of SCD in otherwise healthy adolescents and young adults,⁴ our finding that PM_{2.5} is related to ventricular arrhythmias suggests that PM_{2.5} may contribute to the risk of SCD among youth. It should be noted that increased PM_{2.5} was not related to PACs, which is consistent with previous studies conducted in other general population samples.^{22,23,26} Only Riediker et al²⁴ found that PM_{2.5} exposure was associated with an increased number of both ventricular and supraventricular arrhythmias in a study conducted in young male highway patrol troopers. Highway patrol troopers are usually exposed to high levels of particulate matter air pollution from traffic for an extended period of time. Therefore, their study results may not reflect the association between air pollution and cardiac arrhythmias in a typical youth population.

Multiple causal mechanisms for the association between PM_{2.5} and cardiac arrhythmias have been proposed.^{53,54} As summarized in these 2 comprehensive reviews, particulate matter-induced systematic inflammation responses, oxidative stress, autonomic imbalance, direct effects of particulate matter in circulation, and particulate matter-promoted cardiac structural remodeling may be responsible for the proarrhythmic effects of PM_{2.5}.

The present study has some noteworthy strengths. First, we collected individual-level PM_{2.5} data with a portable nephelometer for 24 hours. The personal monitor enabled us to adequately measure the air quality from the microenvironment around the participants, whereas geostatistical-based estimations generated based on regional-level data may not be able to capture the variations in PM_{2.5} concentrations in small geographical areas. Second, we divided the entire 24-hour recordings into 30-minute-based segments and treated them as time-varying repeated measurements. This approach substantially increased our

statistical power. Because air pollution usually explains a small proportion of the variance in ECG outcomes, especially among healthy populations, the repeated-measurement data structures played a critical role in allowing us to detect the small yet significant effect of PM_{2.5} on PVC. Third, we nested a polynomial distributed lag model within a framework of a negative binomial model to assess the association between PM_{2.5} concentrations and arrhythmia counts. With this model, the autocorrelation in both independent and dependent variables are accounted for simultaneously and consequently minimized the biases in the regression estimates. We further conducted sensitivity analyses by including different polynomial terms and excluding segments with high PVC counts. The consistent results from different models suggests that the observed association was highly robust.

Some of the limitations of the present study should not be ignored. First, because of the limited availability of PM_{2.5} monitors, we were not able to obtain air quality data from 23.5% of the PSSC. However, there was no significant difference between adolescents with and without PM_{2.5} data. Second, although the participants were instructed to bring the air pollution monitor with them when performing outdoor activities, it is possible that some of them kept the monitor indoors. Third, the PACs were identified solely based on the ratio of 2 consecutive R-R intervals. In the meantime, we largely relied on the ECG processing software to identify PVCs. However, the software limited our ability to further stratify the PVC according to its origin or specify the prematurity of PVCs. Therefore, there is a chance for misclassification. However, this misclassification bias is systematic because only 1 research technician was involved in the ECG processing. Fourth, our model selection approach is data driven. As discussed briefly previously, the cumulative effects of PM_{2.5} on PVCs were statistically significant in all of our models except the lag-0 model. Because there was little prior knowledge regarding the time course of the impact of PM_{2.5} on cardiac arrhythmias, we decided, a priori, to select our final model based on the strengths of the cumulative effect and the significance of the individual lag terms. As a result, we chose the model of lags 0 to 3 as our final model, which suggested an acute impact of PM_{2.5} on arrhythmias within 2 hours after exposure. In fact, such an acute effect is supported by some of the previous studies. Lastly, other variables, in particular cigarette smoking, may be an important confounding factor. However, the vast majority of our study participants were younger than the legal smoking age, and their self-reported smoking histories are likely to be underestimated. Nonetheless, the acute impact of PM_{2.5} on PVC remained significant after adjusting for self-reported exposure to cigarette smoking.

CONCLUSIONS

In summary, our study results suggest that PM_{2.5} air pollution is associated with an acute increase in the numbers of ventricular arrhythmias among otherwise healthy adolescents. Importantly, such an adverse health effect of PM_{2.5} on cardiac arrhythmia was observed in this low-risk population in an environment with PM_{2.5} concentrations well below the US Environmental Protection Agency–mandated, health-based air quality standards. In addition, we identified that the time course of the effect of PM_{2.5} on arrhythmia was ≈2 hours, with the most significant impacts occurring between 0.5 and 2.0 hours. Although pending confirmation, such an acute impact of particulate air pollution on ventricular arrhythmias during adolescence may increase the risk of SCD during early adulthood.

SUPPLEMENTAL MATERIAL

Table S1. Comparison of participant characteristics between adolescents with and without PM_{2.5} data.

	With PM _{2.5} (N=322)	Without PM _{2.5} (N=99)	P value *
Age (years)	16.95±2.25	17.88±2.24	0.77
Male (n, %)	180, 55.90%	47, 47.47%	0.14
Non-Hispanic white (n, %)	255, 79.19%	74, 74.75%	0.35
BMI percentile	65.35±29.09	65.35±26.12	0.99
PAC (count)	0.47±3.00	0.44±1.70	0.65
PVC (count)	0.36±3.09	0.34±2.27	0.87

Data are presented as mean±SD for continuous variables and n, percentage for binary variables.

*: T-test and chi-square tests were used to obtain p values.

Table S2. Rate Ratio (95% C) in association between 10 $\mu\text{g}/\text{m}^3$ increase in PM_{2.5} concentration and number of cardiac arrhythmias from models with different numbers of lag terms.

*: Model 1 adjusted for age, race, sex, BMI percentile, temperature, and relative humidity.

†: Model 2 adjusted for age, race, sex, BMI percentile, physical activity level, self-reported exposure to cigarette smoking, temperature, relatively humidity.

Figure S1. Comparison of EKG characteristics of normal heartbeat, PAC, and PVC

EKG: Electrocardiogram

PAC: Premature atrial contractions. Defined as a premature heart beat with $\geq 25\%$ reduction in the R-R interval compare to the immediate prior R-R interval.

PVC: Premature ventricular contraction. Characterized by an absence of P wave and a premature QRS complex with an abnormally large width and amplitude on EKG.
