

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

## Long term neuropsychiatric consequences in COVID-19 survivors: Cognitive impairment and inflammatory underpinnings fifteen months after discharge

Cognitive function  
Systematic inflammation  
Long-COVID

### ABSTRACT

**Background:** Emerging evidence shows that cognitive dysfunction may occur following coronavirus disease 19 (COVID-19) infection which is one of the most common symptoms reported in researches of “Long COVID”. Several inflammatory markers are known to be elevated in COVID-19 survivors and the relationship between long-term inflammation changes and cognitive function remains unknown.

**Methods:** We assessed cognitive function and neuropsychiatric symptoms of 66 COVID-19 survivors and 79 healthy controls (HCs) matched with sex, age, and education level using a digital, gamified cognitive function evaluation tool and questionnaires at 15 months after discharge. Venous blood samples were collected to measure cytokine levels. We performed correlation analyses and multiple linear regression analysis to identify the factors potentially related to cognitive function.

**Results:** The COVID-19 survivors performed less well on the Trails ( $p = 0.047$ ) than the HCs, but most of them did not report subjective neuropsychiatric symptoms. Intensive care unit experience ( $\beta = -2.247$ ,  $p < 0.0001$ ) and self-perceived disease severity ( $\beta = -1.522$ ,  $p = 0.007$ ) were positively correlated, whereas years of education ( $\beta = 0.098$ ,  $p = 0.013$ ) was negatively associated with the performance on the Trails. Moreover, the abnormally elevated TNF- $\alpha$  levels ( $r = -0.19$ ,  $p = 0.040$ ) were negatively correlated with performance on the Trails in COVID-19 group.

**Conclusion:** Our findings suggest that COVID-19 survivors show long-term cognitive impairment in executive function, even at 15 months after discharge. Serum TNF- $\alpha$  levels may be an underlying mechanism of long-term cognitive impairment in patients recovering from COVID-19.

### 1. Background

Coronavirus disease 19 (COVID-19),<sup>2</sup> caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2),<sup>3</sup> primarily causes respiratory symptoms, with fever and cough with or without sputum being the most common manifestations in symptomatic patients. However, the finding that the virus has the potential to cause central nervous

system (CNS)<sup>4</sup> damage suggests a possible role for the virus in the development of long-term neuropsychiatric sequelae (Kumar et al., 2021; Tandon, 2022).

Growing evidence suggests that there is a high frequency of persistent neuropsychiatric symptoms after the initial illness including fatigue, cognitive dysfunction, sleep disorders, mood disorder, and anxiety disorders that often refers to as ‘Long-COVID’ (Badenoch et al.,

<sup>3</sup> SARS-CoV-2: Severe Acute Respiratory Syndrome Coronavirus 2

<sup>4</sup> CNS: Central Nervous System

2022; Hampshire et al., 2021). There are several mechanisms through which SARS-CoV-2 could damage the CNS, including direct invasion and indirect infection (Alvarez et al., 2022; Du et al., 2021; Iodice et al., 2021; Kumar et al., 2021). SARS-CoV-2 can invade the nervous system through the recognition of the virus's spike proteins by cell membrane receptors (Amruta et al., 2021; Du et al., 2021). Another possible mechanism that the virus can indirectly infect the nervous system is the cytokine storm which refers to an uncontrolled excessive inflammatory reaction. It starts locally and spreads further in the body through systemic circulation. (Jose and Manuel, 2020). However, it is unclear which is the dominant mechanism that underlies the neuropsychiatric sequelae.

Several inflammatory markers, including interleukin (IL)<sup>5</sup>-1 $\beta$ , IL-6, interferon (IFN)<sup>6</sup>- $\gamma$ , tumor necrosis factor (TNF)- $\alpha$ ,<sup>7</sup> chemokine interferon- $\gamma$  inducible protein-10, Monocyte chemoattractant protein-1, and macrophage inflammatory protein 1- $\alpha$ , and T helper 2 cytokines, including the IL-4, IL-10, and IL-1 receptors, are elevated in the serum of patients with COVID-19 during the cytokine storm particularly related to the illness (Coperchini et al., 2020; Mehta et al., 2020). The persistence of the SARS-CoV2 and extension and amplification of the inherent immune mechanism will cause the dysfunction of immune response once the human immune system could not produce an appropriate immune response to the virus. This will lead a high inflammatory state of cytokine storm. (Pelaia et al., 2020) Previously, systemic inflammation has been shown to lead to cognitive decline, suggesting that COVID-19 survivors could experience cognitive deficits in the following years (Gorelick, 2010; Poletti et al., 2022).

It is known from previous pandemics that there are not only acute effects of the viral infection but also long-term sequelae such as depressed mood, anxiety symptoms, insomnia, loss of smell, ageusia, fatigue, and headache due to the virus infection itself as well as social effects due to quarantine, social distancing, and lockdown (Han et al., 2022; Kumar et al., 2021; Méndez et al., 2022). The COVID-19 pandemic has prompted many countries to adopt restraining measures to mitigate the spread of the disease (Nogueira et al., 2021). As the disease has a high level of transmissibility, the patients with COVID-19 are required to stay in isolated units. In Wuhan, patients with mild symptoms received treatment in temporary quarantined hospital facilities, whereas those with more severe symptoms received treatment from a designated hospital for more aggressive therapy (Hu et al., 2020). Isolation has been shown to influence cognitive function (Wang et al., 2022).

Some earlier studies found significant differences between patients with COVID-19 and matched control groups via self-report questionnaires on various measures, indicating short-term memory loss, trouble focusing attention, and concentration impairment/disorder in the patients (Amin-Chowdhury et al., 2021; González-Hermosillo et al., 2021; Klein et al., 2021). However, most of the existing studies have focused on assessing patients at 5 days to one year of follow-up after discharge from the hospital (Ceban et al., 2022; Miskowiak et al., 2022). Research focusing on neuropsychiatric consequences over one year is limited and should be investigated (Kawakami et al., 2022). Furthermore, changes in the levels of inflammatory factors in people who recovered from COVID-19 and their relationship with cognitive function remain unknown. Moreover, most of the existing studies rely on patients' complaints in medical records or self-reported symptoms via telephone to evaluate and describe neuropsychiatric symptoms and neurocognitive function. Few studies have evaluated the neurocognitive function of COVID-19 survivors using integrated tools in which both self-reported questionnaires and neuropsychological tests were used.

In summary, SARS-CoV-2, which causes neuronal damage, can have a prolonged negative impact on cognitive function, daily functioning,

and quality of life. It is important to understand the neuropsychiatric consequences as millions of individuals have been affected and more unbound. Similarly, evaluating cognitive consequences following COVID-19 is essential, particularly by evaluating the capacity of an individual to work effectively, participate in daily family activities, or make reasoned decisions (Kumar et al., 2021).

This study aimed to evaluate the cognitive function and neuropsychiatric symptoms in patients who recovered from COVID-19 at 15 months of follow-up after their discharge from hospital, and to investigate the potential associated factors, including systematic inflammation. We assessed the cognitive function of COVID-19 survivors using THINC-integrated tool (THINC-it),<sup>8</sup> which is a digital, gamified cognitive function evaluation tool (Harrison et al., 2018; Zhang et al., 2020). Using this tool, we evaluated comprehensive neuropsychiatric/cognitive function in COVID-19 survivors after 15 months and in matched healthy controls (HC).

## 2. Methods

### 2.1. Study design and participants

This was an observational cross-sectional study. We recruited 66 patients hospitalized for SARS-CoV-2 infection who were willing to participate in this study. Voluntary COVID-19 survivors who visited the second outpatient clinic, West China Hospital, Sichuan University, about fifteenth-month after their discharge from April 2021 to August 2021 were enrolled in the study. Healthy volunteers were recruited from nearby communities between August 2021 and December 2021. All subjects gave written informed consent.

### 2.2. The patients with COVID-19 group

The criteria for enrollment of patients with COVID-19 were as follows: (1) patients who were hospitalized and willing to participate in the follow-up process, and (2) participants who signed an informed consent form and were able to understand and complete the tests. The exclusion criteria were as follows: (1) Patients have some neurological diseases such as cerebrovascular disease, neurodegenerative diseases, encephalitis, and traumatic brain injury which may cause cognitive impairment based on MRI examination (3-T MRI system Philips Achieva) (2) patients who could not understand or read the informed consent form, and (3) patients who is taking psychotropic medicines. Finally, we recruited 66 COVID-19 survivors aged 13–66 years old into the study.

### 2.3. HC group

In total, 79 healthy participants matched with sex, gender, and education level were recruited voluntarily. Both male and female participants aged between 17 and 61 years were included. Clinical examination eliminated cognitive impairment caused by physical illness, as well as family history of psychiatric disorders. We excluded participants who were pregnant or lactating women and those who had hearing or visual impairments.

## 3. Assessment

### 3.1. Demographic data and basic clinical information

Demographic data, including age, sex, marital status, educational background, smoking history, occupation, and religion were collected. Meanwhile, routine clinical data, including length of hospital stay, isolation time, duration of nucleic acid positivity, and self-perceived disease severity were collected. The self-perception of disease severity

<sup>5</sup> IL-: Interleukin-

<sup>6</sup> IFN-: Interferon-

<sup>7</sup> TNF- $\alpha$ : Tumor Necrosis Factor alpha

<sup>8</sup> THINC-it: THINC-Integrated Tool

was registered on an ordinal scale.

### 3.2. Neuropsychiatric interview

The Mini International Neuropsychiatric Interview (MINI version 5.0.0)<sup>9</sup>(Si et al., 2009) was conducted to determine the mental health diagnoses of all participants. The results were evaluated by a trained physician. In addition, the severity of anxiety, depression symptoms, and post-traumatic stress disorder (PTSD)<sup>10</sup> symptoms was self-reported using the Generalized Anxiety Disorder Assessment (GAD-7)<sup>11</sup>(He et al., 2010) Patient Health Questionnaire-9 (PHQ-9)<sup>12</sup>(Sun et al., 2017) and a 4-item Post-traumatic Stress Disorder Checklist for Diagnostic and Statistical manual of Mental disorders-5 scale (PCL-5)<sup>13</sup>(Fung et al., 2019) for the COVID-19 group.

### 3.3. Cognitive assessment

Cognitive assessment was performed using a digital, simplified Chinese version of the THINC-it tool, which has been proven to have good reliability and validity in the Chinese adult population (Liu et al., 2021). It includes a 5-item Perceived Deficits Questionnaire for Depression (PHQ-5D),<sup>14</sup> Spotter, Symbol Check, Codebreaker, and Trails (Hou et al., 2020; Zhang et al., 2020). The validity of the four objective test sections of the THINC-it tool (Spotter, Symbol Check, Codebreaker, and Trails) was used to evaluate the subjunctive's attention/concentration, executive function, working memory, and processing speed. The five consistent criterion tests were the Deficits Questionnaire for Depression (PDQ-5D), Reaction time paradigm (RTI),<sup>15</sup> Digit Symbol Substitution Test (DSST),<sup>16</sup> Trail Making Test-Part-B (TMT-B),<sup>17</sup> and One-back Task (1-back)<sup>18</sup> (Zhang et al., 2020). RTI was selected as a measure of attention and executive function; 1-back paradigm was selected to test the attention, memory, and reaction speed of the participants; DSST was chosen to identify the executive function, processing speed, and attention/concentration; and TMT-B was selected to assess the executive function of the participants.

In addition to these four objective measures of cognition, the PHQ-5D questionnaire was included as a subjective measure of general cognitive function, including attention/concentration, retrospective and prospective memory, and planning/organization, using a 5-points ordinal categorical response scale to reflect the frequency of experiencing a specific cognitive problem in the past 7 days (Harrison et al., 2018; Lam et al., 2018).

### 3.4. Social support scale and discrimination evaluation

Xiao revised a Chinese version of the social support scale based on the relevant information (Xiao, 1994). Its validity and reliability have been previously confirmed (Liu et al., 2008). The social support scale contains 10 items, including 3 objective support, 4 subjective support, and 3 support utilizations. The score varies from 12 to 65 points, with a higher score representing greater social support and diversity of social networks (Su et al., 2012). We also gathered information regarding discrimination factors, including being ostracized by neighbors, family

members, relatives, and friends, and being insulted by others. All the above factors were registered on an ordinal scale assigning degrees of "none," "somewhat," "moderate," "severe," and "extraordinarily severe."

### 3.5. Serum sample collection and analysis

Venous blood samples (5 ml) were collected from each patient. The blood samples were centrifuged at 3500 r/min for 15 min, and serum was extracted for analysis. Cytokines in the serum/plasma were measured by a multiplexed flow cytometric assay using a human cytokine (kit catalog number: HSTCMAG-28SK) on a Luminex® system (MAGPIX® WITH xPONENT, version 4.2, Merck Millipore, USA). In serum/plasma, measurements of interferon-inducible T cell alpha chemottractant (I-TAC), granulocyte-macrophage colony-stimulating factor (GM-CSF),<sup>19</sup> fractalkine, IFN- $\gamma$ , IL-10, macrophage inflammatory protein-3 $\alpha$  (MIP-3 $\alpha$ ),<sup>20</sup> IL-2(p70), IL-13, IL-17A, IL- $\beta$ , IL-2, IL-4, IL-23, IL-5, IL-6, IL-7, IL-8, MIP-1, MIP- $\beta$ , and TNF- $\alpha$  were performed. The analysis was performed according to the manufacturer's instructions (MILLIPLIX Analyst 5.1, Merck Millipore, USA). The samples were measured in duplicates. The range of the standard curves for all measured cytokines was pg/ml.

## 4. Statistical analysis

In this study, the COVID-19 survivors and HC group were matched by propensity score matching to control for covariates including age, sex, and years of education. All the collected data were analyzed using the R (version 4.1.1) package with an alpha set for significance at  $p < 0.05$ , which represents an acceptable probability of Type I error in a statistical test. The Shapiro-Wilk method was used to assess the normality of continuous variables. T-tests were used for normally distributed data, and non-parametric Mann-Whitney U tests were applied for continuously skewed data. Categorical data were analyzed using the chi-square test. An association test was conducted using the Spearman method if the data were not normally distributed. Multiple linear regression analysis was used to explore factors related to cognitive function. Outlier and influential points were detected before all analyses. The sample size with adequate power was calculated by GPower (version 3.1.9.7). For non-normally distributed data, effect size  $r$  were estimated (Fritz et al., 2012).

Demographic data and basic clinical information were displayed as frequencies and expressed as percentages (n, %). In the cognitive test, Symbol Check and Codebreaker were negatively associated with the severity of cognitive impairment; however, the scores of Spotter and Trails showed the opposite trend. To maintain the direction of each test result consistently, the results of PDQ-5D, Spotter, and Trails were converted into standard z-scores and multiplied by  $-1$ , so that the results of each sub-part of THINC-it would follow a trend where the higher the score, the better the cognitive function (McIntyre et al., 2017; Zhang et al., 2020).

A multiple linear regression model was used to assess the independent predictors of the test scores for significantly different cognitive functions. We included 13 independent variables, including age, sex, years of education, length of hospital stay, nucleic acid test positive time, isolation time, self-perception of disease severity, being ostracized by family, neighbors, and community, being verbally abused, social support score, PHQ-9 score, and GAD-7 score. All categorical independent variables were recoded into dummy variables, which were used in the regression analysis to represent subgroups of the sample in the model.

## 5. Result

### 5.1. Demographic information and clinical characteristics

The demographic information, cognitive performance, and neuropsychiatric data of the participants are presented in [Table 1](#). In total, 66 patients hospitalized for COVID-19 and 79 HC volunteers were included in the present study after adjusting for age, sex, and educational background. There were no significant differences in age, sex, or education. Only 4 COVID-19 survivors had a MINI diagnosis consistent with depression and anxiety and most COVID-19 survivors did not report subjective neuropsychiatric symptoms. The COVID-19 group performed less well in the Trails with a small effect size ( $r = 0.21$ ,  $p = 0.047$ ) than the HC group.

The clinical characteristics of the COVID-19 survivors are displayed in [Table 2](#). The median length of hospital stays, isolation time of hospitalized survivors, and duration of nucleic acid positivity were 20.50 (14.25–30.00), 45.00 (30.00–60.00), and 20.00 (10.00–30.00) days, respectively. The majority of the survivors' self-perceived disease severity was general and mild. Furthermore, participants rarely had the experience of intensive care unit (ICU) stay, and none of them had extraordinarily severe ostracization by neighbors, community, family members, relatives, or friends.

### 5.2. Multiple linear regression for the prediction of cognitive function

To streamline the presentation of the results, [Table 3](#) reports the findings from the linear multiple regressions. The associations between the basic clinical data, discrimination data, and cognitive function are summarized in [Table 3](#). In the model, the results of multiple linear regression indicated that the four predictors explained 32.76 % of the variance ( $R^2 = 0.328$ ,  $F(20,38) = 2.584$ ,  $p = 0.004$ ). Multiple linear regression analysis revealed a significant association between ICU experience ( $\beta = -2.247$ ,  $p < 0.0001$ ), years of education ( $\beta = 0.098$ ,  $p = 0.013$ ), and self-perception of disease severity (somewhat severe) ( $\beta = -1.522$ ,  $p = 0.007$ ). The factors of ICU stay and self-perceived disease severity were negatively associated with cognitive function. In contrast, years of education was positively associated with executive function.

### 5.3. Associations between neuropsychiatric symptoms, inflammatory factors, and the cognitive test

There is no statistically significance between scores for depression/anxiety/PTSD and cytokine levels and cognition. Comparison tests revealed significant differences after false discovery rate (FDR)<sup>21</sup> correction between the COVID-19 ( $n = 55$ ) and HC groups ( $n = 79$ ) with regard to the I-TAC (adjusted  $p = 0.021$ ), IL-8 (adjusted  $p < 0.0001$ ), and TNF- $\alpha$  (adjusted  $p < 0.0001$ ). The HC groups show higher I-TAC level ( $87.68 \pm 32.56$ ) compared with COVID-19 group ( $33.95 \pm 9.59$ ) in follow-up. Similarly, the IL-8 level is  $18.58 \pm 11.54$  for HC groups which is higher than COVID-19 group ( $6.55 \pm 6.51$ ). However, the TNF- $\alpha$  is  $8.39 \pm 1.76$  which is elevated in COVID-19 group than in HC group ( $6.58 \pm 1.76$ ). Eleven COVID-19 survivors did not participate in blood sample collection. Moreover, the correlation analyses indicated that TNF- $\alpha$  levels were negatively correlated with the composite z-score of the Trails after FDR correlation (Spearman's Rho;  $r = -0.19$ ,  $p = 0.040$ ) ([Fig. 1](#)).

## 6. Discussion

To our knowledge, this is the first study on neurocognitive evaluation using the THINC-it tool for COVID-19 survivors in a 15-month follow-up time. Our analysis exhibited differences in the performance on the

Trails, which evaluates executive function, compared with the HC group at 15-months of follow-up. A potential correlation between serum TNF- $\alpha$  levels and executive function has also been reported. In hospitalized COVID-19 survivors, executive function was negatively correlated with the experience of ICU stay and self-perceived disease severity. These associations were independent of age, sex, and years of education.

Cognitive deficit is one of the most common symptoms reported in research into Long COVID. Those who experienced "post-COVID-19 syndrome"/ "post-acute sequelae SARS-CoV-2"/ "Long COVID" following the COVID-19 infection may have cognitive dysfunction ([Guo et al., 2022](#)). Based on our understanding of the mechanism of the virus in the CNS and the emerging evidences available, one can expect to have a variety of cognitive consequences of COVID-19 infection including attention, dysexecutive symptoms and hypoperfusion ([Kumar et al., 2021](#)). In this study, COVID-19 survivors were admitted for a clinical physical examination to rule out cognitive impairment due to physical illness. We examined the objectively cognitive function of the 66 hospitalized COVID-19 survivors 15 months after hospital discharge, as well as in 79 recurrent healthy participants based on age, sex, and educational background. We reported the differences in executive function between the two groups. Our results are in line with the results of a previous study that reported a significant difference in executive function between patients with COVID-19 and a healthy control group ([Johnsen et al., 2021](#)). Similarly, another study showed that the most pronounced impairments in patients with COVID-19 were seen in verbal learning and executive function evaluated using TMT-B, based on age, sex, and education, compared to a matched HC group ([Miskowiak et al., 2021](#)).

We did not find any group differences in attention, memory, reaction speed, or processing speed, which is contrary to earlier research ([Ferrucci et al., 2021](#)). A previous study using the Montreal Cognitive Assessment indicated an improvement in cognitive function from discharge time to 6 months of follow-up, while another study showed a greater increase in duration to complete the TMT-B at follow-up time in patients with COVID-19 compared to healthy controls ([Douaud et al., 2022](#); [Nersesjan et al., 2022](#)). We can only speculate that the possible reason for the difference in results from previous studies might be that the cognitive function of COVID-19 survivors improved over time, and most of the earlier evaluations were performed using objective tools.

Further, we found that the experience of ICU stay and self-perceived disease severity were negatively associated with cognitive function. Patients with COVID-19 who had experienced ICU stay showed worse executive function at 15 months of follow-up. This result was in line with that from an earlier study which indicated that new or worse cognitive impairment commonly occurs and persists in survivors of ICU stay ([McLoughlin et al., 2020](#)). The COVID-19 survivors suffered some degree of isolation and discrimination; however, no significant correlation between discrimination or other social isolation factors and cognitive function have been identified. One possible reason might be that most of the discrimination faced by the patients with COVID-19 was mild, and none of them had experienced extraordinarily severe discrimination. As shown in [Table 2](#), they received adequate social support from family members, friends, and society. Another possible reason is that the privacy of patients in Sichuan is well-protected and a certain degree of psychological education is provided to them, making them less vulnerable to social isolation and discrimination.

SARS-CoV-2 can damage the nervous system through indirect infection such as cytokine storm which refers to an uncontrolled excessive inflammatory reaction ([Du et al., 2021](#)). In current study, we demonstrated that there were differences in I-TAC, IL-8, and TNF- $\alpha$  levels after FDR correction between the two groups. Our finding is consistent with the higher levels of inflammatory factors reported in other studies ([Heneka et al., 2020](#); [Huang et al., 2020](#)). In contrast, we did not find any differences in the levels of IL-13, IL-1b, IL-6, IL-23, fractalkine, MIP-3a, IL-17A, IL-5, IFN- $\gamma$ , GM-CSF, IL-7, IL-4, IL-21, MIP-1a, IL-2 between the COVID-19 and HC groups. Furthermore, there was a significant correlation between the serum TNF- $\alpha$  levels and

<sup>21</sup> FDR: false discovery rate

executive function at 15 months of follow-up. A previous study showed the systemic inflammation was a predict factor to the neurocognitive performance (Mazza et al., 2021). Inflammatory markers including TNF- $\alpha$ , TNF- $\beta$ , IL-1 $\beta$ , IL-4, IL-6, IL-8, and IL-13 was found to be correlated with post-acute sequelae of COVID-19 (Schultheiss et al., 2022).

Pro-inflammatory mediators can compromise the permeability of BBB via upregulation of cyclooxygenase-2 and activation of matrix metalloprotease (Dehghani et al., 2022). This enables cytokines to enter the CNS, causing microglial activation and oxidative stress, leading to the development of synergistic cognitive impairment (Baker et al., 2021). TNF- $\alpha$  is a prototypic proinflammatory cytokine that is crucial in initiating and sustaining the inflammatory response (Belarbi et al., 2012). Large amount of evidences show that TNF is a main mediator of secondary CNS damage after acute injury and under conditions of chronic inflammation (Probert, 2015). It exerts both homeostatic and pathophysiological effects in the CNS (Montgomery and Bowers, 2012). In healthy adults, TNF is constitutively expressed at low level, and has regulatory functions on crucial physiological processes while in pathological ones, astrocytes and mainly microglia release large amounts of TNF- $\alpha$  (Olmos and Lladó, 2014; Probert, 2015). Over release of TNF- $\alpha$

pathologically can be involved in the process of increased apoptosis and decreased neuroplasticity of nerve cells through neurotoxicity and lead to cognitive impairment (Olmos and Lladó, 2014).

In an earlier study, compared with wild-type mice, TNF- $\alpha$  deficient mice demonstrate a decreased latency in finding the underwater platform in the Morris water maze testing. This suggests enhanced hippocampal memory function in TNF- $\alpha$  knock-out mice (Golan et al., 2004). Moreover, Fiore et al. conducted the same assessments to invest whether endogenous brain TNF- $\alpha$  elevation in transgenic mice was associated with changes in learning capabilities; overexpression of TNF- $\alpha$  impaired hippocampal learning/memory function, indicating a suppressive role for high-level TNF- $\alpha$  in cognition (Fiore et al., 2000).

However, we did not find any correlation between depression/anxiety/PTSD scores and cytokine levels. This is in line with an earlier study which evaluate the relationship between psychiatric symptoms and hematological inflammatory markers. This may because that most COVID-19 survivors recovered from psychiatric symptoms, thereby inflammation is not a significant contributor to psychiatric morbidity in patients with COVID-19 in the long term. (Swami et al., 2022).

The current study was an observational cross-sectional study that

**Fig. 1.** Association analysis between the composite z-score of Trail and inflammatory factors. The matrix diagram shows the correlation coefficient and significance level after FDR correction. The TNF- $\alpha$  level is statistically significantly correlated with the composite z-score of Trail. ( $r = -0.19$ ,  $p = 0.040$ ). The “\*” represents significance level, and the more of it, the more significance.

evaluated the cognitive functions of hospitalized patients with COVID-19 at 15 months of follow-up, and its related risk factors. However, this study has some limitations. First, we could not gather the information which is related to the cognitive impairment, including prolonged hypoxia, requirement for ventilatory support, and steroid therapy from the hospitals. Second, although existing studies have shown that systemic or CNS inflammation can cause psychiatric symptoms and cognitive deficits, we did not find any correlation between depression/anxiety/PTSD symptoms and cognition. This may be because only 4 COVID-19 survivors in present study had symptoms of depression or anxiety. Third, the blood sample was collected only once at follow-up visiting so that we could not determine whether inflammatory levels remain correlated with cognitive decline over time. A further study on longitudinal changes in neuropsychiatric symptoms, cognitive function and inflammatory levels would be necessarily.

## 7. Conclusions

In conclusion, we observed that COVID-19 survivors remain subtle cognitive impairment compared with healthy ones, especially on executive function at 15-month from hospital discharge. Additionally, the experience of ICU stay and self-perceived illness severity were associated with executive function. The serum TNF- $\alpha$  level continued to be abnormal compared with matched HC and was correlated with executive function in COVID-19 survivors even at 15 months after recovery. This study provides evidence of long-term cognitive function impairments in patients with COVID-19, and its relationship with inflammatory profiles.

## Funding

This work was supported by China National Key Research and Development Program (2020AAA0105005), Department of Science and Technology of Sichuan Province (Grant numbers 2020YFS0582, 2020YFS0231), 1-3-5 Project for Disciplines of excellence, West China Hospital, Sichuan University (Grant number ZYJC21004), the National Natural Science Foundation of China (Grant numbers 81871061), and by Postdoctoral Foundation of West China Hospital (Grant number 2020HXBH041 to M.Y.).

## Declaration of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Acknowledgements

The authors would like to thank all the participants, as well as all facilitators that contributed to this research and especially Minlan Yuan.

### Ethics Approval and Consent to Participate

The research processes adhered to the Declaration of Helsinki (2008) Ethical Principles for Medical Research Involving Human Subjects and were approved by the Medical Ethics Committee of West China Hospital, Sichuan University. Besides, all the voluntary subjects gave written consents and were informed they were at liberty to withdraw from the study at any time, with an additional examination.

### Consent for Publication

Not applicable.

### Authors' contributions

DMH collected data on patients who came to the hospital for follow-up visits, analyzed data collected, and wrote the manuscript. RLY, LB, JYY, XL, BL, SYL, and SMZ collected patients' follow-up data as well. MLY designed this research and the revised the draft critically for important intellectual content. WZ is the peer reviewer and designed this research. All authors read and gave the final approval of the version to be published.
