Abstract

Plasmodium falciparum hypoxanthine–guanine–xanthine phosphoribosyltransferase (*Pf*HGXPRT) is essential for purine salvage of hypoxanthine into parasite purine nucleotides. Transition state analogue inhibitors of *Pf*HGXPRT are characterized by kinetic analysis, thermodynamic parameters, and X-ray crystal structures. Compound **1**, 9-deazaguanine linked to an acyclic ribocation phosphonate mimic, shows a kinetic K_i of 0.5 nM. Isothermal titration calorimetry (ITC) experiments of **1** binding to *Pf*HGXPRT reveal enthalpically driven binding with negative cooperativity for the binding of two inhibitor molecules in the tetrameric enzyme. Crystal structures of **1** bound to *Pf*HGXPRT define the hydrogen bond and ionic contacts to complement binding thermodynamics. Dynamics of ribosyl transfer from 5-phospho-α-D-ribosyl 1-pyrophosphate (PRPP) to hypoxanthine were examined by ^{18}O isotope exchange at the bridging phosphoryl oxygen of PRPP pyrophosphate. Rotational constraints or short transition state lifetimes prevent torsional rotation and positional isotope exchange of bridging to nonbridging oxygen in the α-pyrophosphoryl group. Thermodynamic analysis of the transition state analogue and magnesium pyrophosphate binding reveal random and cooperative binding to *Pf*HGXPRT, unlike the obligatory ordered reaction kinetics reported earlier for substrate kinetics.

Graphical Abstract
INTRODUCTION

De novo purine synthesis is essential in maintaining human pools of adenylate and guanylate compounds for DNA and RNA synthesis.[1,2] Protozoan parasites, including *Plasmodium falciparum*, lack *de novo* purine synthesis and require the purine salvage pathway as an essential alternative. As a purine auxotroph, *P. falciparum* requires the salvage of purine bases from the host erythrocytes to perform purine nucleotide and nucleic acid synthesis. Purine salvage enzymes are attractive targets in the development of novel therapeutics for malaria. In *P. falciparum*, hypoxanthine–guanine–xanthine phosphoribosyltransferase (*Pf*HGXPRT) is an essential component of this pathway.[3–5]

Malaria is the leading cause of death in Sub-Saharan Africa and regions of Southeast Asia. Global malaria cases have remained over 200 million yearly with approximately 400 thousand malaria-associated deaths.[6–9] Malaria disproportionately affects children under 5 years old. Although several species of *Plasmodium* parasites cause the disease, *P. falciparum* accounted for 50% of malaria infections in Southeast Asia and over 99% of cases in Sub-Saharan Africa in 2019.[8] A substantial reduction in malaria infections has been achieved by public health measures in Southeast Asia over the past two decades. However, malaria still plagues Sub-Saharan Africa, accounting for greater than 90% of the global malaria burden.[7,10] Resistance to the current WHO-approved first-line therapy, artemisinin-based combination therapy (ACT), has been reported in Southeast Asia and, more recently, in Sub-Saharan Africa.[11,12] Growing resistance has prompted several efforts to develop new therapies to malaria in addition to a vaccine prevention strategy.[13]

The essential enzyme *Pf*HGXPRT incorporates hypoxanthine (as well as guanine and xanthine), a key precursor of nucleotide biosynthesis, into the nucleotide pool of the parasite.[14,15] Hypoxanthine and inosine are formed in host erythrocytes and are available to the parasites through the *P. falciparum* purine base and nucleoside transporters in the parasite membrane. 6-Oxopurine nucleosides are in equilibrium with 6-oxopurine bases by the action of purine nucleoside phosphorylases (PNP) present both in erythrocytes and in *P. falciparum*.[16–18] We and others have previously reported *Pf*HGXPRT to be a target for the development of novel antimalarials and demonstrated that transition state analogue (TSA) inhibitors and their lipophilic prodrugs of *Pf*HGXPRT block incorporation of extracellular purines and inhibit the growth of *P. falciparum* parasites in culture.[14,15,19] Other reports have demonstrated the validity of the *Pf*HGXPRT target by inhibition with nucleoside phosphonates.[20,21] Targeting PNP with transition state analogues in cells and *Aotus* primates blocks hypoxanthine formation and results in antiparasitic activity.[5] However, parasite-specific *Pf*HGXPRT inhibitors are proposed to be an improvement over PNP inhibition, as a PNP blockade can be bypassed by metabolic conditions with increased hypoxanthine.[22] TSA inhibitors immucillin-H 5′-phosphate (ImmHP), immucillin-G 5′-phosphate (ImmGP), and the acyclic nucleoside phosphonates (AIP) have been reported for *Pf*HGXPRT, with dissociation constants of 0.65–14 nM. ImmHP and ImmGP were the first generation of transition state analogues for *Pf*HGXPRT. Although they are potent enzymatic inhibitors, the anionic phosphomonoesters are membrane-impermeable, susceptible to phosphatases, and exhibit low selectivity for the parasite *Pf*HGXPRT relative to the human HGPRT (*Hs*HGPRT).[19,23] The AIP compounds provide a biologically stable phosphonate group to

mimic the phosphate group of the substrates and have greater selectivity for *Pf*HGXPRT relative to *Hs*HGPRT. Phosphonate groups are established precursors for conversion to membrane-permeable prodrugs.[19,24]

*Pf*HGXPRT is a magnesium-dependent bi-substrate enzyme, utilizing the purine bases hypoxanthine, guanine, and xanthine with phosphoribosyl pyrophosphate (PRPP) to form the corresponding nucleotide monophosphates. The kinetic mechanism of *Pf*HGXPRT has been reported to be ordered with PRPP binding first followed by purine base binding.[25] Steady-state kinetic analyses of *Pf*HGXPRT are complicated by a lag in reaction rates before reaching the steady state, a phase attributed to a conversion from inactive monomers to the active tetrameric form. Tetramer formation is influenced by the binding of PRPP, also supporting the ordered kinetic mechanism of *Pf*HGXPRT.[25,26] Additional studies of *Pf*HGXPRT report slow interconversion of the ternary complexes with ordered release of the product (IMP released first) and an alternative ping-pong mechanism.[27,28] Human HGPRT is reported to have a similar sequential kinetic mechanism with PRPP binding before binding of the base.[29]

Here, we use protein cross-linking, inhibitor structure–activity relationships, catalytic site titration, isothermal titration calorimetry (ITC), crystal structures, isotope trapping, and positional isotope exchange (PIX) experiments as definitive tools to probe the mechanism and inhibition of the enzyme.[30,31] *Pf*HGXPRT catalyzes its N-ribosyl transferase activity with an S_N1-like ribooxocarbenium transition state structure where the leaving group and attacking nucleophile have low bond orders to the anomeric carbon of PRPP and the ribosyl group is a well-developed ribocation, a design element for transition state analogues.[32,33]

We extend the design, synthesis, and testing of novel TSAs and characterize the structural and thermodynamic interactions by kinetics, ITC, and X-ray crystallography. New insights into the ternary species and chemical intermediates of *Pf*HGXPRT are provided by PIX and isotope trapping experiments. Conditions for the formation of the active tetrameric enzyme from inactive monomers are defined by protein chemical cross-linking.

RESULTS AND DISCUSSION

*Pf*HGXPRT Activation to the Tetramer.

Steady-state kinetic analysis with *Pf*HGXPRT displayed a lag phase prior to product formation (Figure 1A–C). The lag phase disappeared following enzyme activation by incubation with hypoxanthine, PRPP, and $MgCl_2$ (substrate activated). Following activation, the enzyme could be diluted 60-fold into reaction mixtures containing the desired substrate and inhibitor concentrations to initiate steady-state kinetic analysis, thereby avoiding the lag phase (Figure 1A).

Oligomeric analysis of *Pf*HGXPRT before and after activation used glutaraldehyde cross-linking followed by SDS-PAGE to view the oligomeric species under different 'activating' conditions. Purified *Pf*HGXPRT without activation appears predominantly as the ~26 kDa monomer. Incubation with the substrates, hypoxanthine, PRPP, and $MgCl_2$ gave predominantly the tetrameric enzyme (Figure 1D,E). Activation conditions stabilizing

the tetramer eliminated the lag phase of the initial rate curves (Figure 1A). Tetrameric *Pf*HGXPRT was also formed when the enzyme was preincubated with Mg-PPi and the transition state analogue inhibitors, ImmHP and compound **1** (Figure 1E). Preincubation of the enzyme with PRPP, IMP, or magnesium pyrophosphate (Mg-PPi) as single agents resulted in a mixture of enzyme oligomeric species (Figure 1B–D). Full activation of *Pf*HGXPRT for kinetic activity requires binding of all substrates or filling the catalytic site with a transition state analogue. Substrate activation of *Pf*HGXPRT was carried out prior to all steady-state kinetic and inhibition measurements.

ImmHP is a transition state analogue of *Pf*HGXPRT, and its activation of the enzyme captures the enzyme in a configuration near the transition state, consistent with stabilizing the active tetrameric form of the enzyme (Figure 1E). Because ImmHP is a powerful inhibitor of *Pf*HGXPRT, its slow release from the enzyme makes it incompatible as an activating agent.[23,34] Earlier reports for *Pf*HGXPRT activation involved incubation of (1) 30 μM *Pf*HGXPRT with 60 μM IMP, (2) 1 mM PRPP and 12 mM MgCl$_2$, in 5 mM DTT and 10 mM phosphate buffer pH 7.0 at 0 °C for 3 h, or (3) 1 mM MgCl$_2$, 1 mM pyrophosphate, and 5 mM DTT in 10 mM phosphate buffer pH 7.0 at 0 °C for 3 h.[25,26,35] In our hands, these protocols provided an equilibrium of monomeric, dimeric, and tetrameric species in the cross-linking analysis (Figure 1). *Pf*HGXPRT from *Escherichia coli* extracts copurifies with substoichiometric amounts of purine and may account for the results obtained by activation with PRPP as a single agent.[25,26,32,35]

Activated *Pf*HGXPRT gave K_m values for hypoxanthine and PRPP of 10 ± 1 and 185 ± 14 μM, respectively, with a k_{cat} of 0.12 ± 0.01 s^{-1}. Kinetic assays with unactivated *Pf*HGXPRT gave K_m values for hypoxanthine and PRPP of 2.7 ± 0.3 and 55 ± 11 μM, respectively, and a k_{cat} of 0.020 ± 0.002 s^{-1}. The sixfold increase in the k_{cat} resulted in a 1.6-fold increase in catalytic efficiency (k_{cat}/K_m) for the activated enzyme.

Forward Commitment.

The kinetic mechanism of *Pf*HGXPRT has been reported to be steady-state ordered, requiring the binding of PRPP prior to hypoxanthine (Hx) and IMP as the first product released (Scheme 1).[25,36] We tested the kinetic mechanism and reversibility from the Michaelis complex using activated *Pf*HGXPRT in forward commitment experiments.

The ternary Michaelis complex was formed in a modified isotope trapping experiment using hypoxanthine and [5-^{14}C]PRPP in a pre-steady-state incubation serving to initiate tetramer formation and form a competent catalytic complex (see the Methods section). The chemical fate of [5-^{14}C]PRPP in the E-Hx-[5-^{14}C]PRPP complex was determined by dilution of the complex with excess unlabeled PRPP and hypoxanthine followed by reaction monitoring for the labeled and total IMP product (Figure 2). In a compulsory ordered mechanism (Scheme 1), saturation with the second substrate (hypoxanthine) traps the first substrate ([5-^{14}C]PRPP) where it is converted to the product without equilibration with the unbound PRPP pool (Scheme 1). This extension of the approach reported by Rose[30] also permits the estimation of a forward commitment (C_f), a partition coefficient for the relative probability of bound [5-^{14}C]PRPP being converted to the product relative to its release as unreacted [5-^{14}C]PRPP. A high probability of a bound substrate being converted to the product (C_f

> 1.0) is predicted from the proposed mechanism. In contrast, the measured C_f was 0.017 ± 0.003 [Figure 2 (▲)], establishing that bound [^{14}C]PRPP can escape from the Michaelis complex even when near-saturating hypoxanthine is present. For the purpose of comparison, the dashed line of Figure 2 would be expected for a modest $C_f = 0.5$. The total IMP formed during the initial 8 s continued at the same rate following dilution with unlabeled PRPP and hypoxanthine [Figure 2 (●). Escape of [^{14}C]PRPP from the ternary complex is inconsistent with a compulsory ordered mechanism and supports random binding of substrates. The C_f obtained here is similar to the small C_f previously reported for *Pf*HGXPRT.[32] However, the previously reported value was obtained with undefined activation of the enzyme, resulting in low catalytic efficiency. The C_f reported here does not alter the intrinsic kinetic isotope effect (KIE) values or transition state structure reported earlier.

Positional Isotope Exchange (PIX).

Transition state analysis of *Pf*HGXPRT reports a cationic riboxocarbenium transition state structure.[32] Transition state analysis by KIE gives information at the transition state but does not provide temporal information of the riboxocarbenium lifetime. The possibility of an enzyme-stabilized riboxocarbenium reaction intermediate was explored with PIX. The conversion of [1-^{13}C, bridge-^{18}O]PRPP to IMP was monitored continuously by NMR (Figure 3B,C). A PIX effect is observed when ^{18}O in the bridging position of PRPP scrambles to the non-bridging position in the PRPP pool.

This occurs if a stabilized ribocation has a lifetime sufficient to permit rotation of the α-phosphoryl group, reformation of [1-^{13}C, bridge-^{16}O]PRPP, and release to the substrate PRPP pool. No isotope scrambling in PRPP was observed by monitoring the ^{13}C chemical shift as influenced by the adjacent bridge-^{18}O (Figure 3B). The growth of the IMP peak at 6.2 ppm established that no PIX occurred in the presence of ongoing product formation (Figure 3C). A reversible riboxocarbenium intermediate with phosphoryl freedom of rotation in the *Pf*HGXPRT reaction can be eliminated by the lack of PIX.

PIX isotopic scrambling is expected if a reversible riboxocarbenium intermediate is formed during the reaction (Figure 3A), the Michaelis complex releases the substrate faster than is converted to products, and there is free torsional rotation of the pyrophosphate α-phosphoryl in the active site.[37] A new downfield resonance signal corresponding to ^{16}O in the bridging position would be observed by NMR.[38] Taking into consideration the low forward commitment factor and the S_N1-like mechanism from transition state analysis,[23] the lack of an ^{16}O–^{18}O PIX demonstrates constrained torsional rotation of the pyrophosphate. Strong coordination of the pyrophosphate leaving group to the divalent magnesium ions or a transition state lifetime shorter than phosphoryl rotation could prevent phosphoryl rotation to prevent isotope scrambling.[39,40] The crystal structure of *Pf*HGXPRT with ImmGP at the catalytic site shows that two magnesium ions coordinated four oxygens of the pyrophosphate, bridging the pyrophosphate to the vicinal iminoribitols of the inhibitor.[40] In contrast, inhibitor **1** has a single magnesium ion in contact with O2, O6, and O7 of the pyrophosphate (see below). These Mg-PPi contacts are candidates to immobilize the pyrophosphate within the active site.[19]

PfHGXPRT Inhibition.

The kinetic activity of *Pf*HGXPRT in the physiological direction of IMP formation (Figure 4A) was monitored by coupling to IMP dehydrogenase (IMPDH) and the production of NADH at 340 nm (see the Methods section). For the tightest-binding inhibitors, the dissociation constants were calculated using the Morrison equation[41] with a K_m for hypoxanthine of 10 μM.

Inhibitors to mimic the riboxocarbenium transition state structure of *Pf*HGXPRT were designed, synthesized, and tested for inhibitory activity (Figure 4B,C). The most potent of these was compound **1**, with a K_i value of 0.50 ± 0.05 nM. Compound **1** is a weaker inhibitor of *Hs*HGPRT with a K_i of 20 ± 0.3 nM, therefore displaying a selectivity index (SI) of 40 for the *P. falciparum* enzyme (Figure 4B and Table 1). Inhibition by the 9-deazahypoxanthine analogue (**2**) was similar to **1**, reflecting the preference of *Pf*HGXPRT for hypoxanthine and guanine as substrates (Figure 4C). Although the substrate specificity of *Pf*HGXPRT would suggest that the 9-deazahypoxanthine phosphate derivative (**3**) should share similar affinity, it does not, with the affinity decreased by 30-fold (Figure 4B,C). *Pf*HGXPRT presents an unusual case where a phosphonate improves binding relative to the phosphate monoester.

The crystal structures of the complex provide additional insights into inhibitor affinity (see below). Methylation of the serinol nitrogen of **2** forms **4** which retains its cationic character in solution but introduces steric interference for ion pair formation between the inhibitor, serinol nitrogen, and an oxygen of bound pyrophosphate, reducing affinity by 210-fold (Figure 4B,C) (see structural analysis below). Iminoribitol 5′-phosphates demonstrate a 14-fold preference for the 9-deazahypoxanthine relative to 9-deazaguanine (**5** and **6**) (Figure 4C). Linear cationic phosphonate derivatives of 9-deazapurines bind with higher affinity when the cation and phosphonate are separated by a propyl bridge (**9**, **11**, and **12**). In this configuration, 9-deazahypoxanthine (**9**) is preferred to 9-deazaguanine (**10**) by a factor of 6 (Figure 4C). Azetidine phosphate derivatives of 9-deazahypoxanthine (**13** and **14**) and an additional hydroxyl group (**15**) decreased affinity. All 9-deazaxanthine derivatives were poor inhibitors for *Pf*HGXPRT (**16–19**) (Figure 4C).

Most active-site residues are conserved between *Hs*HGPRT and *Pf*HGXPRT with similar contacts to the inhibitor. The difference in the binding of compound **1** from other acyclic transition state analogue inhibitors might be attributed to the differences in the energetic contribution of N7 to hydrogen bonding in the enzymes, as revealed by NMR analysis of this interaction,[42] or to interactions with the exocyclic N2 of 9-deazaguanine. Many of the best inhibitors for *Pf*HGXPRT also demonstrate a high selectivity index for *Pf*HGXPRT of 9 to >240 (Table 1). Structural analysis explored these interactions.

Crystal Structure of 1 with PfHGXPRT.

*Pf*HGXPRT was co-crystallized with **1** in the presence of magnesium and pyrophosphate. The structure was determined by molecular replacement and refined to 1.62 Å resolution (Table 2). *Pf*HGXPRT co-crystallized with compound **1** as a homotetramer (four *Pf*HGXPRT monomers in the asymmetric unit; Figure 5A), consistent with previous

reports.[19,39,40] Tetramerization of *Pf*HGXPRT buries a total 11,660 Å^2 of solventexposed surface area, demonstrating the tetramer stabilization by catalytic site filling. The tertiary structures for each of the four subunits are similar with an average rmsd of <0.6 Å over 180 aligned Cα atoms with a typical PRTase-like fold (Figures 5A,B and S4A). Small differences between subunits are observed in regions that are involved in crystal contacts. Catalytic sites are at the base of the central β-sheet structure composed of six parallel β-strands (Figure 5B). The four distinct but equivalent active sites in the assembly are distal from the tetramer interface (Figure 5A). Electron densities in the active sites were identified as co-crystallized transition state analogue, compound **1**, pyrophosphate, and Mg^{2+} ions (Figure S4B). Interactions between *Pf*HGXPRT and the catalytic site ligands are nearly identical in all four subunits of the tetrameric assembly. The subsequent structural analysis is taken from the atomic contacts of subunit 1 (Figure 5A,B).

Catalytic Site Interactions.

Four functional regions of the catalytic site for *Pf*HGXPRT include the (i) purine binding site, (ii) ribose binding site, (iii) 5′-phosphate binding site, and (iv) magnesium pyrophosphate binding site.[19] The purine binding site is a combination of hydrophobic and hydrogen bond interactions. The 9-deazapurine of compound **1** stacks between the sidechains of Tyr116 and Ile146 with additional hydrophobic interactions to the sidechains of Phe197, Val198, and Leu203 (Figure 5C,D). The N1 and exocyclic N2 atoms of 9-deazaguanine form hydrogen bonds with the carbonyl oxygen of Val198 (2.6 Å and 2.8 Å, respectively; Figure 5D). The exocyclic N2 atom also interacts with the carbonyl oxygen of Asp204 (2.8 Å). The sidechain of Lys176 forms a hydrogen bond with the purine O6 (2.8 Å), while the amide nitrogen of Val198 is more distant (3.2 Å). The purine N7 atom forms a hydrogen bond with the carboxyl group of Asp148 (2.7 Å). A weaker water-mediated interaction is observed with the deazapurine N3 atom (3.0 Å) (Figure 5C,D). The ribose binding site of the enzyme is formed by the sidechains of Tyr116, Glu144, and Asp145 (Figure 5C,D). The acyclic amino alcohol phosphonate of **1** replaces the ribose, with the serinol cationic nitrogen as a mimic of the cationic transition state. The serinol nitrogen ion pairs with the nucleophilic pyrophosphate anion (2.9 Å), a proposed mimic of the riboxocarbenium ion transition state structure. The 5′-phosphate binding site involves hydrogen bonds with the sidechains of Tyr116 (2.5 Å), Thr149 (2.9 Å), and Thr152 (2.6 Å) and the amide nitrogens of Asp148 (3.0 Å), Thr149 (3.0 Å), Gly150 (2.7 Å), and Thr152 (2.9 Å). The phosphate monoester binding site is remarkable by the lack of ion pairs to the dianionic phosphate. Pyrophosphate in the active site of *Pf*HGXPRT is coordinated by the sidechains of Arg112 (2.6 Å) and Arg210 (2.9 Å), the backbone amide nitrogens from Lys77 (2.8 Å), Gly78 (3.1 Å), Ser115 (2.9 Å), and Tyr116 (2.9 Å), and the bidentate magnesium ion forming 2.0 Å ionic bonds with both phosphoryl groups of the pyrophosphate (Figures 5D and S5). The bound magnesium ion is octahedrally coordinated with the carboxyl of Asp204 (2.1 Å), two oxygens of the pyrophosphate (both 2.0 Å), and three water molecules (2.0–2.2 Å) (Figures 5C and S5). Compound **1** interactions with *Pf*HGXPRT active site residues are similar to the interactions reported for the complex with the 9-deazahypoxanthine analogue of **1** (RCSB ID 3OZG)[19] with a key difference by the added hydrogen bonds between the exocyclic N2 of **1** and the carbonyl oxygens of Val198

and Asp204, absent in the complex with RCSB ID 3OZG. This additional interaction with **1** is proposed to contribute to the greater affinity of 9-deazaguanine inhibitors.

Interactions of Inhibitors with *Pf*HGXPRT.

Purified *Pf*HGXPRT is an equilibrium of subunit forms in the presence of Mg-PPi (Figure 1D). Catalytic site titration of *Pf*HGXPRT with compound **1** in the presence of Mg-PPi activates the enzyme twofold as the inhibitor binds to a single subunit of the *Pf*HGXPRT tetramer (Figure 6A). This is a stoichiometric "one per tetramer" interaction and is interpreted as tetramer formation causing activation of subunits not filled with compound **1**. Inhibition occurs as compound **1** is titrated to the tetramer (Figure 6A). Therefore, titrations of the inhibitor into the enzyme and Mg-PPi involve activation to tetramers followed by binding and inhibition of the tetramer.

Stoichiometry of Compound 1 Binding by ITC.

Transition state analogues convert the energy for catalysis into thermodynamic binding energy.[45] The 0.5 nM inhibition constant of compound **1** in kinetic assays is readily explained by the 12 hydrogen bonds between the inhibitor and the catalytic site (3.0 Å) and an ion pair between bound pyrophosphate and the serinol nitrogen of **1** (Figure 5A). All four catalytic sites are saturated at the high inhibitor concentration used in crystallization studies. Thermodynamic and stoichiometric contributions of inhibitor binding were quantitated by ITC. ITC isotherms were fit to a two-site binding model using MicroCal PEAQ-ITC analysis software. Binding the first equivalent of compound **1** to *Pf*HGXPRT ($N = 0.23 \pm 0.01$ per monomer, approximately one per tetramer) in the presence of Mg-PPi revealed a large change in enthalpy (H) of -15.3 ± 0.3 kcal/mol, assigned to 0.5 nM on the basis of kinetic experiments (Figure 6B,C). Subsequent binding of compound **1** involves approximately half the catalytic sites ($N = 0.4 \pm 0.02$ per monomer, approximately two per tetramer) with a K_{d2} of 229 ± 15 nM, 500-fold weaker binding affinity than the 0.5 nM K_i associated with the first subunit binding event (K_{d1}).

Kinetic analysis of catalytically active tetrameric *Pf*HGXPRT indicates tight binding of compound **1** with a K_i of 0.5 nM. Binding of compound **1** by ITC in the presence of Mg-PPi is consistent not only with a tight interaction but also a second subunit catalytic site filling with negative cooperativity, a more weakly bound interaction. At high compound **1** concentrations, all sites are filled as observed in X-ray crystallography (Figure 5).

The thermodynamic values for the initial tight binding (0.5 nM) of compound **1** from ITC have a H of -15.3 ± 0.3 kcal/mol and a G of -11.30 ± 0.03 kcal/mol, giving a small entropic penalty of 4.0 ± 0.3 kcal/mol (Figure 6C). Thus, compound **1** is dominated by enthalpy, reflecting the multiple hydrogen and ionic bond contributions involved in inhibitor binding.

CONCLUSIONS

*Pf*HGXPRT is essential in the purine salvage pathway of *P. falciparum* and a target for development of novel antimalarials. The catalytic mechanism, inhibitor kinetics, structure,

and thermodynamics are defined for the novel high-affinity binding of transition state analogues. Inhibitors with iminoribitol and serinol ribocation scaffolds are nanomolar inhibitors and demonstrate the dynamic linkage between the catalytic site protein elements, the 9-deazapurines common to the inhibitors, the ribocationic mimics, and the phosphate or phosphonate binding sites. Forward commitment, inhibitor and pyrophosphate binding experiments establish a random, rather than obligatory sequential binding mechanism for *Pf*HGXPRT. The transition state has a lifetime too short or too constrained to permit reversible phosphoryl group rotation. Bound PRPP in the ternary complex of *Pf*HGXPRT-hypoxanthine-PRPP freely equilibrates with unbound substrates more rapidly than the chemical steps. This new information for the catalytic mechanism and inhibitor design defines precursors for improved candidates as antimalarials. Inhibitors for *Pf*HGXPRT are phosphate- or phosphonate-containing compounds. As anions present membrane permeability issues, prodrug approaches to protect the phosph(on)ate are likely to be required. Synthesis of neutral compounds using prodrugs or phosphate bio-isosteres will yield the next generation of inhibitors of *Pf*HGXPRT suitable for testing in biological systems.

METHODS

Expression and Purification of *Pf*HGXPRT, *Hs*HGPRT, and *Sp*IMPDH.

*Pf*HGXPRT was expressed and purified as previously published.[22] Briefly, a thrombin-cleavable N-terminal six-histidine tag was cloned into pDEST-14. The plasmid was overexpressed in *E. coli* BL21-AI competent cells (Invitrogen) to an OD_{600} of 0.6 at 37 °C, and the temperature was decreased to 18 °C for 45 min. The culture was induced with 0.2% L-arabinose overnight at 18 °C and harvested by centrifugation at 5000g for 20 min at 4 °C. All protein purification was performed at 4 °C. Cells were suspended in 20 mM Tris-HCl, 5 mM imidazole, 500 mM NaCl, and 1 mM DTT, pH 7.9, with DNase I, lysozyme (Sigma), and protease inhibitor tablet (Roche) for 30 min, lysed by sonication, and centrifuged at 20,000g for 20 min. Ni-NTA resin (Qiagen) was washed with 10 column volumes of cell suspension buffer after which the clarified lysate was added and incubated for 45 min with rocking. The mixture was transferred to a gravity column and washed with 10 column volumes of cell suspension buffer. A stepwise elution was performed in 50–500 mM imidazole. Collected fractions were analyzed by SDS-PAGE. Fractions highly enriched in *Pf*HGXPRT (~26 kDa) were pooled and dialyzed in 50 mM potassium phosphate, 5 mM imidazole, 150 mM KCl, 1 mM DTT, and 10% glycerol, pH 7.5. The enzyme solution was concentrated to approximately 300 μM, aliquoted, frozen in liquid nitrogen, and stored at −80 °C. *Hs*HGPRT was purified and stored as previously described.[19]

A six-histidine tagged protein sequence with a TEV cleavage site of *Streptococcus pyogenes* IMP dehydrogenase (*Sp*IMPDH) was designed and cloned into pET-28b(+) by GenScript. The plasmid was overexpressed in *E. coli* BL21 (DE3) to an OD_{600} of 0.6 at 37 °C and induced with 1 mM IPTG overnight at 18 °C. All protein purification steps were performed at 4 °C. Cells were suspended in 50 mM potassium phosphate, 500 mM KCl, 5 mM imidazole, and 0.5 mM TCEP, pH 8.0, with added protease inhibitor tablet (Roche), DNase I, and lysozyme (Sigma) for 30 min. Cells were lysed by sonication and clarified

by centrifugation at 20,000 g for 20 min. The supernatant was added to washed Ni-NTA resin and incubated for 45 min with shaking. Protein was eluted in a stepwise imidazole concentration from 50 to 250 mM and analyzed by SDS-PAGE. Fractions highly enriched in *Sp*IMPDH (protein band at 52.8 kDa) were pooled and dialyzed in 50 mM HEPES, 100 mM KCl, and 20% glycerol, pH 7.9. The enzyme was aliquoted, frozen rapidly, and stored at −80 °C. Yield of *Sp*IMPDH was 600 mg from a 4 L culture.

*Pf*HGXPRT Activation and Cross-Linking.

*Pf*HGXPRT was activated by preincubating 30 μM *Pf*HGXPRT with 1 mM hypoxanthine, 2 mM PRPP, 10 mM MgCl$_2$, 1 mM DTT, and 50 mM potassium phosphate pH 7.4 in a 50 μL reaction mix for 30 min at 25 °C. Activation by magnesium pyrophosphate, IMP, and PRPP was performed according to the method outlined by Roy et al.[25,26,35] A 60-fold dilution of the activation mix was made into assay mixtures described below to determine the efficiency of activation. For activation by ImmHP or compound **1**, 30 μM *Pf*HGXPRT was preincubated with 30 μM ImmHP or compound **1**, 1.4 mM MgCl$_2$, 1.4 mM pyrophosphate, and 50 mM potassium phosphate pH 7.4 in a 50 μL reaction mix for 30 min at 25 °C.

Glutaraldehyde cross-linking was performed by incubating activation mixes with 1% glutaraldehyde in a total volume of 100 μL for 5 min at 37 °C. The cross-linking reaction was quenched by adding 10 μL of 1M Tris-HCl pH 8.0. Samples were analyzed by SDS-PAGE to determine the protein oligomeric states. Molecular weight analysis of the *Pf*HGXPRT bands was performed using Image Lab software by comparison to molecular weight standards (Biorad).

Synthesis of Transition State Analogue Inhibitors.

Compounds **1**, **4**, **8**, and **19**,[46] **2**, **3**, and **9**-**12**,[24] and **5** and **6**[23] were synthesized as reported. The synthetic procedures and NMR spectra for all new compounds are in the Supporting Information. The NMR spectra reported earlier for **19**, **9–12**, and **6** were for the same batch of compounds used here.

*Pf*HGXPRT Kinetics and Inhibition Assays.

Steady-state kinetics and inhibition of *Pf*HGXPRT and human enzyme (*Hs*HGPRT) were measured spectrophotometrically using an IMPDH coupled assay. The IMP product produced by *Pf*HGXPRT and *Hs*HGPRT from hypoxanthine and PRPP was coupled to the formation of XMP, and the spectral change of NAD$^+$ to NADH was measured at 340 nm. All assays were performed in 50 mM HEPES pH 7.4 containing 500 nM *Pf*HGXPRT or 78 nM *Hs*HGPRT, 3 μM *Sp*IMPDH, 1 mM hypoxanthine, 2 mM PRPP, 5 mM NAD$^+$, 10 mM MgCl$_2$, and 1 mM DTT. For inhibition assays, inhibitor concentration was varied between 0 and 100 μM in reaction mixtures containing 1.4 mM pyrophosphate. Inhibitors were tested against both *Pf*HGXPRT and *Hs*HGPRT to measure selectivity of the inhibitors. Selectivity indices were calculated as the ratio of the inhibitory constants of *Hs*HGPRT to *Pf*HGXPRT. Data were analyzed using Prism 9 software by fitting to the Michaelis–Menten equation for steady-state calculations and to the Morrison equation for calculation of the inhibition constants (K_i) for tight-binding inhibitors.[41]

Co-crystallization of *Pf*HGXPRT in Complex with Compound 1.

*Pf*HGXPRT (190 μM) was mixed with compound **1** + pyrophosphate + MgCl$_2$ at a 1:2:5:5 molar ratio and incubated on ice for 2 h. Initial screening of the complex was performed using 1 μL (protein/mother liquor = 1:1) sitting drops by vapor diffusion at 22 °C against 70 μL of reservoir solution in 96-well Intelli plates with a Crystal Gryphon (Art Robbins Instruments) utilizing MCSG (1-4, Microlytic) and Crystal Screen HT (Hampton Research) sparse matrix crystallization suites. Diffraction quality crystals were obtained within 2 weeks against well solutions containing 0.2 M lithium acetate 20% (w/v) PEG 3350. Crystals were cryo-preserved by flash-cooling in liquid nitrogen.

Data Collection and Processing, Structure Refinement, and Analysis.

Data from the crystals of the complex were collected with a CCD Pixel Dectris Pilatus 6M detector, with a wavelength of 0.97931 Å, on the ID-31 (LRL-CAT) beamline at the Argonne National Laboratory (Table 2). Single crystal data were integrated and scaled using iMOSFLM and AIMLESS,[47] respectively. Diffraction was consistent with the orthorhombic space group C222$_1$ (unit cell dimensions are in Table 2) and extended to 1.62 Å resolution with four molecules (chain A, B, C, and D) in the asymmetric unit. Initial phases were determined by molecular replacement (MR) with PHASER[48] using refined coordinates of *Pf*HGXPRT (RCSB ID 1CJB);[42] the initial MR coordinate was manually inspected and corrected using COOT.[49] The model was refined with PHENIX-REFINE.[50] During initial rounds of refinement, inhibitor molecules were not included in the model, and after incorporating water molecules into the model, inhibitor molecules were built into their respective electron densities. Analyses of the structures were performed in COOT and evaluated using MOLPROBITY;[44] B-factors were calculated using the BAVERAGE program in the CCP4 suit. The crystallographic model exhibited excellent geometry with no residues in disallowed regions of the Ramachandran plot.[51] Crystallographic statistics and RCSB accession codes are provided in Table 2. All figures depicting the structure were generated with PyMol,[52] unless stated otherwise.

Catalytic Site Titration.

*Pf*HGXPRT catalytic sites were titrated with compound **1** at varying ratios of the inhibitor to tetrameric enzyme. Incubation mixtures contained 30 μM *Pf*HGXPRT, compound **1** from 0 to 40 μM, 1.4 mM MgCl$_2$, 1.4 mM pyrophosphate, and 50 mM potassium phosphate buffer pH 7.4. Incubations were carried out for 30 min. Following incubation, samples were diluted into an assay mix containing 100 μM guanine, 1 mM PRPP, 10 mM MgCl$_2$, and 1 mM DTT in 50 mM HEPES pH 7.4. The final concentration of the enzyme in the assays was 500 nM. The conversion of guanine to GMP was followed by the absorbance change at 258 nm (extinction coefficient = 5800 M^{-1}·cm^{-1}).

Isothermal Titration Calorimetry (ITC).

Purified *Pf*HGXPRT was dialyzed against buffer containing charcoal to remove purines that co-purify with the enzyme. Size exclusion chromatography (AKTA-FPLC) was used to purify the protein followed by dialysis in 50 mM HEPES, 1.4 mM MgCl$_2$, 1.4 mM pyrophosphate, and 0.5 mM TCEP, pH 7.4. Compound **1** was prepared in the protein

dialysate (150 μM), loaded into the syringe, and titrated into 20 μM *Pf*HGXPRT in the cell. Titration was performed at 25 °C using a series of 2 μL individual injections for a total of 19 titrations spaced at 150 s intervals. ITC experiments used a MicroCal PEAQ-ITC. The sample cell was filled with approximately 300 μL of *Pf*HGXPRT, and the injection syringe was loaded with approximately 40 μL of the ligand solution. The reference cell was filled with 300 μL of filtered (Millipore 0.2 μm) Milli-Q water. Binding isotherms were fit to the two-site binding model using MicroCal PEAQ-ITC analysis software. The K_{d1} of the first binding site (K_{d1}) was estimated as the K_i for compound **1** determined from kinetic assays in the fitting model. ITC binding experiments were performed four times to obtain average changes in enthalpy values (ΔH), binding ratio (N), and K_{d2} of the second binding site. The Gibbs free energy (ΔG_1 and ΔG_2) values were determined from the K_{d1} and K_{d2} respectively, using eq 1. The entropic terms ($-T\Delta S_1$ and $-T\Delta S_2$) were calculated from the respective ΔG values using eq 2. Control titrations of the inhibitor into the ITC buffer were performed and the heats were subtracted from the inhibitor: enzyme titrations during data analysis.

$$\Delta G = RT \ln K_i \tag{1}$$

$$\Delta G = \Delta H - T\Delta S \tag{2}$$

[1-^{13}C, 1-^{18}O]PRPP Synthesis.

[1-^{13}C, 1-^{18}O]PRPP was synthesized chemoenzymatically from *D*-[1-^{13}C]ribose (Sigma) and ^{18}O water (Cambridge Isotope Laboratories). *D*-[1-^{13}C]ribose was converted to *D*-[1-^{13}C, 1-^{18}O]ribose by ^{18}O exchange in ^{18}O water and 5 mM potassium phosphate pH 7.0 at 61 °C overnight. SpeedVac evaporation of the solvent yielded *D*-[1-^{13}C, 1-^{18}O]ribose. [1-^{13}C, 1-^{18}O]PRPP was synthesized from 2 mg of *D*-[1-^{13}C, ^{18}O]ribose, 500 μM ATP, 5 mg/mL phosphoenolpyruvate (PEP), 5 mM MgCl$_2$, 4.5 μM ribokinase, 2 U PRPP synthase, 2 U pyruvate kinase, and 3 U myokinase in a 1 mL reaction of 50 mM phosphate buffer pH 7.4 at 25 °C (Figure S1). The reaction was stopped after 1 h by the addition of 5 mM EDTA, and proteins were removed using an Amicon ultrafiltration tube, centrifuged at 14,000 g for 1 h at 4 °C. The filtrate was frozen and stored at −80 °C prior to additional purification.

[1-^{13}C, 1-^{18}O]PRPP was purified by HPLC with a 5 mL HiTrap QFF column (GE Life Sciences) in a water (solvent A) and 1.5 M ammonium acetate (solvent B) gradient. The HPLC gradient was varied from 0 to 100% solvent B in 65 min and maintained for 5 min and 100–0% solvent B in 1 min and maintained for 35 min. Purified [1-^{13}C, 1-^{18}O]PRPP was frozen and lyophilized. Excess ammonium acetate was removed by several rounds of water dilution, freezing, and lyophilizing. Solid [1-^{13}C, 1-^{18}O]PRPP was stored at −80 °C prior to use. Purity and concentration of [1-^{13}C, 1-^{18}O]PRPP were determined by NMR (Figure S2).

Positional Isotope Exchange (PIX).

PIX was monitored by measuring ^{16}O/^{18}O isotope scrambling at C-1 of [1-^{13}C, 1-^{18}O]PRPP by 2D ^{1}H–^{13}C HSQC NMR. A reaction mixture containing 4.8 mM [1-^{13}C, 1-^{18}O]PRPP, 1

mM hypoxanthine, 10 mM $MgCl_2$ and 2 μM PfHGXPRT, and 50 mM HEPES pH 7.4 in a final volume of 200 μL was dissolved in D_2O and put into a 3 mm NMR tube. NMR data were acquired at 25 °C using a Bruker AVIII 600 MHz spectrometer running TopSpin 3.6 and equipped with a 5 mm H/F-TCI cryogenic probe. The 1-^{13}C of PRPP was monitored in a high-resolution 2D ^{1}H–^{13}C HSQC to resolve the cross peak belonging to the 1-^{13}C bonded to ^{18}O from that bonded to ^{16}O expected to appear if PIX occurred during the enzymatic reaction. Each HSQC timepoint was run for 13 min with eight scans acquired for each increase using a spectral width of 14 ppm and 1 ppm for ^{1}H and ^{13}C, respectively, and a recycle delay of 1.1 s. The data sets were collected using 4096 and 32 complex points for ^{1}H and ^{13}C, respectively, and the time-domain NMR data were linear predicted in the indirect dimension and multiplied with a shifted sine-bell function (SSB = 3) in each dimension prior to Fourier transformation. The reaction was monitored for a total of 135 min during which a total of 10 HSQC spectra were collected. Control reactions measured the effect of $MgCl_2$ on spectral acquisition by measuring the 1-^{13}C chemical shifts of PRPP in natural abundance PRPP in the presence and absence of $MgCl_2$ (Figure S3). Additional controls mixed natural abundance PRPP with [1-^{13}C, 1-^{18}O]PRPP to establish the ^{18}O-induced shifts by 2D ^{13}C NMR. These controls ensured the reliable detection of ^{18}O to ^{16}O shifts during the PIX reaction.

Forward Commitment.

[5-^{14}C]PRPP was synthesized from [5-^{14}C]AMP according to a previously published method.[32] The forward commitment (C_f) was measured for PfHGXPRT using the isotope trapping method developed by Rose[30] with some modifications to ensure that a catalytically active complex was formed during enzyme loading with [5-^{14}C]PRPP and hypoxanthine. Briefly, 114 μM PfHGXPRT was preincubated for 8 s in a 320 μL reaction mixture containing 214 μM [5-^{14}C]PRPP, 1 mM hypoxanthine, 1.4 mM $MgCl_2$, 0.1 mM DTT, and 50 mM HEPES, pH 7.4. This period involves binding of substrates, oligomerization toward active tetramers, and catalysis. During the 8 s, 22.5 ± 0.02 μM [5-^{14}C]PRPP was converted to [5′-^{14}C]IMP, establishing the presence of the functional enzyme-[5-^{14}C]PRPP-hypoxanthine complex. The reaction mixture was diluted at 8 s with excess unlabeled PRPP and hypoxanthine by the addition of 180 μL containing 2.5 mM hypoxanthine, 2 mM unlabeled PRPP, 1.4 mM $MgCl_2$, 0.1 mM DTT, and 50 mM HEPES pH 7.4. At dilution, the enzyme-bound [5-^{14}C]PRPP partitions to the IMP product (forward reaction) or releases to the PRPP pool (dissociation). The partition ratio determines the C_f. Reaction samples (120 μL) were quenched with 5 mM EDTA at 5, 10, 15, and 20 s following isotopic dilution and flash-frozen in liquid nitrogen. The product [5′-^{14}C]IMP from each timepoint was purified by HPLC using a Luna C18(2) 15 μm, 100 Å, 250 mm × 4.6 mm column (Phenomenex).[22] Radiolabeled analyses were performed on samples dried by vacuum centrifugation, dissolved in 500 μL of H_2O, mixed with 10 mL of scintillation fluid, and counted to estimate [5′-^{14}C]IMP formed at the various timepoints. [5′-^{14}C]IMP formed following the dilution is based on the PRPP present in the initial ternary complex. [5′-^{14}C]IMP formed from the E-[5-^{14}C]PRPP-Hx complex following the chase with excess unlabeled PRPP and hypoxanthine at 8 s was determined from the graphical analysis. The K_m value of PRPP for activated PfHGXPRT was used to estimate the fraction of PfHGXPRT saturated with [5-^{14}C]PRPP. The C_f is defined as the probability for a bound PRPP molecule

in the E-PRPP-Hx to convert to the product relative to being released as the unreacted substrate where equal probability is $C_f = 1.0$.

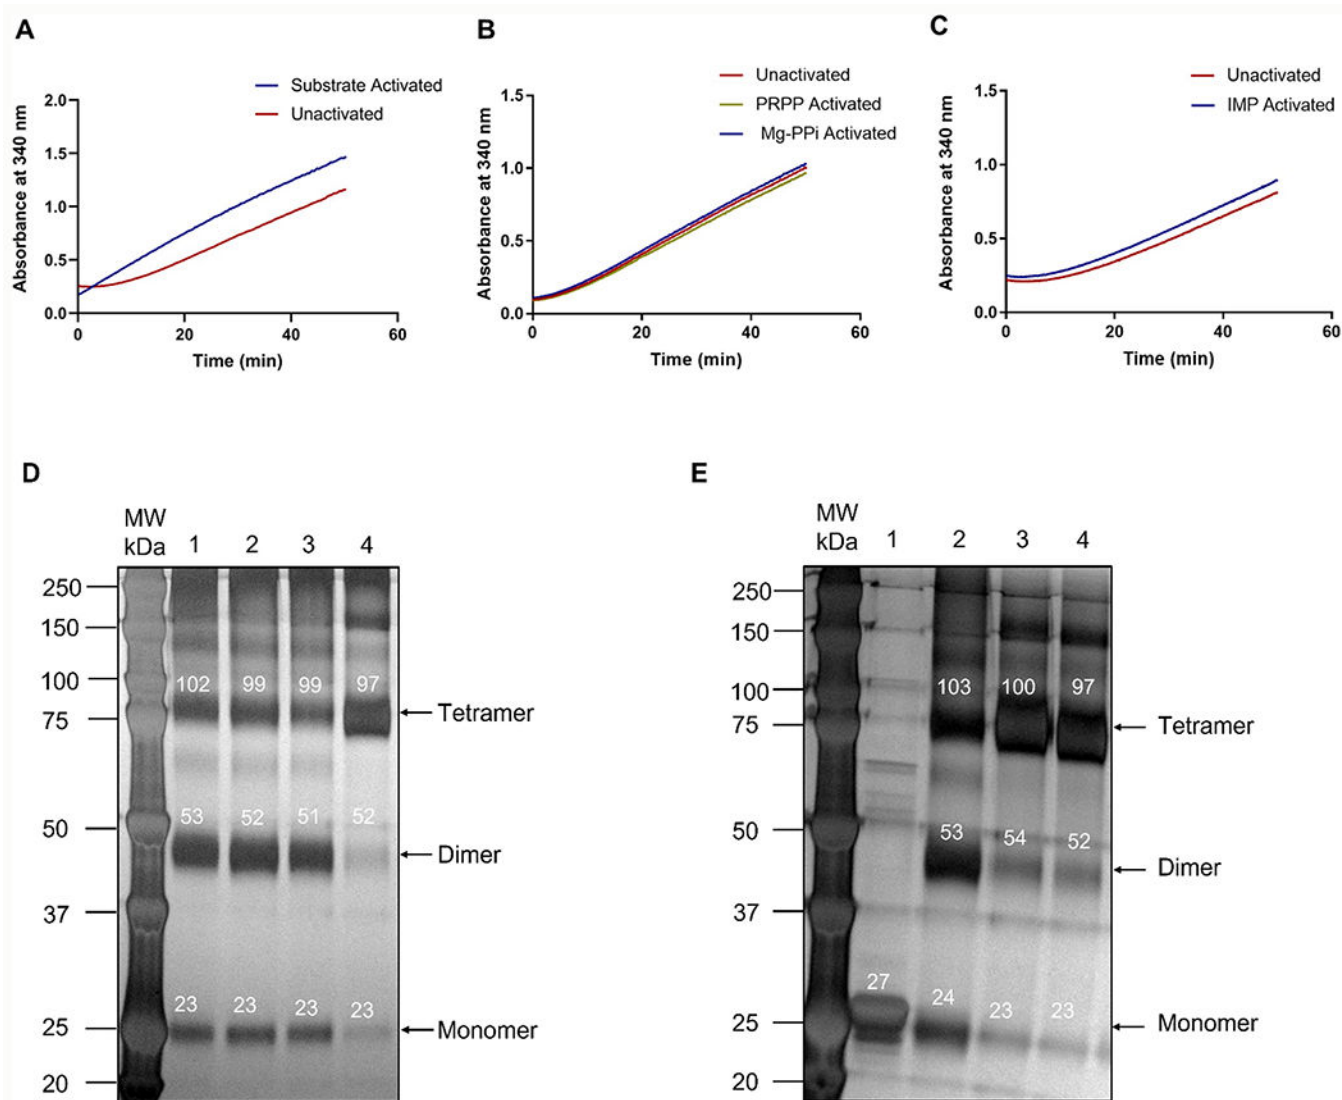

Figure 1.
Activation of *Pf*HGXPRT by (A) substrates, (B) PRPP or magnesium pyrophosphate (Mg-PPi), and (C) IMP. Preincubation of *Pf*HGXPRT creates the right condition for the formation of active tetramers and the fully active enzyme. (D,E) Cross-linking gel electrophoresis for activating *Pf*HGXPRT. Gel-scan molecular weights are shown above the relevant bands in white. (D) 1—IMP activated; 2—Mg-PPi activated; 3—PRPP activated; and 4—substrate activated. (E) 1—*Pf*HGXPRT in buffer not cross-linked; 2—*Pf*HGXPRT in buffer, cross-linked; 3—*Pf*HGXPRT incubated with ImmHP; and 4—*Pf*HGXPRT incubated with compound 1 (Figure 4). Conditions for activation are described in the methods.
Figure 2.
Forward commitment (C_f value) from isotope trapping of [5-^{14}C]PRPP in the ternary complex of *Pf*HGXPRT. *Pf*HGXPRT was incubated briefly with hypoxanthine and [5-^{14}C]PRPP to form the Michaelis complex (8 s of mix to Chase). Rapid dilution with excess unlabeled PRPP and hypoxanthine (Chase) allowed analysis of the [5′-^{14}C]IMP produced from trapped [5-^{14}C]PRPP (▲). The amount of IMP formed during the 8 s mix continued at the same rate during the Chase with excess unlabeled PRPP and hypoxanthine (·). The ordinate displacement at 8 s (1.4 μM) is the amount of [5′-^{14}C]IMP formed from the E-[5-^{14}C]PRPP-Hx complex existing at the time of the Chase. The dashed line for $C_f = 0.5$ would be observed if bound [5-^{14}C]PRPP partitions 2:1 in favor of substrate release relative to product formation. The ordered mechanism in Scheme 1 predicts a C_f value > 1.0.
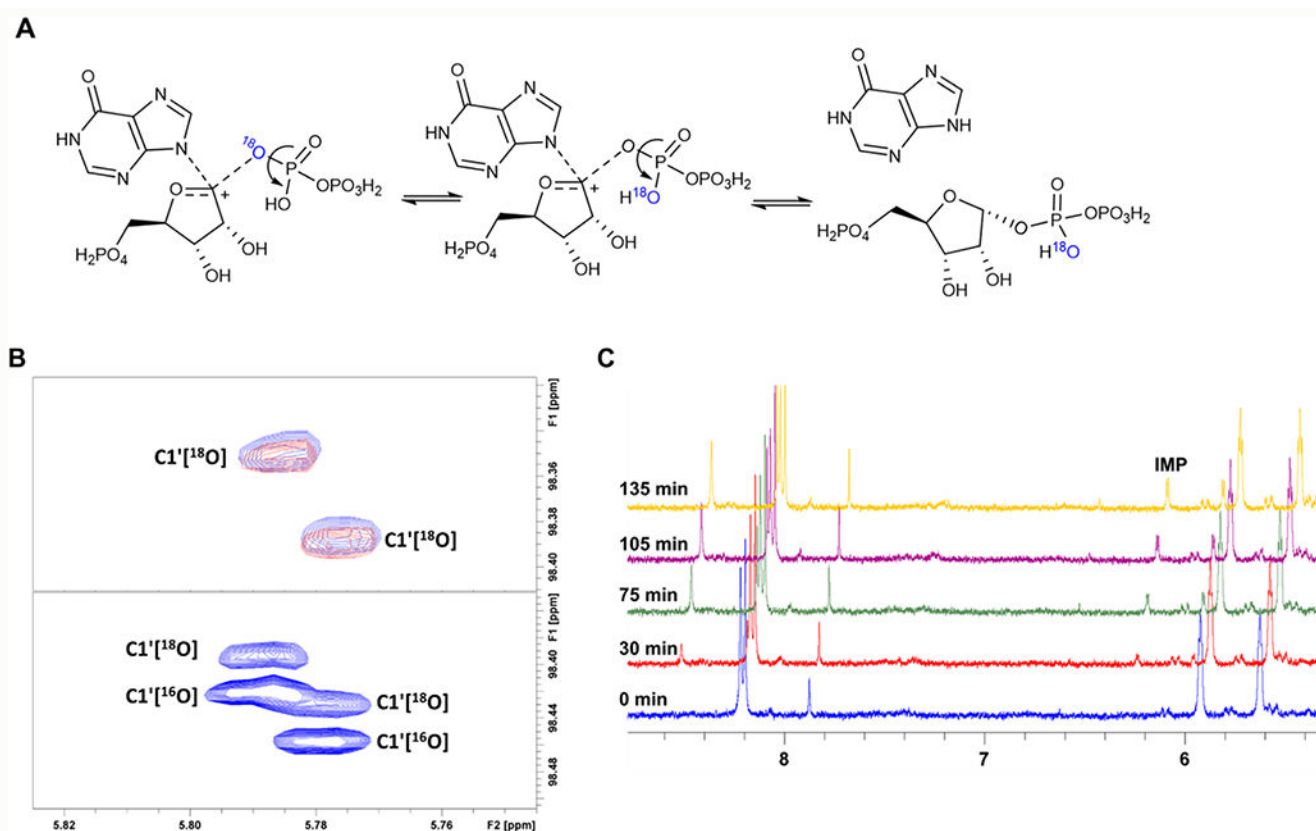

Figure 3.
(A) Reaction scheme for PIX of *Pf*HGXPRT. Isotope scrambling from the bridging oxygen happens when the riboxocarbenium intermediate forms, and there is free torsional rotation of the pyrophosphate ion. Reformation of the substrate from the breakdown of the Michaelis complex results in PRPP with ^{18}O in the non-bridging position. (B) Upper panel, 2D ^{1}H–^{13}C HSQC NMR monitoring isotope scrambling; lower panel: an overlay of natural abundance PRPP and [1-^{13}C,^{18}O]-PRPP. No isotope scrambling was observed. (C) 1D ^{1}H NMR monitoring reaction progress and the formation of IMP at approximately 6.2 ppm.

Figure 4.
(A) Reaction catalyzed by *Pf*HGXPRT. IMP formation was assayed by coupling to the formation of xanthine monophosphate (XMP) by inosine 5′-monophosphate dehydrogenase (IMPDH) with NADH absorbance monitored at 340 nm. (B) A transition state analogue inhibitor of *Pf*HGXPRT demonstrates selectivity for the parasite enzyme (top) relative to the human HGPRT (bottom). (C), Serinol, pyrrolidine, and azetidine transition state analogues synthesized and tested for inhibitory activity against *Pf*HGXPRT. Morrison K_i values reported as nanomolar concentrations. Compounds **5** and **6** represent ImmHP and ImmGP,

respectively. 9-Deazaxanthine analogue molecules generally have weak or no inhibitory activity against *Pf*HGXPRT. [a]Values reported in ref 24, and [b]values reported in ref 23. Errors reported are the standard errors (SE) of at least two replicates. Inhibitors with $K_i > 1$ μM were tested once, and errors represent SE of fits to inhibition as a function of inhibitor concentration.
Figure 5.
Crystal structure and assembly of compound **1** bound to *Pf*HGXPRT. (A) *Pf*HGXPRT tetramer (subunit 1 in gray, subunit 2 in cyan, subunit 3 in yellow, and subunit 4 in pink) shown as ribbons for helices and arrows for β strands. Bound compound **1** (magenta) and pyrophosphate (orange) are shown in stick representation, and the magnesium ion is shown as a green sphere. (B) Subunit 1 of the tetramer shown as in panel (A). (C) Stereoview of the active site of the *Pf*HGXPRT- **1** complex (subunit 1). Selected residues from *Pf*HGXPRT are shown in stick representation (gray). Compound **1**, pyrophosphate, and the magnesium ion
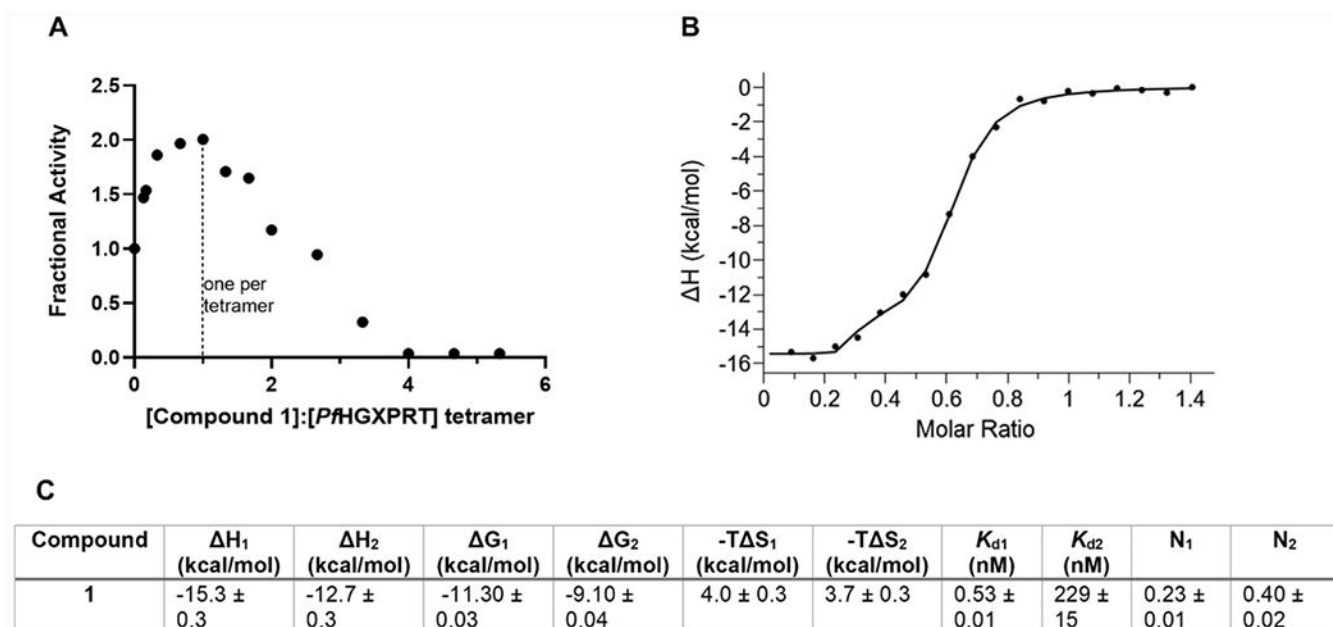

are as in panel (A). Waters are shown in red spheres. Distances (Angstroms) are indicated by dashed lines. (D) 2-D ligand contact map depicts interactions of compound **1** and magnesium with the enzyme, pyrophosphate, and water. Not all pyrophosphate contacts are shown.

Figure 6.
Interaction of compound **1** with *Pf*HGXPRT. (A) Catalytic site titration of *Pf*HGXPRT with compound **1**. The enzyme was preincubated with substoichiometric amounts of compound **1**. The catalytic activity of enzyme-inhibitor mixes was compared to the no inhibitor control to determine the fractional activity. (B) ITC binding isotherm of compound **1** binding showing large favorable enthalpy. *Pf*HGXPRT (20 μM) was titrated with 150 μM compound **1** in 2 μL injections at 25 °C in 1.4 mM Mg-PPi, 0.5 mM TCEP, and 50 mM HEPES, pH 7.4. (C) Thermodynamic parameters from ITC. ΔH values, K_{d1}, K_{d2}, and binding ratios (N_1 and N_2) are reported directly from the ITC and are the average of four experimental titrations. ΔG and $-T\Delta S$ values were determined from eqs 1 and 2, respectively, using the K_{d1} and K_{d2} (see methods) with standard errors determined from the average of four replicates.
Scheme 1.
Compulsory Ordered Reaction Mechanism of *Pf*HGXPRT Proposed from Earlier
Reports[25,36]

Table 1.

Transition State Analogues of *Pf*HGXPRT and Their Selectivity Indices for *Hs*HGPRT

inhibitor	*Pf*HGXPRT (K_i, nM)	*Hs*HGPRT (K_i, nM)	selectivity index (SI)
1	0.50 ± 0.05	20 ± 0.3	40
4	103 ± 4	4600 ± 70	43
7	19.0 ± 0.2	4500 ± 110	220
8	>20,000	>20,000	
9	21 ± 1	1350 ± 30	64
10	107 ± 12	1000 ± 5	9.3
13	85 ± 3	>20,000	>240
19	8000 ± 510	>20,000	>3

clash score	100th percentile
MOLPROBITY score	100th percentile
RCSB code	7TUX

[a] Statistics are calculated using REFMAC5,[43] values in highest resolution shells indicated in parentheses.

[b] Calculated with the program MOLPROBITY.[44]

[c] $R_{merge} = (\Sigma_{hkl}\Sigma_i|I_i(hkl) - \langle I(hkl)\rangle|)/\Sigma_{hkl}\Sigma_i\langle I_i(hkl)\rangle$, where $I_i(hkl)$ is the intensity of the ith measurement of reflection (hkl) and $\langle I(hkl)\rangle$ is the mean intensity.

[d] I is the integrated intensity, and $\sigma(I)$ is the estimated standard deviation.

[e] $R_{work} = (\Sigma_{hkl}|Fo - Fc|)/\Sigma_{hkl}Fo$ where Fo and Fc are the observed and calculated structure factors, respectively.

[f] R_{free} is calculated as for R_{work} but from a randomly selected subset of the data (5%), excluded from the refinement calculation.
