### Abstract

Following a request from the European Commission, the EFSA Panel on Nutrition, Novel Foods and Food Allergens (NDA) was asked to deliver a scientific opinion on the tolerable upper intake level (UL) for selenium. Systematic reviews of the literature were conducted to identify evidence regarding excess selenium intake and clinical effects and potential biomarkers of effect, risk of chronic diseases and impaired neuropsychological development in humans. Alopecia, as an early observable feature and a well-established adverse effect of excess selenium exposure, is selected as the critical endpoint on which to base a UL for selenium. A lowest-observed-adverse-effect-level (LOAEL) of 330 µg/day is identified from a large randomised controlled trial in humans (the Selenium and Vitamin E Cancer Prevention Trial (SELECT)), to which an uncertainty factor of 1.3 is applied. A UL of 255 µg/day is established for adult men and women (including pregnant and lactating women). ULs for children are derived from the UL for adults using allometric scaling (body weight<sup>0.75</sup>). Based on available intake data, adult consumers are unlikely to exceed the UL, except for regular users of food supplements containing high daily doses of selenium or regular consumers of Brazil nuts. No risk has been reported with the current levels of selenium intake in European countries from food (excluding food supplements) in toddlers and children, and selenium intake arising from the natural content of foods does not raise reasons for concern. Selenium-containing supplements in toddlers and children should be used with caution, based on individual needs.

## 1. Introduction

### 1.1. Background as provided by the European Commission

On 19 October 2000, the Scientific Committee on Food (SCF) expressed an opinion on the Tolerable Upper Intake Level (UL) for selenium. The SCF derived a UL of 300 µg Se/day for adults that covered selenium intake from all sources of food, including supplements. The SCF extrapolated the UL from adults to children on a body weight basis as follows: 1–3 years of age – 60 µg Se/day; 4–6 years of age – 90 µg Se/day; 7–10 years of age – 130 µg Se/day; 11–14 years of age – 200 µg Se/day; 15–17 years of age – 250 µg Se/day.

On 18 December 2019, the Authority adopted an opinion on the “Safety of selenium-enriched biomass of *Yarrowia lipolytica* as a novel food pursuant to Regulation (EU) 2015/2283”. In its opinion, the Authority noted that newly emerging data, including the results of large population-based randomised controlled trials made available in recent years, warranted a reassessment of the UL for selenium as established in 2000.

Consequently, the European Commission would like to ask the Authority to re-evaluate the safety in use of selenium, and to provide revised tolerable upper intake levels that are unlikely to pose a risk of adverse effects from intake of this nutrient, for all population groups.

### 1.2. Terms of Reference as provided by the European Commission

In accordance with Article 29(1)(a) of Regulation (EC) No 178/2002, the European Commission asks the European Food Safety Authority to:

- re-evaluate the safety in use of selenium;
- if necessary, provide revised tolerable upper intake levels for selenium for all relevant categories of the population that are unlikely to pose a risk of adverse health effects.

### 1.3. Interpretation of the Terms of Reference

The UL is defined as ‘the maximum level of total chronic daily intake of a nutrient (from all sources) which is not expected to pose a risk of adverse health effects to humans’ (EFSA NDA Panel, 2022).

‘Tolerable intake’ in this context connotes what is physiologically tolerable and can be established based on an assessment of risk, i.e. the probability of an adverse effect occurring at a specified level of exposure. The UL is not a recommended level of intake. As the intake increases above the UL, the risk of adverse effects increases.

ULs should be protective for all members of the general population, including the most sensitive individuals, throughout their lifetime. The derivation of ULs accounts for the expected variability in sensitivity among individuals. In principle, individuals under medical care are not excluded from the application of the UL unless: (a) there is an expected interaction between the medical condition and the occurrence of possible adverse effects of a nutrient, or (b) they are under medical treatment with the nutrient under assessment.

On the other hand, the UL may exclude sub-populations with extreme and distinct vulnerabilities to adverse effects of the nutrient due to specific genetic predisposition or other factors. The exclusion of such sub-populations must be considered on a nutrient-by-nutrient basis and is an area of scientific and expert judgement and of risk management (EFSA NDA Panel, 2022).

### 1.4. Context of the assessment

The Scientific Committee on Food (SCF) in 2000 set a UL of 300 µg/day in adults, including pregnant and lactating women, based on evidence from observational studies on long term selenium exposure carried out in selenium-rich areas in China (Yang et al., 1989a; Yang and Zhou, 1994) and in the US (Longnecker et al., 1991), where selenium poisonings are endemic due to high selenium concentrations in soil (SCF, 2000a). For children, the SCF extrapolated the UL from adults on a body weight basis, using reference weights (SCF, 1993). No UL was established for infants. ULs set by SCF (2000a) are summarised in Table 1. These values cover selenium intakes from all food sources, including food supplements.

In 2014, the NDA Panel published an opinion on Dietary Reference Values (DRVs) for selenium (EFSA NDA Panel, 2014). As per the terms of reference for this task, a review of the UL for selenium was out of the scope of the assessment. The NDA Panel focused on providing advice on the

requirement for the micronutrient. The levelling off of plasma selenoprotein P concentration with increasing selenium intakes was considered indicative of an adequate supply of selenium to all tissues and to reflect saturation of the functional selenium body pool, ensuring that selenium requirement is met. This criterion was used for establishing DRVs for selenium in adults. Evidence from human studies on the relationship between selenium intake and plasma selenoprotein P concentration was reviewed. Given the uncertainties in available data on this relationship, they were considered insufficient to derive an Average Requirement (AR). Instead, the Panel established an Adequate Intake (AI) for adults of 70 µg/day. No specific indicators of selenium requirements were available for infants, children or adolescents. For infants aged 7–11 months, an AI of 15 µg/day was derived by extrapolating upwards from the estimated selenium intake from breast milk of younger exclusively breast-fed infants (i.e. 12 µg/day), taking into account differences in reference body weights. For children and adolescents, the AIs for selenium were extrapolated from the AI for adults by isometric scaling (i.e. proportionately to body weight) and application of a growth factor. AIs range from 15 µg/day for children aged one to 3 years to 70 µg/day for adolescents aged 15–17 years. Considering that adaptive changes in the metabolism of selenium occur during pregnancy, the AI set for adult women applies to pregnancy. For lactating women, an additional selenium intake of 15 µg/day was estimated to cover the amount of selenium secreted in breast milk, and an AI of 85 µg/day was set.

EFSA evaluated the safety and bioavailability of various forms of selenium as a source of selenium for use in food supplements or addition to foods. The safety and bioavailability of selenium-enriched yeast (Se-yeast) as a source of selenium were established under the proposed conditions of use, for addition to foods for particular nutritional uses and foods, including food supplements (EFSA AFC Panel, 2008). The safety and bioavailability of L-selenomethionine (SeMet) (EFSA ANS Panel, 2009b) and selenious acid (EFSA ANS Panel, 2009d) were established for use in food supplements, under the proposed conditions of use. In contrast, data provided in the application dossiers were inadequate to establish the safety and bioavailability of selenium-humic acid/fulvic acid chelate (EFSA ANS Panel, 2009a) and Se-methyl-L-selenocysteine (EFSA ANS Panel, 2009c), under the proposed conditions of use.

EFSA's Panel on Additives and Products or Substances used in Animal Feed (FEEDAP Panel) has assessed the safety of several selenium compounds in the context of their use as additives in animal feed and have considered them to be safe for consumers provided that the total maximum authorised content of selenium in complete feed is respected (EFSA FEEDAP Panel, 2013a,b, 2015, 2016a,b,c, 2018a,b, 2019a,b, 2021).

## 1.5. Previous assessments by other bodies

As for the SCF assessment, clinical selenosis (see Section 3.5.2) was the critical effect used by other authoritative bodies in charge of establishing ULs for adults (IOM, 2000; EVM, 2003; WHO/FAO, 2004; NHMRC, 2006; FSCJ, 2012) considering the findings reported by Yang et al. (1989a), Yang and Zhou (1994) and Longnecker et al. (1991). Regarding lactating mothers, most risk assessments refer to the study by Brätter and Negretti de Brätter (1996). The studies by Shearer and Hadjimarkos (1975) and Brätter et al. (1991), which collected data on selenium concentration in human milk in women in the US and Canada, and in Germany respectively, were used as reference to establish the ULs for infants.

An overview of ULs for selenium established by other risk assessment bodies is provided in Table 1 below (see Appendix B of the protocol (Annex A) for further details).

**Table 1:** Overview of existing tolerable upper intake levels (ULs) for selenium, in µg/day

(a): Safe upper level (SUL).

(b): Extrapolated from the UL for infants aged 0–6 months (7 µg/kg body weight/day) on a body weight basis.

(c): Extrapolated from the UL for adults on a body weight basis.

(d): Including pregnant and lactating women.

## 2. Data and methodologies

For this scientific assessment, a protocol (Annex A) has been developed in line with EFSA's existing methodology (EFSA, 2020).

### 2.1. Problem formulation

In accordance with the draft NDA Panel guidance on establishing and applying ULs for vitamins and essential minerals (EFSA NDA Panel, 2022), the assessment questions underlying the UL evaluation are formulated as follows:

What is the maximum level of total chronic daily intake of selenium (from all sources) which is not expected to pose a risk of adverse health effects to humans? (*Hazard identification and hazard characterisation*)

What is the daily intake of selenium from all dietary sources in EU populations? (*Intake assessment*)

What is the risk of adverse effects related to the intake of selenium in EU populations, including attendant uncertainties? (*Risk characterisation*)

The hazard identification and hazard characterisation relate to the identification of adverse health effects of a given nutrient and the qualitative and quantitative evaluation of the adverse health effects associated with the nutrient, including dose–response assessment and derivation of an UL, if possible.

Adverse (health) effects are defined as 'a change in the morphology, physiology, growth, development, reproduction or life span of an organism, system or (sub)population that results in an impairment of functional capacity to compensate for additional stress or an increase in susceptibility to other influences (FAO/WHO, 2009; EFSA Scientific Committee, 2017a). The observable effects of high nutrient intake within the causal pathway of an adverse health effect can range from biochemical changes without functional significance (e.g. certain changes in enzyme activity) to irreversible clinical outcomes. Notably, some changes that occur before clinical manifestations could be used as surrogate or predictive markers of subsequent adverse health effects, i.e. biomarkers of effect' (EFSA NDA Panel, 2022).

Available risk assessments on dietary selenium intakes from authoritative bodies (IOM, 2000; EVM, 2003; WHO/FAO, 2004; NHMRC, 2006; FSCJ, 2012) and expert reviews (Fairweather-Tait et al., 2011; Rayman, 2012; Vinceti et al., 2014; Jablonska and Vinceti, 2015; Vinceti et al., 2016b; Vinceti et al., 2017b; Brigelius-Flohe and Arner, 2018; Dinh et al., 2018; Vinceti et al., 2018b; Rayman, 2020; Naderi et al., 2021) were used to identify adverse health effects that have been associated with excess selenium intakes in humans. As a result, the following effects were prioritised for the risk assessment: selenosis (including biomarkers of effect of excess selenium intake), hypertension, Alzheimer's dementia, amyotrophic lateral sclerosis (ALS), impaired neuropsychological

development in children, thyroid diseases, prostate cancer, skin cancer, type 2 diabetes mellitus (T2DM) and overall mortality. The rationale for the prioritisation is detailed in the protocol (Annex A).

As a result of the problem formulation, the overarching risk assessment questions were further specified into assessment sub-questions (sQs) and the methods to address each sQ was selected, as outlined in Table 2.

**Table 2:** Assessment sub-questions

|            | <b>Sub-question</b>   | <b>Method</b>  |
|------------|---|--|
| <b>sQ1</b> | a. What are the clinical effects associated with selenosis <sup>(a)</sup> in humans?<br>b. What are biomarkers of effect <sup>(b)</sup> of excess selenium intake in humans? What is their biological relevance?  | Systematic review  |
| <b>sQ2</b> | a. Is there a causal positive relationship between selenium intake and risk of diseases in humans, with a focus on hypertension, Alzheimer's dementia, amyotrophic lateral sclerosis (ALS), thyroid diseases, prostate cancer, skin cancer, type 2 diabetes mellitus, and overall mortality?<br>b. Is there a causal positive relationship between selenium intake and risk of impaired neuropsychological development in children?<br>c. Is there a positive relationship between selenium intake and excess overall mortality risk in humans? | Systematic review  |
| <b>sQ3</b> | What is the quantitative relationship between selenium intake and plasma selenium concentrations in humans?   | Narrative review and dose–response modelling (if applicable)   |
| <b>sQ4</b> | What is the dose–response relationship between selenium intake and clinical effects of selenosis <sup>(a)</sup> and/or biomarkers of effect of excess selenium intake in humans?  | Systematic review and dose–response modelling (if applicable)  |
| <b>sQ5</b> | What is the dose–response relationship between selenium intake and risk of disease in humans?   | Systematic review and dose–response modelling (if applicable)  |
| <b>sQ6</b> | What is the absorption, distribution, metabolism and excretion (ADME) of selenium and specific selenium species from different sources in humans?   | Narrative review   |
| <b>sQ7</b> | What are the potential mode(s) of action for the relationships found between selenium intake and adverse health effects?  | Narrative review   |
| <b>sQ8</b> | a. What are the levels of selenium in foods, beverages and food supplements in the EU?<br>b. What is the distribution of daily selenium intake from all dietary sources in EU populations and subgroups thereof?  | Collection of data based on existing EFSA intake estimates and complementary searches in relevant databases and inquiries to competent Authorities of European Countries |

sQ: subquestion.

- (a): In the clinical setting, the term selenosis refers to a specific clinical condition resulting from excess selenium exposure, as diagnosed based on accepted signs and symptoms (integumental features in particular). This condition is observed especially in populations living in seleniferous areas. This term can also be more generally used to refer to selenium toxicity and associated features. In the context of the formulation of sQ1 and sQ4, the term selenosis is to be understood in a wide sense.
- (b): Biomarker of effect: 'a measurable biochemical, physiological, behavioural or other alteration within an organism that, depending upon the magnitude, can be recognised as associated with an established or possible health impairment or disease' (WHO/IPCS, 1993; EFSA Scientific Committee, 2017a). Its biological relevance depends on its relation to the mode of action and the linkage with the adverse effect or the relevant adverse outcome pathway (EFSA Scientific Committee, 2017a).

## 2.2. Hazard identification and characterisation (sQ1 to sQ7)

### 2.2.1. Data

A brief description of the processes applied for evidence retrieval, study selection and data extraction is provided below (see the protocol (Annex A) for further details).

#### 2.2.1.1. Priority adverse health effects (sQ1 and sQ2)

To address sQ1 and sQ2, relevant human studies on the selected adverse health effects were identified through systematic searches of the literature in PubMed, Embase and the Cochrane library for articles published in English. The search strategy was created by EFSA's information specialist and is further detailed in the protocol (Annex A). Grey literature was not searched. No limit was applied regarding the inception date. The searches were performed on the 7 May 2021 regarding sQ1 and 3 May 2021 regarding sQ2. An update of the literature search focusing on T2DM was performed on the 7 February 2022.

Retrieved articles were screened in duplicate in Distiller SR<sup>®</sup> at title and abstract and full-text levels for inclusion/exclusion according to the criteria defined in the protocol. Conflicts were solved by a third reviewer, if necessary. Relevant systematic reviews were hand-searched for additional pertinent studies. Reviews, expert opinions, editorials, letters to the editors, abstracts, posters and theses were excluded.

*Eligible designs:* For selenosis and related potential biomarkers of effects (sQ1), all experimental and observational study designs in humans (including case reports) were considered relevant. For other health effects (sQ2), eligible study designs were limited to prospective designs, i.e. human controlled trials (HCTs; randomised or non-randomised), prospective cohort studies (PCs) and nested case-control studies (NCCs).

*Eligible study populations:* Studies were eligible if they involved individuals of any age, either healthy individuals or diseased individuals if the disease was considered not to be related to the exposure-outcome relationship. Decision on the inclusion/exclusion of studies conducted in diseased individuals were taken by the experts of the EFSA working group on ULs and the rationale for the decisions is available in Annex E.

*Eligible exposure measurements:* studies were eligible if they measured selenium intake by dietary assessment methods or used accepted biomarkers of selenium intake, i.e. whole blood/plasma/serum/red blood cell (RBC) selenium, urinary selenium, toenail/hair selenium, whole blood/plasma/serum selenoprotein P concentrations and whole blood/plasma/serum/RBC glutathione peroxidase activity (see Section 3.3).

In relation to sQ1, 6,004 unique references were identified after removing duplicates (flow chart in Appendix B). The title and abstract screening left 207 relevant articles that underwent a full-text review. Of those, 130 were excluded. A total of 77 publications reporting on 45 HCTs and 32 observational studies were included.

In relation to sQ2, 7,873 unique references were identified after removing duplicates (flow chart in Appendix B). The title and abstract screening left 363 relevant articles that underwent a full-text review. Of those, 224 were excluded and additional 31 were excluded during the data extraction step (see below). A total of 108 publications reporting on 33 HCTs and 75 observational studies were included.

For the purpose of data plotting and analysis, data were extracted into Microsoft Excel<sup>®</sup> by one EFSA staff member and double checked by another. Evidence tables were prepared in Microsoft Word<sup>®</sup> and are provided in Appendix D.

#### 2.2.1.2. Dose-response between selenium intake and plasma/serum concentration (sQ3)

Many studies investigating the relationship between selenium exposure and health effects use serum/plasma selenium as a biomarker of dietary selenium intake. A predictive equation for estimating selenium intake from serum/plasma selenium concentrations was needed to integrate these data in the risk assessment. In particular, the equation was instrumental for performing the dose-response meta-analysis on selenium exposure and incidence of T2DM (see Section 2.2.2.2).

Studies used to characterise the quantitative relationship between selenium intake and plasma or serum selenium concentrations were identified through the searches described in Section 2.2.2.1 (sQ1 and sQ2) (see Annex A). The reviews by Haldimann et al. (1996), Jenny-Burri et al. (2010) and

Noisel et al. (2014) were used to retrieve additional relevant studies. Additionally, a separate search in PubMed was tailored for similar reviews published after 2011, the date up to when the literature had been searched by Noisel et al. (2014). No additional reviews were retrieved. However, the Panel notes that publications reviewing equations by which selenium intake can be assessed from plasma or serum concentrations may not be classified consistently as reviews in literature databases. In total, 43 studies were identified through the searches performed to address sQ1 and sQ2 and an additional 11 were found by searching the reference list of the reviews mentioned above, yielding a total of 54 studies.

HCTs, PCs, NCCs, case-control studies (CCs) and cross-sectional studies (CSs) were included when they reported cross-sectionally on the dietary selenium intake from all sources (i.e. food plus food supplements), using 24-h recalls and dietary records, and on plasma or serum selenium concentrations. There was no restriction regarding study location (to explore ethnicity as an influencing factor for plasma selenium as a biomarker of selenium intake). Owing to the fact that inorganic selenium forms have a different effect on plasma selenium concentrations than organic forms of selenium (see also Section 3.2), inorganic forms are to be considered separately from organic forms. As, however, only two studies reported on inorganic forms (i.e. selenate Levander et al., 1983; selenite Martin et al., 1989), the study arms in which inorganic selenium was consumed in these studies were excluded from further analyses and only studies that administered organic selenium or in which selenium originated from mixed diets were included (Annex B).

### 2.2.1.3. Other background information (sQ6 and sQ7)

For questions addressed through narrative reviews (sQ6 and sQ7), searches were conducted in PubMed to retrieve articles reporting on the absorption, distribution, metabolism and excretion (ADME) of selenium, on the potential mechanisms by which selenium may exert an adverse health effect, and on the potential confounders or effect modifiers to be considered in the risk of bias (RoB) assessment of individual studies.

In addition, an expert review was contracted out through a procurement procedure with the aim to identify the most recent evidence on ADME, potential pathways to adverse health effects and potential biomarkers of effect.<sup>1</sup>

## 2.2.2. Methodologies

The methodology for this assessment follows the approach for deriving ULs for nutrients laid down by the SCF (2000b), the principles established by the EFSA NDA Panel (2022), EFSA's guidance on the application of the systematic review methodology in food and feed safety assessments (EFSA, 2010), its principles and processes for dealing with data and evidence in scientific assessments (EFSA, 2015), the guidance on statistical significance and biological relevance (EFSA Scientific Committee, 2011), the guidance on the assessment of the biological relevance of data in scientific assessments (EFSA Scientific Committee, 2017a), the guidance on the use of the weight of evidence approach in scientific assessments (EFSA Scientific Committee, 2017c) and the draft guidance on appraising and integrating evidence from epidemiological studies for use in EFSA's scientific assessments (EFSA Scientific Committee, 2020).

### 2.2.2.1. Evidence appraisal (sQ2)

A RoB appraisal, i.e. evaluation of the internal validity of studies, was applied to eligible studies which addressed sQ2.

The appraisal was performed using the Office of Health Assessment and Translation (OHAT) RoB tool developed by the US National Toxicology Program (NTP) (OHAT-NTP, 2015). The RoB criteria and rating instructions provided therein were tailored to the specific research questions, for the questions addressing: (1) consideration of potential confounders, (2) confidence in the exposure characterisation, and (3) confidence in the outcome assessment (Appendix C).

The appraisal was performed in duplicate by the experts of the EFSA Working Group (WG) on ULs and EFSA staff in Distiller SR<sup>®</sup>. Discrepancies in the assessment in relation to the RoB judgement of each domain were discussed among the assessors. In case of disagreement, the WG was consulted.

The OHAT RoB tool proposes five response options for each RoB question: definitely low RoB (++), probably low RoB (+), not reported (NR), probably high RoB (-), definitely high RoB (---). For the appraisal of intervention studies, the scale was aggregated to three options (high RoB, NR, low RoB) as it was considered sufficiently discriminatory for this design in the context of the present assessment.

<sup>1</sup> Contract No PO/EFSA/NIF/2022/01.

Studies were categorised according to their overall RoB based on a three-tier system (i.e. at low (tier 1), moderate (tier 2) or high (tier 3) RoB), according to the strategy proposed by OHAT (OHAT-NTP, 2019) (Appendix C).

#### 2.2.2.2. Evidence synthesis (sQ2, sQ3 and sQ5)

The methods applied for the evidence synthesis to address sQ2, sQ3 and sQ5 are outlined below. Detailed information is provided in Annex B.

Descriptive forest plots of studies investigating selenium exposure and health effects.

Results from eligible studies were plotted using descriptive forest plots, when three or more studies reported on the same outcome. For intervention studies with several selenium doses, the mean difference between the highest dose group and control group was selected for the plot, unless specified otherwise. For observational studies reporting both continuous and categorical analyses, the latter was selected for the plot.

##### *Dose–response relationship between selenium intake and plasma/serum concentration*

A dose–response meta-analysis was conducted by EFSA to characterise the relationship between mean selenium intake and mean plasma/serum selenium concentration. Parametric dose–response models were estimated based on summarised data. Both linear and non-linear (piecewise linear splines) dose–response relationships were investigated. Random-effects models were fitted on mean values from both observational and experimental designs via restricted maximum likelihood. The between-study heterogeneity was investigated with Cochran's Q test and the  $I^2$  statistic. Different knots for the piecewise linear function were explored and potential modifying factors were characterised; sensitivity analyses were run to address the uncertainty in the choice of spline knots, the influence of individual studies, aspects of study design and the reliability of studies' features.

##### *Dose–response relationship between selenium exposure and incidence of T2DM*

A dose–response meta-analysis was conducted by EFSA to characterise the relationship between plasma/serum selenium concentrations and incidence of T2DM based on observational studies. The analysis included studies using plasma/serum selenium concentrations as exposure variable as well as studies which estimated selenium intake based on dietary assessment methods. In the latter case, the piecewise regression equation described above was used to convert mean selenium intakes into estimates of plasma/serum selenium concentrations for inclusion in the dose–response analysis.

Parametric dose–response models were estimated based on summarised data. Both linear and non-linear (restricted cubic splines) dose–response relationships were investigated. Random-effects models were fitted on risk ratios (RR) from most adjusted multivariable models via restricted maximum likelihood using a one-stage approach (Crippa et al., 2019) and a two-stage approach (Orsini et al., 2012) to estimate pooled effects of individual studies across exposure categories. The reference dose chosen corresponded to the lowest mean plasma concentration observed or estimated in the sample. The between-study heterogeneity was investigated with Cochran's Q test and the  $I^2$  statistic; sensitivity analyses were run to address the uncertainty in the choice of spline knots, in the type of exposure assessment and in the influence of individual studies. Publication bias was assessed using Egger's test and funnel plot on study-specific RRs.

#### 2.2.2.3. Evidence integration (sQ1 and sQ2)

##### *Hazard identification*

Regarding sQ1, a causal relationship between 'high' selenium intake and clinical selenosis is well-established and the assessment focussed on the characterisation of the dose–response. As proposed in the guidance for establishing and applying ULs for vitamins and essential minerals (EFSA NDA Panel, 2022), some changes that occur before clinical manifestations of excess selenium intake could be used as surrogate or predictive markers of subsequent adverse health effects, i.e. biomarkers of effect. Thus, data that could inform the identification of potential biomarkers of effect were also gathered and explored.

Regarding sQ2, the hazard identification step consisted of assessing the evidence for a causal positive relationship between selenium intake and the health effects identified. For each health effect, HCTs and prospective observational studies (PCs/NCCs) are organised in separate lines of evidence (LoE), which are classified in hierarchical order:

- Standalone main LoE: Studies on disease endpoints (e.g. incidence of hypertension, incidence of T2DM). These studies could, on their own, answer the sQ directly.
- Standalone surrogate LoE: Studies on endpoints which are surrogate measures of the disease risk (e.g. blood pressure for hypertension, fasting blood glucose for T2DM). These studies also could, on their own, answer the sQ, on the assumption that a sustained increase in the surrogate measure over time (e.g. blood pressure) would eventually lead to an increased risk of disease (e.g. hypertension). However, the Panel is aware of the uncertainty inherent in this assumption, and this was considered in the uncertainty analysis (UA) for each sQ (see for example Section 3.5.10).
- Complementary LoE: Studies on endpoints which are relevant to the disease but less directly than those included in standalone LoE (e.g. risk factors, upstream indicators, other biologically related endpoints). These studies, on their own, cannot answer the sQ but can be used as supporting evidence to the standalone LoEs.

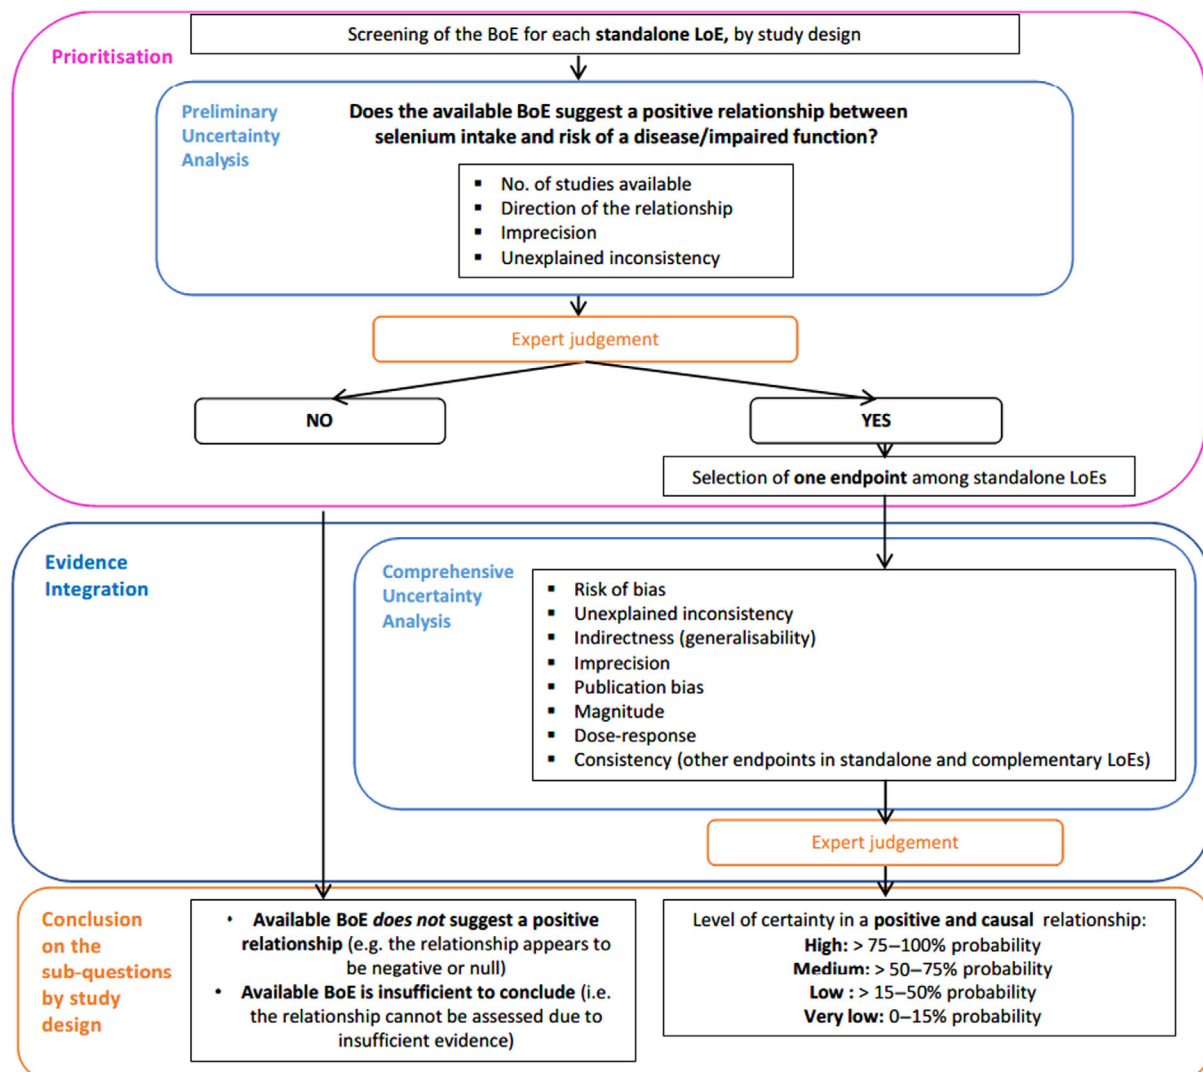

Conclusions on each health effect are reached by study design (HCTs separately from PCs/NCCs), through considering the uncertainties in the body of evidence (BoE) and in the methods.

A stepwise approach is applied as illustrated in Figure 1 and described below:

#### Prioritisation

A prioritisation step is applied to identify health effects for which the available BoE suggests a positive relationship between dietary intake of selenium and risk of disease/impaired function based on a preliminary UA and expert judgement. The Panel considers that health effects for which the available BoE (i) does not suggest a positive relationship (i.e. the relationship appears to be negative or null) or (ii) is insufficient to conclude on a relationship, cannot be used to inform the setting of a UL for selenium. Data gaps and research needs are identified, where appropriate.

When the available BoE indicates a positive association between selenium intake and the risk of a disease/impaired function, a comprehensive UA is performed to inform the formulation of the hazard identification conclusions, i.e. judgement on the level of certainty for a causal relationship. For health effects with more than one standalone LoE, the comprehensive uncertainty analysis is undertaken for the endpoint with the highest level of evidence for a positive relationship with the exposure.

BoE: body of evidence; LoE: line of evidence.

**Figure 1:** Stepwise approach for evidence integration and uncertainty analysis applied to sQ2, by study design

#### Evidence integration and conclusions on the prioritised SQs, by study design

The OHAT-NTP framework for the formulation of hazard identification conclusions is used and adapted (OHAT-NTP, 2019). According to the OHAT-NTP approach, available studies on a particular outcome are initially grouped by study design (i.e. trials vs prospective cohort studies) and the BoE on a particular sQ is given an initial level of certainty based on study design. In the OHAT's framework, the 'initial confidence rating' is expressed through four qualitative descriptors, i.e. 'high', 'moderate', 'low', 'very low'. It is assigned by considering four features of the design i.e. exposure is experimentally controlled, exposure occurs prior to the endpoint, endpoint is assessed at individual level and an appropriate comparison group is included in the study. As a result, OHAT assigns a 'high' confidence rating (likely to comply with all four the above-mentioned criteria) to HCTs, while PC studies (where the exposure is unlikely to be controlled) start with a 'low' to 'moderate' confidence rating,<sup>2</sup> depending on whether the exposure precedes the outcome or not (OHAT-NTP, 2019). The Panel agrees with the rationale behind this initial rating but notes that qualitative descriptors bear some ambiguity. The EFSA Scientific Committee recommends the use of probability as the preferred measure for expressing uncertainty (EFSA Scientific Committee, 2018). Therefore, OHAT's 'initial confidence ratings' have been translated into 'initial levels of certainty' expressed as approximate probabilities. Similarly, the final level

<sup>2</sup> See Table 8 of OHAT's Handbook for Conducting Systematic Reviews for Health Effects Evaluations (OHAT-NTP, 2019).

of certainty for a positive and causal relationship between the exposure and risk of disease is expressed in terms of probabilities, rather than using qualitative descriptors (Figure 2).

A schematic representation of the approach for assessing the final level of certainty in the hazard identification conclusions by study design is provided in Figure 2. This initial rating is downgraded on the basis of factors that decrease certainty in the results (RoB, unexplained inconsistency, indirectness or lack of applicability, imprecision, and publication bias) and upgraded for factors that increase certainty in the results (large magnitude of effect, dose–response, consistency across study designs/populations/animal models or species, and consideration of residual confounding or other factors that increase the certainty in the causal nature of the relationship).

| Initial level of certainty by study design  | Factors decreasing certainty  | Factors increasing certainty  | Final level of certainty <sup>(a)</sup>   |
|---|---|---|---|
| <b>High:</b><br>>75–100% probability<br>HCTs<br><br><b>Moderate:</b><br>>50–75% probability<br>PCs <i>assessing the exposure prior to the endpoint</i><br><br><b>Low:</b><br>>15–50% probability<br><br><b>Very low:</b><br>0–15% probability | <ul style="list-style-type: none"> <li>• RoB across studies (limitations to internal validity)</li> <li>• Unexplained inconsistency (heterogeneity)</li> <li>• Indirectness</li> <li>• Imprecision</li> <li>• Publication bias</li> </ul> | <ul style="list-style-type: none"> <li>• Large magnitude of the effect (or a strong association/response)</li> <li>• Dose-response (monotonic or not)</li> <li>• Residual confounding               <ul style="list-style-type: none"> <li>i) studies report an effect and residual confounding is toward the null</li> <li>ii) studies report no effect and residual confounding is away from the null</li> </ul> </li> <li>• Consistency (across endpoints in standalone and complementary LoEs)</li> </ul> | <b>High:</b><br>>75–100 % probability<br><br><b>Moderate:</b><br>>50–75 % probability<br><br><b>Low:</b><br>>15–50% probability<br><br><b>Very low:</b><br>0–15 % probability |

Adapted from OHAT-NTP (2019).

LoE: line of evidence; PC: prospective cohort study; HCT: human controlled trial; RoB: risk of bias.

(a): As an example, a 'high level of certainty' means that, based on the available evidence, experts are 75%–100% certain that selenium is positively and causally associated with the disease of interest.

**Figure 2:** Approach applied to assign the final level of certainty in a causal relationship

#### Reaching overall conclusions on the prioritised SQs

Adapted from the OHAT-NTP approach, the overall conclusion regarding the relationship is formulated as follows:

- hazard identification conclusions are primarily based on the BoE providing the highest level of certainty on the relationship;
- consistent results across study designs could result in higher level of certainty on the causality of a positive relationship;
- mechanistic or mode-of-action data are considered as other relevant supporting types of evidence; they could provide strong support or opposition for biological plausibility and could thus result in higher or lower certainty on the causality of the positive relationship.

It is noted that the formulation of hazard identification conclusions necessarily requires expert judgement. The value of this type of approach is that it involves using a reproducible and transparent framework for expressing uncertainty in the evidence and in the methods.

#### Hazard characterisation

At this step, evidence is integrated to select the critical effect(s) and identify a reference point (RP) for establishing the UL. As proposed in the guidance for establishing and applying ULs for vitamins and essential minerals (EFSA NDA Panel, 2022), when available data are not suitable for dose–response

modelling, a no-observed-adverse-effect level (NOAEL) or a lowest-observed-adverse-effect level (LOAEL) can be identified and used as the RP. In view of the available BoE, this approach is applied. To derive the UL, an uncertainty factor (UF) is applied to the RP to account for the uncertainties associated with extrapolating from the observed data to the general population. ULs should be protective for all members of the general population, including sensitive individuals, throughout their lifetime. The rationale for the selection of the RP and UF are documented in Section 3.6 of the Opinion.

## 2.3. Dietary intake assessment (sQ8)

The assessment follows the approach outlined in the protocol for the intake assessments performed in the context of the revision of Tolerable Upper Intake Levels for selected nutrients (EFSA, 2022). It is briefly summarised below.

### 2.3.1. Data

Selenium intakes from foods, excluding food supplements, have previously been estimated for all population groups in the context of the Scientific Opinion on DRVs (EFSA NDA Panel, 2014). Food intake data from the EFSA Comprehensive European Food Consumption Database (hereinafter referred as Comprehensive Database)<sup>2</sup> and data on selenium content in foods from the EFSA food composition database (FCDB)<sup>3</sup> (Roe et al., 2013) were used. Given that the EFSA FCDB has not been updated since then and the number of national surveys that were newly integrated in the Comprehensive Database is limited, the intake estimates published in 2014 are still considered adequate for the purpose of the present assessment and were not updated, except for the addition of data for infants aged < 1 year (Section 2.3.2).

Regarding the use of selenium food supplements, data in the Comprehensive Database suffer from important limitations, in particular due to partial reporting in the database of the nutrient(s) contained in food supplements. In view of the uncertainties associated with these data, the Panel relied on information available at national level (see below).

To complement EFSA intake assessment from 2014, selenium intake estimates from natural sources, from addition to foods and from food supplements based on nationally-representative food consumption surveys and Total Diet Studies (TDS) published after 2014 were collected. Data on selenium intakes from fortified foods and/or food supplements published before 2014 were also considered as the contribution of those sources was not addressed in EFSA's previous assessment. Data were collected between September and November 2021 by contacting 64 competent authorities in 37 European countries through EFSA Focal Points<sup>3</sup> and the EFSA Food Consumption Network.<sup>4</sup> An additional search in sources of bibliographic information (Google Scholar, PubMed) was performed to collect reports of national surveys included in the Comprehensive database which had not been obtained through the competent authorities.

The Mintel Global New Products Database (GNPD)<sup>5</sup> was used as a data source to identify the type of selenium containing food supplements and fortified foods available on the EU market. The search was limited to the past 5 years, from January 2016 to December 2021.

### 2.3.2. Methodology

EFSA intake estimates were calculated by matching the food intake data from the Comprehensive Database and the data on selenium content in foods from the EFSA FCDB as available in 2014 (EFSA NDA Panel, 2014) (Section 3.4.2). Data on intake estimates for infants ( $\geq 4$  to < 12 months), which were not in the remit of the DRV Opinion from 2014, have been added to the present assessment. The methodology applied to estimate intakes in this population group is the same as for the other age groups.

Selenium intake data from recent national food consumption surveys and TDSs, including specific estimates of selenium intake from food supplements and/or fortified foods, were extracted.

<sup>3</sup> <http://www.efsa.europa.eu/en/people/fpmembers>

<sup>4</sup> <http://www.efsa.europa.eu/sites/default/files/dcmfoodconsnetworklist.pdf>

<sup>5</sup> The Mintel GNPD contains information on over three million food and beverage products, of which more than one million are or have been available on the European food market. Twenty five out of the 27 EU Member States and Norway are present in the database. The database provides the compulsory ingredient information reported on product labels and the nutrition declaration when available. <http://www.mintel.com/globalnew-products-database>.

Information on food products fortified with selenium and selenium-containing supplements available on the EU market, and their selenium content as reported on the label, were extracted from the GNPD database. These data were used qualitatively to describe the types of fortified foods and food supplements available and to gain insight into their potential contribution to total selenium intake.

## 2.4. Public consultation

In line with EFSA's policy on openness and transparency, and for EFSA to receive comments from the scientific community and stakeholders, the draft Scientific Opinion was released for public consultation from 14 September 2022 to 19 October 2022.<sup>6</sup> The outcome of the public consultation is described in a technical report published as Annex F to this Scientific Opinion.

## 3. Assessment

### 3.1. Chemistry of selenium

Selenium (CAS number 7782-49-2) resembles sulfur in its organic and inorganic forms (EFSA NDA Panel, 2014). Selenium is found in organic compounds, such as SeMet, selenocysteine (SeCys), dimethylselenide (DMSe), dimethyldiselenide and Se-methyl-selenocysteine (MeSeCys), and inorganic forms, such as selenite ( $\text{SeO}_3^{2-}$ ), selenide ( $\text{Se}^{2-}$ ), selenate ( $\text{SeO}_4^{2-}$ ) and elemental selenium (Mehdi et al., 2013; Naderi et al., 2021). The main inorganic selenium compounds, selenite and selenate, are water soluble, while elemental selenium is not (ATSDR, 2013). Selenium is a component of a number of selenoproteins which are mediating the biological effects of selenium and include glutathione peroxidases, thioredoxin reductases, iodothyronine deiodinases and selenoprotein P (EFSA NDA Panel, 2014).

### 3.2. Absorption, distribution, metabolism and excretion

The most abundant forms of selenium in the diet are organic, SeMet and SeCys in particular. Selenite and selenate (inorganic selenium compounds) normally represent a minor proportion of the overall dietary intake (EFSA NDA Panel, 2014; see Section 3.4.1). *Brassica* and *Allium* species are sources of the non-proteinogenic selenium-containing amino acids Se-methyl-selenocysteine (MeSeCys) and  $\gamma$ -glutamyl-Se-methyl-selenocysteine ( $\gamma$ -Glu-MeSeCys) (see also Section 3.4.1).

SeMet is a methionine analogue that may non-specifically replace methionine in proteins. It can only be synthesised by plants but can be incorporated into proteins by plants and animals into the non-specific protein pool. They are often referred to as selenium-containing proteins, in contrast to selenoproteins (Combs, 2015).

SeCys, which is the only form of selenium used for selenoprotein synthesis (see Section 3.1), is co-translationally synthesised from selenide and serine and can be integrated into peptides through in-frame UGA codons in selenoprotein mRNA (Labunskyy et al., 2014). Plants generally do not have UGA-encoded selenoproteins (White, 2018). With exception of some algae (Jiang et al., 2020), selenoproteins can only be synthesised in animals and some microorganisms (Beilstein and Whanger, 1986; Combs, 2015).

Human studies confirm that all forms of selenium are readily absorbed (Jäger et al., 2016a,b).

As evidenced by animal studies, selenium-containing amino acids require the digestion of the respective proteins and are then absorbed through active transport (Combs, 2015). SeMet is absorbed with the involvement of intestinal methionine transporters, while the absorption of SeCys is less well studied (Burk and Hill, 2015), but might be absorbed in a similar way as cysteine (Ha et al., 2019). Selenite is absorbed via passive diffusion (Burk and Hill, 2015) and, when ingested in physiological amounts, is reduced in the intestinal mucosa cells to selenide. It is, therefore, not expected to occur as such in circulation (Burk and Hill, 2015). Selenate, on the contrary, is absorbed via a carrier-mediated mechanism and can appear unchanged in blood (Combs, 2015; Ha et al., 2019) (Figure 3). The absorption of selenium can be influenced by other dietary components and is in the range of 50%–90% in humans (Burk and Hill, 2015).

Following absorption, the different selenium compounds are mostly transported to the liver (Ha et al., 2019). The liver is the principal site of selenium metabolism. The metabolites are then widely distributed to other organs and tissues such as pancreas, nervous system, skin and hair, bone, both

<sup>6</sup> <https://connect.efsa.europa.eu/RM/s/publicconsultation2/a017U0000011gOQ/pc0265>

skeletal and cardiac muscle, lungs and kidneys (ATSDR, 2013). These organs are variably affected by deficient and excessive intakes of selenium giving rise to site-specific pathological and biochemical features (Alexander, 2022).

Evidence on the fate of selenium in the liver and subsequent transport to cells stems mainly from animal and *in vitro* studies. In the liver, all selenium compounds, except SeMet, MeSeCys and  $\gamma$ -Glu-MeSeCys, are metabolised to the common intermediate, hydrogen selenide (Figure 3).

SeMet can be metabolised via the transsulfuration pathway to SeCys or be randomly incorporated into the non-specific protein pool (Burk and Hill, 2015). SeMet can also be metabolised to methylselenol by  $\gamma$ -lyase in mouse liver (Suzuki et al., 2007; Thiry et al., 2012). However, it is uncertain if this conversion occurs in humans. Selenium deposited in the non-specific protein pool can be released by the degradation of proteins and be used in the formation of selenoproteins as SeCys (Waschulewski and Sunde, 1988a,b).

MeSeCys and  $\gamma$ -Glu-MeSeCys are converted to methylselenol by  $\beta$ -lyase which can be either metabolised to hydrogen selenide or further methylated for excretion (Suzuki et al., 2007; Thiry et al., 2012).

SeCys, either consumed as such or produced from SeMet, is transformed to hydrogen selenide and alanine by SeCys lyase (Burk and Hill, 2015). It is subsequently phosphorylated by selenophosphate synthase 2 to monoselenophosphate ( $H_2SePO_3$ ) (Saito, 2021), which is used for conversion of phosphoseryl tRNA<sup>[ser]<sup>sec</sup> to SeCys tRNA<sup>[ser]<sup>sec</sup> that provides SeCys for insertion into selenoproteins during translation (Burk and Hill, 2015). SeCys is highly reactive and has not been found in free form in tissues, as SeCys lyase which catalyses the reaction from SeCys to hydrogen selenide keeps its level low (Burk and Hill, 2015; Plateau et al., 2017; Hoffman et al., 2019). In humans, there is no physiological pathway that allows SeMet to be synthesised from SeCys (Katarzyna et al., 2020).</sup></sup>

Selenate is reduced first to selenite and then to hydrogen selenide through a series of redox reactions coupled to reduced glutathione or with the involvement of thioredoxin reductases (Burk and Hill, 2015).

Hydrogen selenide can be incorporated into selenoproteins, used in the formation of selenosugars or methylated for excretion as shown in a study on the human metabolic profile of urinary selenium (Lajin et al., 2016a).

From the liver, selenium is transported to tissues as SeCys mainly in selenoprotein P, the major selenium transport protein, but also in other selenoproteins (Burk and Hill, 2015). The distribution is differential, as some tissues, such as the brain and the testes, require more selenium than others for their function, as shown in animal studies (Ha et al., 2019). In *in vitro* studies it has been observed that in order to use selenium that had been transported by selenoprotein P, selenoprotein P is incorporated into cells where it is degraded in the lysosome and the liberated SeCys can be used in selenoprotein synthesis (Saito, 2021).

In plasma, selenium is also present as SeMet, which non-specifically substitutes for methionine in plasma proteins, and as small molecules such as selenosugars (Burk and Hill, 2015).

Under physiological intakes, the assumption is that selenoproteins make up the majority of tissue selenium, but recent data in turkey liver suggest that the selenosugar 1 ( $\beta$ -methylseleno-N-acetylgalactosamine; SeGalNac) comprises more selenium than all the selenoproteins combined (Katarzyna et al., 2020).

It has been shown that in turkey liver selenosugars can react with low-molecular weight thiols and with cysteine-containing peptides and proteins. Analysis of high-molecular weight selenium species found that selenium was present as SeGalNac (selenosugar 1) linked to thiols on general body proteins. With high selenium supplementation, increased selenosugar formation occurred, further increasing these 'selenosugar-decorated proteins', but also increasing selenosugar linked to low-molecular weight thiols and the excretion of SeGalNac (selenosugar 1) in urine (Katarzyna et al., 2020).

Selenium elimination primarily occurs by urinary excretion (Sunde, 2012). The main human urinary selenium metabolites are the selenosugars 1 and 3, trimethylselenonium ion (TMSe) and, depending on the selenium compound consumed, selenate and selenium-methylselenoneine, the latter originating most likely from methylation of selenoneine in fish (Hadrup and Ravn-Haren, 2021). A considerable part of excreted selenium is in the form of yet unidentified metabolites. The amount of identified and unidentified selenium metabolites in urine is dependent on the selenium compound ingested, on the dose and on the individual genetic background (Kuehnelt et al., 2007; Jäger et al., 2016a,b).

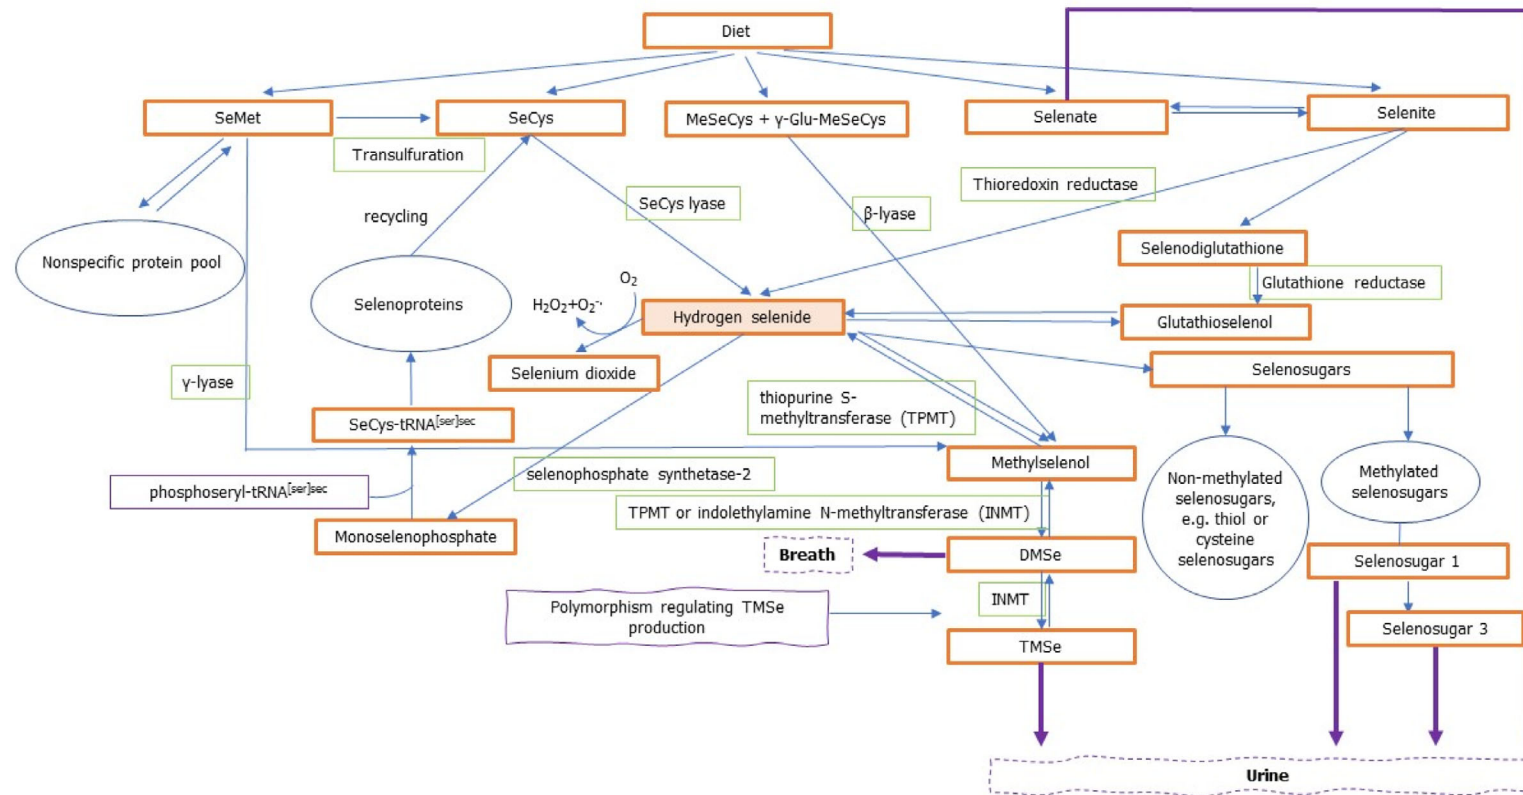

TMSe is produced following methylation of hydrogen selenide first to methylselenol (driven by thiopurine S-methyltransferase (TPMT)), then to DMSe (driven by either TPMT or indolethylamine

*N*-methyltransferase (INMT)) and finally to TMS<sub>e</sub> (driven by INMT). A genetic polymorphism in the human INMT gene results in the fact that some individuals are not able to excrete TMS<sub>e</sub> in substantial amounts (TMS<sub>e</sub> non-eliminators) (Lajin and Francesconi, 2016). It has been suggested that conversion of hydrogen selenide to methylselenol and to DMS<sub>e</sub> takes place in the liver, while the urinary metabolite TMS<sub>e</sub> is produced from DMS<sub>e</sub> in the lungs (Fukumoto et al., 2020). This would explain why following ingestion of large amounts of selenium, when the ability of the lung to convert DMS<sub>e</sub> into TMS<sub>e</sub> is exceeded, DMS<sub>e</sub> is exhaled in breath. There is indication that TMS<sub>e</sub> eliminators excrete TMS<sub>e</sub> in addition to other selenium metabolites and eliminate more selenium than TMS<sub>e</sub> non-eliminators (Kuehnelt et al., 2015; Lajin et al., 2016a). The Panel notes that the reduced capacity of TMS<sub>e</sub> non-eliminators to excrete excess selenium in urine might make them more susceptible to selenium toxicity compared with TMS<sub>e</sub> eliminators. However, current evidence is inadequate to confirm this hypothesis.

In TMS<sub>e</sub> non-eliminators, selenosugars 1 and 3 are the predominant selenium metabolites in urine, while TMS<sub>e</sub> seems to be more prominent in TMS<sub>e</sub> eliminators (Lajin et al., 2016b). Selenosugar 2 is present usually only in trace amounts and is only detected when selenium intakes are high. For example, selenosugar 2 has been reported to be present in urine in individuals who had been supplemented with 8,000 µg/day SeMet for 7 days and thereafter 4,000 µg/day with urine collections up to day 30 of supplementation (Kuehnelt et al., 2007; Lajin et al., 2016b). With increasing selenium intakes, selenosugar 1 becomes more prominent while the selenosugar 3 rise is less pronounced. The ratio of selenosugar 3 to total urinary selenium metabolites tends to reach a plateau at around 5%, while that of selenosugar 1 to total urinary selenium metabolites continues to rise and stabilises at around 70% (Lajin et al., 2016a).

Selenium ingested as selenate given at a single dose of 50 µg was mostly excreted unmetabolised in humans (Jäger et al., 2016a). Small amounts of ingested selenite are also excreted as selenate, indicating that a fraction of selenite is oxidised to selenate following intake (Jäger et al., 2016b).

Figure 3 provides a schematic overview of selenium metabolism in humans.

Based on Burk and Hill (2015), Combs (2015), Saito (2021), Jäger et al. (2016a,b), Thiry et al. (2012), and Rayman et al. (2008a).

DMSe: dimethylselenide; γ-Glu-MeSeCys: γ-glutamyl-Se-methyl-selenocysteine; INMT: indolethylamine N-methyltransferase; MeSeCys: Se-methyl-selenocysteine; SeMet: selenomethionine; SeCys: selenocysteine; TMsE: trimethylselenonium ion; tRNA: transfer ribonucleic acid; TPMT: thiopurine S-methyltransferase.

**Figure 3:** Schematic representation of selenium metabolism

### 3.3. Biomarkers of intake

#### 3.3.1. Characteristics of selenium biomarkers

Several biological markers have been proposed as potential markers of selenium exposure. High correlations ( $r = 0.63\text{--}0.96$ ) between selenium dietary intake, as estimated from duplicate food portions, and single measurements from whole blood, 2-h-urine, serum/plasma, hair and (toe)nail samples have been reported (Yang et al., 1989a; Longnecker et al., 1996). The characteristics of selenium biomarkers are described in Appendix A, together with their strengths and limitations regarding their use as biomarkers of selenium dietary intake.

Dietary selenium intake is the major determinant of whole blood/serum/plasma selenium concentrations in non-occupationally exposed individuals. Serum/plasma selenium concentrations and, to a lesser extent, whole blood selenium concentrations, are the most commonly used biomarkers of selenium intake in epidemiological studies and reflect short/medium term exposure.<sup>7</sup>

Some equations have been published to estimate selenium intake from whole blood/serum/plasma selenium concentrations. These equations have been developed using data collected in specific populations. Some approximate conversion factors have also been proposed based on observational evidence (Haldimann et al., 1996).

Other markers that have been used include urinary selenium (short term exposure), nail and hair selenium concentrations (medium/long term exposure<sup>8</sup>).

Glutathione peroxidases are selenoproteins which are part of the human antioxidant network. Measures of glutathione peroxidase activity in plasma (glutathione peroxidase 3) and other blood compartments (glutathione peroxidase 1 activity in platelets and RBCs; whole blood glutathione peroxidase activity) have been commonly used as biomarkers of selenium status (EFSA NDA Panel, 2014). Selenoprotein P has a central role in selenium storage and transport and has also been used as a biomarker of selenium status (EFSA NDA Panel, 2014). The utility of these markers as biomarkers of intake is limited to the lower range of selenium intake as they reach a plateau as selenium intake increases (glutathione peroxidases were found to reach maximum activity at an intake of 40–60 µg/day (Yang et al., 1987; Duffield et al., 1999; Xia et al., 2005; Xia et al., 2010), while plasma selenoprotein P was found to reach such a plateau with selenium intakes of 60–70 µg/day (Duffield et al., 1999; Persson-Moschos et al., 2000; Xia et al., 2010); in addition, these proteins are upregulated by oxidative stress, and therefore their levels and activity may increase as a response to free radicals even in the absence of any change in selenium supply.

#### 3.3.2. Dose–response relationship between selenium intake and plasma/serum selenium concentration

A dose–response meta-analysis was conducted by EFSA to characterise the relationship between mean selenium intake and mean selenium plasma concentrations. The method and results are summarised below. More details are given in the technical report in Annex B.

Data points from studies in which the standard error (SE) of the mean values was not available or could not be calculated were excluded from the analysis. For each study only results from one analysis among alternative ones were chosen (e.g. overall vs. sex-specific estimates). After sensitivity and subgroup analyses were conducted, 63 pairs of mean values and related standard errors (plasma concentrations and intakes) from 39 studies were included in the final set for the dose–response analysis. The data points corresponding to the intervention phase of trials (25 data points) were excluded as, in a sensitivity analysis, the slope obtained using datapoints from only this subgroup was much different from the slope obtained from analysis of datapoints originating from observational settings (i.e. observational studies, baseline characteristics of participants in intervention studies), possibly due to the manipulation of the diet for relatively short periods. Therefore, intake estimates corresponded to intakes from mixed diets containing different selenium compounds.

The shape of the relationship was explored by applying linear splines; these were considered a convenient way of capturing the non-linearities in the relationship while keeping the conversion process simple. Different numbers and types of knots were tested, including one at 70 µg/day which is the AI for selenium established by the NDA Panel in 2014 (EFSA NDA Panel, 2014). This knot was

<sup>7</sup> Short term: hours/days; medium term: weeks.

<sup>8</sup> Medium term: weeks; long term: months/years.

finally chosen as it corresponded to the best fitting model. Accordingly, the model estimated two different slopes depending on whether the intake values were below or above the cut-off of 70  $\mu\text{g}/\text{day}$  and related constant terms.

The estimated coefficients were 1.25 (95% confidence interval (CI) 0.88, 1.61) below 70  $\mu\text{g}/\text{day}$  and 0.43 (95% CI: 0.29, 0.58) above 70  $\mu\text{g}/\text{day}$ , with a constant term for the first spline of 23.10 (95% CI: 1.92, 44.28) and a constant term for the second spline of 79.90 (95% CI 58.72, 101.08) – not shown (Figure 4); at 70  $\mu\text{g}/\text{day}$  of mean selenium intake the predicted mean plasma concentrations were 99 (95% CI: 93, 105)  $\mu\text{g}/\text{L}$  in the linear meta-regression model (not shown) and 111 (95% CI 102, 119)  $\mu\text{g}/\text{L}$  in the non-linear model (see Figure 4).

The outcome of the stratified and sensitivity analyses conducted on this model are presented in Annex B.

Se: selenium.

**Figure 4:** Dose–response meta-analysis on the relationship between mean selenium intakes and mean selenium plasma concentrations. At 70  $\mu\text{g}/\text{day}$  one knot was identified from the best fitting linear splines model and coefficients estimated below and above such a cut-off ( $\beta_1 = 1.25$ ,  $\beta_2 = 0.43$ ,  $\alpha = 23.10$ )

### 3.4. Intake assessment

#### 3.4.1. Sources of dietary selenium

Dietary selenium from plant and animal sources occurs mainly as organic compounds, primarily SeMet and SeCys (Rayman et al., 2008a; Cubadda et al., 2010; Fairweather-Tait et al., 2011; Rayman, 2012; Mehdi et al., 2013). Almost 90% of selenium in (non-selenium-enriched) plants is present as SeMet (Burk and Hill, 2015). In food of animal origin, SeMet is also present as a major species alongside SeCys specifically incorporated into selenoproteins (Bierla et al., 2008a,b; Lipiec et al., 2010). In fish, SeMet or selenoneine are the major selenium forms depending on the fish species (Yamashita and Yamashita, 2010; Sele et al., 2018).

The richest food source of selenium are Brazil nuts (*Bertholletia excelsa*). Mean concentrations between 5 and 72  $\mu\text{g}/\text{g}$  dry weight (up to 400  $\mu\text{g}/\text{nut}$ ) have been reported in samples collected in Brazil and the Amazon Basin, indicating large variability depending on their region of production (Pacheco and Scussel, 2007; Cardoso et al., 2017). There may be high seed-to-seed variation in selenium content within commercially available batches (Lima et al., 2019).

Other rich foods of selenium include offals (e.g. mean content in kidney (pig, lamb, beef: 1–3  $\mu\text{g}/\text{g}$ )) and fish and crustaceans (e.g. mean content in tuna: 1–3  $\mu\text{g}/\text{g}$ ; shrimps, crabs, prawns: 1–2  $\mu\text{g}/\text{g}$ ) (Anses, 2020; Public Health England, 2021; Finnish Institute for Health and Welfare, 2022).

In EFSA's intake assessment of selenium in European populations, the main food groups contributing to selenium intake were found to be milk and dairy products, meat and meat products,

grains and grain-based products and fish and fish products (EFSA NDA Panel, 2014) (see also Section 3.4.2).

There is a large variability in the selenium concentration of foods, which depends, to a large extent, on where crops and fodder are grown (Johnson et al., 2010; Mehdi et al., 2013). The amount of selenium available in soil is a major determinant of the amount of selenium in the plant foods. Seleniferous soils are present in parts of the United States, Canada, South America, India, China and Russia, while New Zealand, some parts of China, Nordic European countries and parts of Eastern Europe are characterised by selenium content in soils which are lower than the average content worldwide (Combs, 2001; Oldfield, 2002). Other factors affect the uptake of selenium into plants, such as soil pH, rainfall or microbial activity (Mora et al., 2015).

Selenium in water is mainly present as inorganic compounds, predominantly as selenate (WHO, 2011; LeBlanc et al., 2018). As per Directive (EU) 2020/2184<sup>9</sup> the parametric value for the selenium content of drinking water is 20 µg/L in the EU, which can be increased to 30 µg/L in regions where geological conditions could lead to high levels of selenium in groundwater.

#### *Selenium-enriched foods*

Food items with an artificially increased content of selenium can be produced by means of selenium-enriched fertilisers or growth medium. They are hereinafter referred to as selenium-enriched foods (sometimes called selenised or biofortified foods in the literature). Examples include selenised wheat, garlic, onion, broccoli, potatoes and selenised yeast (Demirci et al., 1999; Heard et al., 2004; Fisinin et al., 2008; Fairweather-Tait et al., 2011).

Soil enrichment is usually performed with inorganic selenium salts (selenate, rarely selenite, e.g. as sodium salt). In most plants, inorganic selenium is taken up and biotransformed into SeMet. For example in cereal grains grown in areas with selenium-rich soil, the major selenium compound is protein-bound SeMet. Inorganic selenium and water soluble low molecular weight seleno-compounds, including selenosugars, are also present and are non-protein bound (Aureli et al., 2012). In plants of the *Brassica* genus (e.g. broccoli) and the *Allium* genus (e.g. onion and garlic) enrichment with inorganic selenium results in the biosynthesis of notable amounts of the non-protein selenoamino acids MeSeCys and  $\gamma$ -Glu-MeSeCys (Rayman et al., 2008a).

Se-yeast is the most widespread selenium-enriched source and contains predominantly SeMet, with a large variety of other organic species present as minor compounds (Fairweather-Tait et al., 2011; Bierla et al., 2012; Bierla et al., 2018).

#### *Fortified foods*

The selenium content of foods can be increased by its addition to foods during processing (hereinafter referred to as fortified foods). In the EU, sodium selenate, sodium hydrogen selenite, sodium selenite, and Se-yeast are authorised for addition to foods<sup>10</sup> and foods for specific groups.<sup>11</sup>

The Mintel GNPD database<sup>12</sup> was used to identify foods and beverages to which selenium has been voluntarily or mandatorily added in the EU market in the last 5 years (from January 2016 to December 2021). A total of 1,847 packaged food products available in 22 EU Member States (MSs) and Norway were identified as containing added selenium in the ingredient list. The majority of the products belong to the Mintel categories 'baby foods'<sup>13</sup> (41%) and 'nutritional drinks & others' (34%). Most products were found in Germany, Italy, France and Spain. Data on selenium content per serving based on labelled information were available for 19% of the products. Among those, this information was available for 2% of 'baby foods' only (n = 18): range 1.5–11 µg selenium per serving (median = 5.7 µg selenium); and 29% of 'nutritional drinks & others' (n = 179): range 6.4–165 µg

<sup>9</sup> Directive (EU) 2020/2184 of the European Parliament and of the Council of 16 December 2020 on the quality of water intended for human consumption (recast). OJ L 435, 23.12.2020, pp. 1–62.

<sup>10</sup> Regulation (EC) No 1925/2006 of the European Parliament and of the Council of 20 December 2006 on the addition of vitamins and minerals and of certain other substances to foods. OJ L 404, 30.12.2006, pp. 26–38.

<sup>11</sup> Regulation (EU) No 609/2013 of the European Parliament and of the Council of 12 June 2013 on food intended for infants and young children, food for special medical purposes, and total diet replacement for weight control and repealing Council Directive 92/52/EEC, Commission Directives 96/8/EC, 1999/21/EC, 2006/125/EC and 2006/141/EC, Directive 2009/39/EC of the European Parliament and of the Council and Commission Regulations (EC) No 41/2009 and (EC) No 953/2009. OJ L 181, 29.6.2013, pp. 35–56.

<sup>12</sup> <http://www.mintel.com/globalnew-products-database>

<sup>13</sup> 'Baby foods' as categorised by Mintel; the definition applied differs from the EU regulatory category 'baby food' as specified in Regulation 609/2013 of the European Parliament and of the Council on food intended for infants and young children, food for special medical purposes, and total diet replacement for weight control. OJ L 181, 29.6.2013, p. 35.

selenium per serving (median = 18 µg selenium), with the highest contents per serving reported in some weight management products such as meal replacement shakes.

### Food supplements

In the EU, authorised forms of selenium for use in food supplements are sodium selenate, sodium hydrogen selenite, sodium selenite, Se-yeast, L-SeMet and selenious acid.<sup>14</sup>

The Mintel GNPD database was used to identify selenium containing food supplements present in the EU market in the last 5 years (from January 2016 to December 2021). The Mintel category 'vitamins and dietary supplements', including supplements formulated for special nutrition needs such as 'maternal & infants nutrition' and 'performance nutrition', was searched. It yielded a total of 1,238 products available in 24 EU MSs and Norway. Most of the products were found in Germany, France and the Netherlands. The labelled recommended daily dose ranged from 2.5 up to 220 µg of selenium, with an average of 49 µg per daily dose (median 50 µg per daily dose) (Figure 5). A proportion of 15% of the food supplements contain  $\geq 70$  µg per daily dose, which is the AI for selenium in adults, and 4% contain  $> 100$  µg per daily dose. Among selenium containing products, only 2.6% were single-nutrient supplements.

Source: Mintel GNPD database. Search for selenium-containing supplements available in the EU market in the last 5 years (from January 2016 to December 2021). A total of 1,238 products available in 24 EU Member States and Norway were identified.

**Figure 5:** Distribution of selenium-containing supplements available in EU Member States and Norway according to the recommended daily dose displayed on labels

### 3.4.2. EFSA's intake assessment

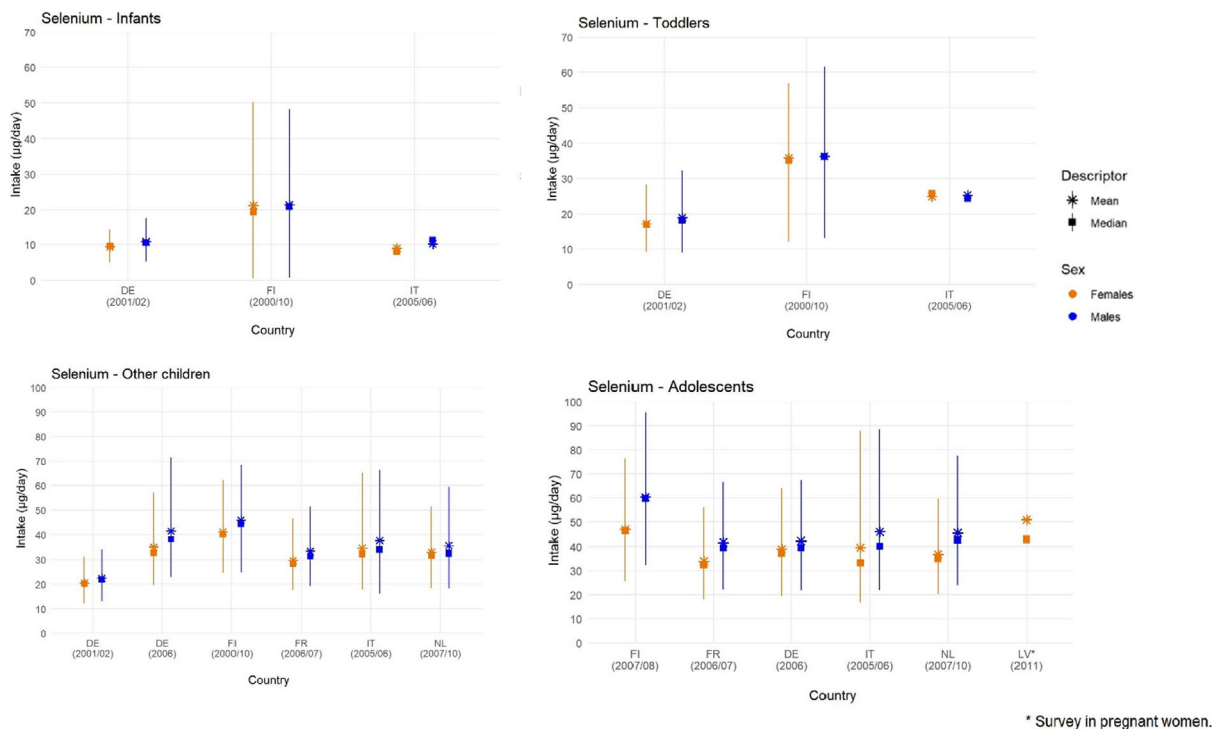

Selenium intakes from food sources (excluding food supplements) in European populations were calculated in the context of the Scientific Opinion of DRVs for selenium, based on the data from the EFSA Comprehensive Database and the EFSA FCDB (EFSA NDA Panel, 2014). Food consumption surveys of Finland, France, Germany, Ireland, Italy, Latvia, the Netherlands and Sweden were used for the assessment. The period of data collections covered by the surveys ranged between 2000 and 2012. Further information on the characteristics and methods used for the data collection in the respective surveys are provided in Annex C.

<sup>14</sup> Directive 2002/46/EC of the European Parliament and of the Council of 10 June 2002 on the approximation of the laws of the Member States relating to food supplements. OJ L 183, 12.7.2002, pp. 51–57.

Food composition data from Finland, Germany, Italy, the Netherlands and the UK were used to calculate selenium intake in these countries. For nutrient intake estimates of Ireland and Latvia, food composition data from the UK and Germany, respectively, were used, because no specific composition data from these countries were available. The proportion of borrowed selenium values in the five composition databases varied as follows: Germany 100%, Italy 91%, the UK 68%, Finland 58% and the Netherlands 50%.

The intake assessment of 2014 did not distinguish between selenium 'naturally present' or 'added' to foods by manufacturers. As data on the consumption of foods fortified with selenium available in the Comprehensive Database<sup>15</sup> and on the concentration of selenium in fortified foods available in EFSA FCDB database are scarce, EFSA's intake estimates can be considered to reflect selenium intake from natural sources.

The estimated distributions of intake are presented below by age group, sex and country of origin (Figures 6 and 7). A summary overview, providing the ranges of means and 95th percentiles (P95) across EU surveys is given in Table 3.

Lines represent the range between the 5th and 95th percentiles. Estimated intakes from 5th and 95th percentiles are not presented when sample size is below 60 participants.

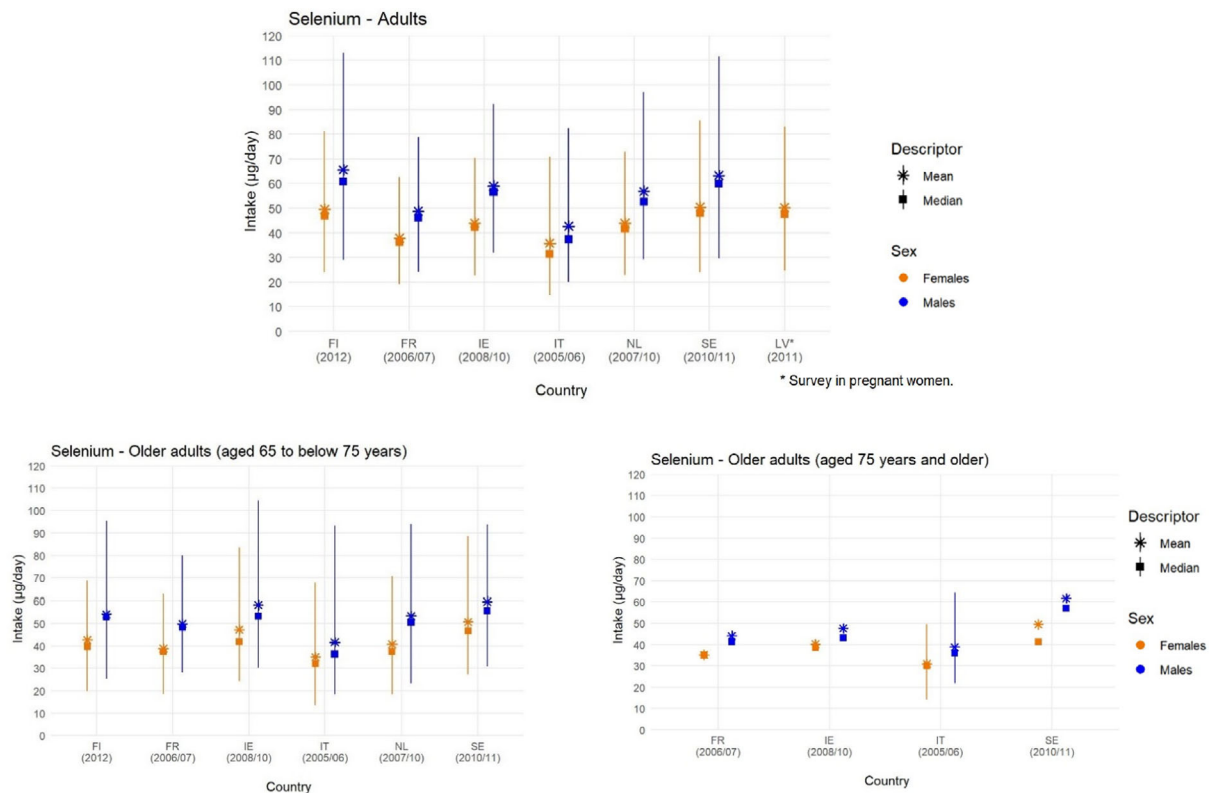

DE: Germany; FI: Finland; FR: France; IT: Italy; LV: Latvia; NL: Netherlands.

Source: (EFSA NDA Panel, 2014), except for infants.

**Figure 6:** Mean, median, 5th and 95th percentiles of selenium intakes in infants (< 1 year old), toddlers (≥ 1 year to < 3 years old), other children (≥ 3 years to < 10 years old) and adolescents (≥ 10 years to < 18 years old), by sex and country

<sup>15</sup> Indicatively, 2.2% of the overall eating occasions reported a fortification descriptor (e.g. 'F09.Fortification agent') in the latest version of the Comprehensive Database (updated in July 2021), of which 0.01% report a selenium-related fortification descriptor, for foods such as milk, foods for sports people, and functional drinks. These figures are likely to underestimate the actual consumption of fortified foods, as some surveys did not address the consumption fortified foods or because the survey participants did not know if the food consumed was fortified.

Lines represent the range between the 5th and 95th percentiles. Estimated intakes from 5th and 95th percentiles are not presented when sample size is below 60 participants.

Source: (EFSA NDA Panel, 2014), except for infants.

Across population groups, the main food groups contributing to selenium intake were milk and dairy products, meat and meat products, grains and grain-based products and fish and fish products, with minor differences between sexes (EFSA NDA Panel, 2014) (Annex C).

When available, EFSA selenium intake estimates were compared with values from the same national surveys published in the literature (EFSA NDA Panel, 2014). EFSA average selenium intake estimates were similar to the published results from the Dutch national food consumption survey (van Rossum et al., 2011) ( $\pm 5\%$  difference), while EFSA values were up to 25% higher than the published results from the Swedish Riksmaten survey (Amcoff et al., 2012) and up to 20% lower than the published values from the INCA 2 survey in France (AFSSA, 2009), the FINDIET 2012 survey (Helldan et al., 2013) and NWSSP study in adolescents (Hoppu et al., 2010) in Finland. As previously discussed (EFSA NDA Panel, 2014), several factors may contribute to these differences, including discrepancies in mapping food consumption data according to food classifications and in nutrient content estimates available from the food composition tables, as well as different intake modelling methods. The lower estimates for Finland may be due to borrowed values lower than the selenium contents of Finnish foods that were used in the intake assessments at the national level owing to the national selenium enrichment programme implemented in Finland. As the intake calculations rely heavily on estimates of both food composition and food consumption, it is not possible to conclude which of these intake estimates would be closer to the actual selenium intake.

### 3.4.3. Complementary information from national reports

#### 3.4.3.1. Intake data of selenium from foods and fortified foods

Nationally representative consumption surveys and TDSs published after the surveys included in EFSA's intake assessment were collected. Survey characteristics, mean and P95 intake estimates are presented in Annex D. Key information is summarised below.

##### *Intake estimates from national consumption surveys*

Reports from national consumption surveys providing estimates of selenium intake from foods and fortified foods (excluding food supplements) are available for 10 countries: Denmark, Estonia, Finland, France, Greece, Lithuania, Norway, Spain, Sweden, the Netherlands (Pedersen et al., 2015; Hansen et al., 2016; AECOSAN, 2017; Anses, 2017; Hansen et al., 2017; Lemming et al., 2018; Valsta et al., 2018; Mitsopoulou et al., 2020; van Rossum et al., 2020; Bulotaitė et al., 2021; Kukk et al., 2021; Mitsopoulou et al., 2021). At the P95, the estimated intakes are up to 80.9  $\mu\text{g}/\text{day}$  in male infants (aged  $\geq 3$  to  $< 12$  months; 3 countries), up to 108.6  $\mu\text{g}/\text{day}$  in female toddlers (1 to  $< 3$  years; 5 countries), up to 153.3  $\mu\text{g}/\text{day}$  in male other children (3 to  $< 10$  years; 5 countries), up to 183.7  $\mu\text{g}/\text{day}$  in female adolescents (10 to  $< 18$  years; 6 countries) and up to 227.7  $\mu\text{g}/\text{day}$  in male adults ( $\geq 18$  years; 6 countries). The highest P95 values in all age groups are reported in the Third Individual and National Survey on Food Consumption in France (INCA 3). However, the report of the INCA3 survey (Anses, 2017) stressed large uncertainties related to the food composition tables used for the selenium intake assessment.

##### *Intake estimates from total diet studies*

TDS data from Ireland and the Czech Republic were collected (FSA, 2016; Státní zdravotní ústav, 2021). Unpublished data from the Italian TDS were also obtained (F. Cubadda, personal communication, November 2021). At the P95, selenium intakes from food consumption only in males (i.e. without food supplements and fortified foods) are up to 64  $\mu\text{g}/\text{day}$  in toddlers (1 to  $< 3$  years; one country), up to 116  $\mu\text{g}/\text{day}$  in other children (3 to  $< 10$  years; two countries), up to 144  $\mu\text{g}/\text{day}$  in adolescents (10 to  $< 18$  years; one country) and up to 142  $\mu\text{g}/\text{day}$  in adults ( $\geq 18$  years; two countries). Consistent with other results, intakes are slightly lower in females than in males. For all age groups, the highest P95 values are found in the Italian TDS.

##### *Contribution of fortified and enriched foods*

The majority of the survey reports did not distinguish between selenium intake from natural sources and intake resulting from selenium addition to foods (fortified foods). One report on two national surveys in Estonia, involving children and adults, respectively, estimated selenium intake from fortified foods only (Kukk et al., 2021). Only 1.5% of the total eating occasions included information on fortification. Boys aged 1–9 years was the only population group for which a contribution of fortified foods (0.1  $\mu\text{g}$  selenium per day) could be detected. Challenges related to data gaps in food

composition databases particularly for foods fortified with selenium were noted. In the report from the DNFCs 2007–2010 (van Rossum et al., 2011), the estimated contribution of foods fortified with selenium to total intake of selenium was negligible (< 1%).

Regarding selenium-enriched foods (Section 3.4.1), the addition of sodium selenate to the main fertilisers became mandatory in 1984 in Finland, as a way to enrich the selenium content of local food products, because of the low selenium content of Finnish soils. Following this public health measure, the mean selenium intake in the Finnish population increased from 38 µg/day before enrichment policy to 80 µg/day in 2001 (Rayman et al., 2008a). In other EU MSs, some selenium-enriched foods may be present on the market (e.g. selenised potatoes). However, data on the contribution of these foods to selenium intake are lacking.

### 3.4.3.2. Intake data of selenium from food supplements

Information on selenium intake from food supplements are available for six countries: Norway (Totland et al., 2012; Hansen et al., 2016; Hansen et al., 2017; Astrup et al., 2020; Paulsen et al., 2020), Sweden (Lemming et al., 2018), Finland (Valsta et al., 2018), the Netherlands (van Rossum et al., 2020), Estonia (Kukk et al., 2021) and Poland (Stos et al., 2021). Study characteristics and intake estimates are presented in Annex D.

#### *Intake of selenium from foods supplements in the whole population*

Six national dietary surveys from Estonia, the Netherlands and Norway provide information on the contribution of selenium-containing food supplements to total selenium intake in the whole study population, in different age groups (Table 4). The contribution is estimated to be ≤ 8% for toddlers, children and adolescents in the three countries. Among adults, the contribution ranges between 2% and 4% (adult women in Estonia) and 19% (adult women aged 51–79 years in the Netherlands).

d: days; DNFCs: Dutch National Food Consumption Survey; f: females; FFQ: Food Frequency Questionnaire; FPQ: Food Propensity Questionnaire; m: males; N: number; y: years.

(1): Contribution expressed as a range based on two scenarios: (a) lower value: only accounting for supplements for which the brand was reported (hence, food labelling checked) and, (b) upper value: accounting for all food supplements; when the supplement brand was not reported, the nutrient concentration was estimated based on the label database created in the first exposure scenario.

(2): For children up to 10 years of age.

(3): Women at childbearing age.

#### Intake of selenium from food supplements among users

In the latest national Finnish survey (FINDIET 2017), the percentage of selenium supplement users was 15% among adult males and 22% among adult females of the total survey population (based on 2 × 24-h recalls). Among selenium supplement users, the contribution of supplements to selenium intake was 30% and 34% for males and females, respectively (Valsta et al., 2018) (Table 5).

Among food supplement users of the Riksmaten Adolescents 2016–2017 survey in Sweden (individuals aged 11 to 21 years; n = 350), the contribution of selenium supplements to total mean selenium intake ranged from 18% to 29% across age groups (based on 3 days of web-based dietary record) (Lemming et al., 2018) (Table 5).

Among adult male and female food supplement users of the national survey in Poland (n = 178), around 30% reported to have consumed selenium-containing supplements during the preceding year (based on a food propensity questionnaire) (Stos et al., 2021). Mean ( $\pm$  standard deviation (SD)) selenium intake from food supplements only was  $38.5 \pm 21.5$   $\mu\text{g/day}$  (median: 30  $\mu\text{g/day}$ ) for men and women combined.

#### 3.4.4. Overall conclusions on intake data

The Panel notes the uncertainties associated with selenium intake estimates due to the large variability in the selenium content of foods, which mainly depends on the geochemistry and selenium content of the soil. The origin of the foods can have a substantial impact on the selenium content of some commodities. This may result in inaccuracies in food composition tables if the analytical data that they include do not adequately capture the variability in the selenium content of foods or in the case of borrowed values. Regarding EFSA intake estimates, the Panel notes the large amounts of borrowed values and that there are uncertainties on how accurately the information contained in the nutrient composition database reflects the variability in selenium concentrations in foods. Therefore, the results should be considered indicative and be interpreted with caution (EFSA NDA Panel, 2014). TDSs can address some limitations of the intake assessment based on food consumption tables as they use representative sampling methods and chemical analysis of foods 'as consumed'.

The Panel notes that, at P95, estimated intake of selenium from food consumption only (i.e. without food supplements and fortified foods) are up to 48.3  $\mu\text{g}/\text{day}$  in infants (4 to < 12 months), up to 61.6  $\mu\text{g}/\text{day}$  in toddlers (1 to < 3 years), up to 71.5  $\mu\text{g}/\text{day}$  in other children (3 to < 10 years), up to 95.5  $\mu\text{g}/\text{day}$  in adolescents (10 to < 18 years) and up to 113.0  $\mu\text{g}/\text{day}$  in adults ( $\geq$  18 years), across surveys included in EFSA's intake assessment (EFSA NDA Panel, 2014). Intakes are slightly lower in females, mainly due to smaller quantities of food consumed per day. National reports of more recent data indicate that selenium intakes of high (P95) and average consumers in some EU MSs may exceed EFSA estimates, but comparisons are difficult owing to the different methodologies and food composition tables used.

The Panel notes that fortified foods were found to contribute little to total selenium intake in the two countries for which information is available. The Panel notes the inherent uncertainties related to self-reported intakes of fortified foods in food consumption surveys, as well as uncertainties in the composition data, which can hamper the accurate evaluation of the actual contribution of these foods. The Panel notes that the contribution of fortified foods to total selenium intake could be significant among regular users of these foods but data are too limited for a reliable intake assessment of this group.

In Finland, selenium-enriched foods contribute to total selenium intake to a significant extent. This situation is unique in the EU, being the result of a national policy to increase selenium content of local foods and the selenium status of the population through the use of selenium-supplemented fertilisers. Data on the contribution of selenium-enriched foods to selenium intake in other countries are lacking.

Data on the contribution of food supplements to total selenium intakes are available for a limited number of European countries. The Panel notes that food supplements were found to contribute up to 19% of total selenium intake in the Netherlands. In Finland, a significant proportion of the adult population was found to use selenium-containing supplements (15% of males and 22% of females), with supplements representing about a third of total selenium intake in the user group. In a cohort of supplements users in Sweden, selenium supplements accounted for about 20%–30% of total selenium intake among users. The Panel also notes that data from the Mintel database indicate that half of the products on the EU market provide  $\geq$  50  $\mu\text{g}$  selenium per daily dose and 15% provide daily doses  $\geq$  70  $\mu\text{g}$  (maximum 220  $\mu\text{g}$  per daily dose). The Panel notes that in regular consumers of selenium supplements, the contribution of supplementation to total selenium intake can be substantial.

The Panel also notes that Brazil nuts can have a particularly high selenium content compared to other food sources and may contribute remarkably high amounts of selenium (e.g. a serving of 5 or 6 Brazil nuts could contribute approximately between 100 and 2,000  $\mu\text{g}$  selenium, considering the range of concentration reported in the literature (range of means: 5–72  $\mu\text{g}/\text{g}$  dry weight)).

### 3.5. Hazard identification

#### 3.5.1. Mechanisms of toxicity

In the opinion of 2000, the SCF concluded that 'the molecular mechanisms of selenium toxicity remain unclear' (SCF, 2000a). The mechanisms reviewed included redox cycling of auto-oxidisable selenium metabolites, glutathione depletion, protein synthesis inhibition, depletion of S-adenosyl-methionine (cofactor for selenide methylation), general replacement of sulfur and reactions with critical sulfhydryl groups of proteins and cofactors. However, it was noted that no unifying hypothesis is possible given that several mechanisms may operate and vary among different selenium compounds.

The most often invoked mode of action of excess selenium involves oxidative stress generation and the consequent perturbations of cellular and mitochondrial function. In summary, hydrogen selenide is the central selenium metabolite for selenoprotein synthesis. As the body burden of the element increases, once selenoprotein biosynthesis is saturated, oxidation of excess hydrogen selenide and free selenols (e.g. monomethylselenol) is suggested to lead to the production of superoxide and other reactive oxygen species (ROS) and cellular and subcellular damage, including that of lipids and deoxyribonucleic acid (DNA) (Rayman et al., 2008a) (Figure 3). Generation of superoxide in the presence of thiols such as glutathione would result in redox cycling, cell-cycle arrest and cell death due to apoptosis, necrosis, necroptosis or ferroptosis (Wallenberg et al., 2014; Misra et al., 2015). Another suggested mode of action is inhibition of methylation, the major detoxification pathway for selenium, allowing the accumulation of hepatotoxic hydrogen selenide and other selenides. For instance, overexposure to SeCys has been shown to cause hepatic toxicity in mice by depressing selenium methylation through the inactivation of methionine adenosyltransferase, the enzyme responsible for S-adenosyl methionine synthesis (Rayman et al., 2008a).

Recently, high selenium exposure (as selenite) has been shown to lead to endothelial dysfunction through activation of endoplasmic reticulum stress and increased ROS production *in vitro* (Zachariah et al., 2021). The SCF (2000a) further observed that growth reduction in experimental animals may be caused by selective selenium accumulation and toxicity to growth hormone producing cells in the anterior pituitary gland. It is now appreciated that selenium is necessary for the function of insulin-like growth factor 1 but, as yet, any impact of excess selenium intake on insulin-like growth factor 1 activity, including that on growth, cellular integrity and hair growth has not been reported (Hosnedlova et al., 2017).

Finally, the replacement of sulfur with selenium in proteins, with disruption of structural and functional components, has also been proposed to contribute to selenium toxic effects (Unrine et al., 2007; Lv et al., 2021). This could be the underlying mechanism for the structural damage and loss of hair and nails which are typical of selenosis, through alterations in keratin structure (Webb and Kerns, 2009; Fairweather-Tait et al., 2011; Yu et al., 2018).

The Panel notes that that several modes of action may operate in parallel, and the respective importance might depend on the dose and the chemical form of selenium ingested.

#### 3.5.2. Clinical effects of selenosis and related potential biomarkers of effects

As indicated before, the term 'selenosis' in the formulation of sQ1 broadly refers to selenium toxicity and associated features (Section 2.1). Accordingly, the term selenosis is to be understood in a wide sense in this opinion. In the few cases where the term is employed in accordance with its clinical definition in the articles cited, this is specified in the text.

This section follows the approach for hazard identification that is outlined for sQ1 (Section 2.2.2.3). Accordingly, Section 3.5.2.1 describes the clinical effects, i.e. signs and symptoms, associated with selenosis. Based on the systematic reviews conducted to address sQ1, Section 3.5.2.2 reports data on clinically diagnosed cases of selenosis in humans, as well as data on individual signs and symptoms that are typical of excess selenium intake. Further, using a biologically based model, Section 3.5.2.3 explores potentially relevant endpoints among the homeostatic and adaptive responses to excess selenium intake and increasing body burden. Relevant endpoints may be early biochemical changes or biological markers for which a mechanistic pathway can be discerned, and which can be characterised and validated as predictive of adverse effects ('biomarkers of effects') (EFSA NDA Panel, 2022).

##### 3.5.2.1. Clinical effects of selenosis

In animals, selenium poisoning has been described in livestock, particularly cattle and horses, living in seleniferous areas. Chronic selenosis, often termed Alkali disease, is mainly characterised by hoof

and hair changes and has been suggested to be a result of chronic ingestion of selenium compounds not soluble in water. Blind staggers disease was initially proposed to be a result of feeding on plants containing water soluble selenium compounds. Its symptoms are impaired vision and unsteady gait up to blindness and paralysis. As the symptoms could not be reproduced in experimental settings, its relationship with selenium has been questioned (O'Toole and Raisbeck, 1995; O'Toole et al., 1996).

Signs and symptoms of acute selenium poisoning in humans (sometimes referred to as 'acute selenosis') include hypotension and tachycardia, nausea, vomiting, diarrhoea, abdominal pain, pulmonary oedema and neurologic abnormalities such as tremor, muscle spasms, restlessness, confusion, delirium and coma (Nuttall, 2006; Fairweather-Tait et al., 2011).

The most common signs of chronic selenium poisoning in humans (sometimes referred to as 'chronic selenosis') are brittle thickened nails with white spots and longitudinal streaks as well as brittle hair and hair loss/alopecia. Other signs include discoloration and excessive decay of teeth, garlic odour on the breath, skin lesions and neurological abnormalities, such as fatigue, weakness, peripheral paraesthesia, hyperreflexia, pain in the extremities, unsteady gait, paralysis and decreased cognitive function (Nuttall, 2006; Rayman et al., 2008a; Fairweather-Tait et al., 2011; ATSDR, 2013).

### 3.5.2.2. Evidence from human studies relating selenium intake to clinical effects of selenosis

#### *Studies considered in the assessment by the SCF (2000a)*

The current UL has been derived from the cross-sectional study by Yang et al. (1989a) conducted in the Enshi County in China. A total of 349 individuals aged 1–71 years living in three distinct areas with 'low', 'medium' and 'high' selenium content in the soil were included. Among adults, the average daily selenium-intake estimated in the respective areas (mean  $\pm$  SE) was  $70.5 \pm 4.8 \mu\text{g}$ ,  $194.7 \pm 22.9 \mu\text{g}$  and  $1,438.2 \pm 76.3 \mu\text{g}$  for males, and  $62.0 \pm 3.6 \mu\text{g}$ ,  $198.1 \pm 23.81 \mu\text{g}$  and  $1,238.5 \pm 64.6 \mu\text{g}$  for females (average body weight: male 55 kg, female 53 kg).

A total of 60 cases of selenosis (aged 13–70 years) were identified upon physical examination. Morphological changes in fingernails, stratified by severity and persistence, were used as the main criterion for clinical diagnosis of selenosis. Hair loss or changes in hair structure were also considered when present in combination with changes in fingernails. No clinical signs of selenosis were observed among individuals with whole blood selenium concentration  $< 1,000 \mu\text{g/L}$ , corresponding to intakes of around  $850 \mu\text{g/day}$  selenium (calculated by the authors based on a regression equation presented in Yang et al., 1989b). In a follow-up study, among five cases with long-persisting clinical symptoms of selenosis (all adults aged  $> 30$  years), blood selenium concentrations ranged between  $1,054$  and  $1,854 \mu\text{g/L}$ ;  $1,054 \mu\text{g}$  corresponding to around  $910 \mu\text{g/day}$  selenium intake (calculated). Symptoms disappeared after a change in diet resulting in lower selenium intakes (Yang and Zhou, 1994).

In the same study, a prolonged prothrombin time (defined as  $> 14$  s) was observed in 45% of individuals with whole blood selenium concentrations  $> 1,000 \mu\text{g/L}$ , compared to 2.7% of individuals with whole blood selenium concentrations below this value (analysed among a subset of 84 individuals). Although liver function was not thoroughly investigated, alterations associated with liver fibrosis (assessed by supersonic shear imaging of the liver tissue) were not found in a subgroup of 20 male adults native of the high selenium area, 70% of whom had suffered from heavy hair and nail loss.

Among a subset of 127 individuals, a reduction of the ratio between plasma selenium to RBC selenium was observed at whole blood selenium concentrations  $> 100 \mu\text{g/L}$  and was more pronounced at concentrations  $> 900 \mu\text{g/L}$  (around  $750 \mu\text{g/day}$  selenium intake). The latter was taken by the authors as indicative of an increased body burden (i.e. that it may reflect the nonspecific integration of selenium in proteins, e.g. haemoglobin, after the requirement for the synthesis of selenoproteins has been met). In a subgroup of adult males, a higher white blood cell (WBC) count was observed in those living in the 'high selenium' area (mean  $\pm$  SE  $10,004 \pm 403 \text{ count/mm}^3$ ) compared with those in the 'low selenium' area ( $8,216 \pm 469 \text{ count/mm}^3$ ). The authors also noted that blood concentrations of glutathione were lower in subjects with whole blood selenium concentration  $> 1,000 \mu\text{g/L}$  than those with concentrations  $< 1,000 \mu\text{g/L}$ .

Finally, in school children 7–14 years of age, the prevalence of mottled enamel teeth was 0%, 49% and 95% in groups with 'low' (mean  $130 \mu\text{g/L}$ ), 'medium' ( $370 \mu\text{g/L}$ ) and 'high' ( $1,570 \mu\text{g/L}$ ) whole blood selenium concentrations, respectively.

Based on Yang et al. (1989a), the daily selenium intake of  $850 \mu\text{g}$  has been taken by the SCF (2000a) as a NOAEL in relation to signs and symptoms of selenosis, to which an UF of 3 was

applied to derive the UL of 300 µg/day for adults. The data on mottled teeth did not allow a NOAEL to be derived and the UL from children was extrapolated from adults on a body weight basis.

Additional studies, by Longnecker et al. (1991), Clark et al. (1996) and Brätter and Negretti de Brätter (1996), were considered by the SCF to support the UL of 300 µg/day for adults.

In the study by Longnecker et al. (1991) conducted in seleniferous areas of western South Dakota and eastern Wyoming, 142 adult subjects were recruited from households selected at random and from ranches where unusually high selenium intakes were suspected. About half of the subjects had selenium intakes > 200 µg/day (range 68–724 µg/day), assessed using the duplicate food portion technique. Median serum selenium was of 184 µg/L (range 123–363 µg/L). A physician performed a physical examination of the 78 subjects enrolled in the first year of the study, including 29 ranchers suspected of having high selenium intakes because of previous or current selenosis in livestock. The examination covered a standardised list of signs and symptoms including muscle weakness, asymmetrical reflexes, hyperreflexia, abnormal sensory examination, dermatitis, and nail loss or markings. In all 142 subjects, a self-administered questionnaire inquired about the frequency of symptoms such as weakness, paraesthesia, dyspepsia, loss of hair or nails, and dermatitis, and nail photographs were taken. No symptoms of selenosis were observed in this population, even at the highest estimated selenium intake of around 720 µg/day. There was a positive correlation between selenium intake and alanine aminotransferase (ALT) activity, but this was within the reference and not considered to be of biological relevance.

In the Nutritional Prevention of Cancer (NPC) trial, in which 200 µg/day Se-yeast was given to patients with skin cancer (total dietary selenium intake 300 µg/day), Clark et al. (1996) reported that 'no dermatologic signs of selenium toxicity' were observed regarding the safety endpoints monitored in the study.<sup>16</sup>

In the cross-sectional study by Brätter and Negretti de Brätter (1996) in lactating women in three areas of Venezuela with average (range) dietary selenium intakes of 205 (90–350) µg/day, 274 (170–500) µg/day and 552 (250–980) µg/day (calculated based on selenium breast-milk concentrations), no changes in fingernails or hair loss were reported (method for outcome assessment not reported).

#### *Additional data identified*

To establish whether newly available data would require a revision of this NOAEL, the Panel investigated whether signs and symptoms of selenosis have been reported in the literature below a daily selenium intake of 850 µg (i.e. whole blood selenium < 1,000 µg/L). Given that an intake of 850 µg/day is the current NOAEL, studies reporting signs and symptoms of selenosis at selenium intakes above these values are not described hereunder. In addition, studies which reported such signs and symptoms at plasma/serum selenium concentrations above 850 µg/L were also excluded, under the conservative assumption that a daily intake of 850 µg is equivalent to a plasma or serum selenium concentration of 850 µg/L (the prediction equation described in Section 3.3.2 is not applicable at these levels). As a result, eight publications on case reports or case series of chronic selenium poisoning were not further assessed (No authors listed, 1984; Sutter et al., 2008; Dosary et al., 2009; MacFarquhar et al., 2010; Aldosary et al., 2012; Morris and Crane, 2013; Razmi et al., 2017; D'Oria et al., 2018). In addition, the study by García-Esquinas et al. (2021) was not considered because it only reported on 'weakness', without other signs and symptoms of selenium toxicity (Annex E).

When studies characterised selenium intake by measuring plasma/serum selenium concentration, an estimate of the corresponding selenium intake is provided, applying the prediction equation described in Section 3.3.2.

#### Intervention studies

Five RCTs in adults provided data on signs and symptoms of selenium toxicity collected as part of the monitoring of adverse events (Appendix D.1.1).

In the Selenium and Vitamin E Cancer Prevention Trial (SELECT) in the US (Lippman et al., 2009), 8,752 healthy men, ≥ 50 years of age, received 200 µg/day selenium from SeMet and 8,696 were given placebo for a median duration of 5.5 years. Mean baseline serum selenium concentrations were around 135 and 138 µg/L in the selenium and the placebo group, respectively (this corresponds to an estimated selenium intake of around 130 µg/day which is higher than what is typically observed in European populations) and reached 252 and 140 µg/L, respectively, after 4 years of follow-up. The primary endpoint of the study was the incidence of prostate cancer, while prespecified secondary

<sup>16</sup> Findings regarding the incidence of skin cancer in the NPC trial are assessed in Section 3.5.9.1.

endpoints included lung, colorectal, and other cancers as well as deaths, and cardiovascular events. Adverse events were reported by the participants every 6 months during a study site visit (or a substitute phone call). Staff specifically queried about the following events: alopecia, dermatitis, fatigue, halitosis, nail changes and nausea. The National Cancer Institute Common Toxicity Criteria (version 2) were used for the grading of alopecia, nail changes, fatigue and nausea,<sup>17</sup> while halitosis and dermatitis were graded according to the study protocol.<sup>18</sup> The side effects reported in the paper were the worst grade that study participants experienced over the course of the trial.

The risk of developing alopecia was significantly increased in the selenium group (RR 1.28; 99% CI 1.01, 1.62). There was a slight increase in risk of developing nail changes when compared with placebo (selenium group: RR 1.04; 99% CI 0.94, 1.16). The risks of developing dermatitis, halitosis, fatigue grades 1–2 and nausea grades 1–2 were also higher in the selenium group, i.e. dermatitis grades 1–2 (RR 1.17; 99% CI 1.00, 1.35), dermatitis grades 3–4 (RR 1.74; 99% CI 0.56, 5.44), halitosis (RR 1.17; 99% CI 0.99, 1.38), fatigue grades 1–2 (RR 1.09; 99% CI 0.95, 1.26) and nausea grades 1–2 (RR 1.19; 99% CI 0.94, 1.52). Loss to follow-up, defined as last contact data > 24 months before analysis, was < 5%. The Panel notes that this study shows an increased risk of developing alopecia at selenium intakes of around 330 µg/day compared with selenium intakes of 130 µg/day. Increased risks for other features associated with selenium toxicity were also observed.

Algotar et al. (2013b) reported the evaluation of adverse effects in the Negative Biopsy Trial (NBT) in the US, in which adult men, selected as being at increased risk of prostate cancer, were randomly assigned to receiving a placebo or doses of 200 µg/day selenium or 400 µg/day selenium as Se-yeast (sample size around 230 individuals per group at baseline). Mean baseline plasma selenium concentrations were 126 µg/L (this corresponds to an estimated selenium intake of around 110 µg/day). Collection of adverse event data was performed at each study visit (every 6 months). The median duration of follow-up was about 3 years in all groups. The occurrence of 'brittle nail and hair' was 11.2%, 10.3% and 8.6% in the respective groups. The authors clustered the outcomes 'garlic breath' and 'liver/kidney function test abnormality' and reported an occurrence of 6.0%, 5.6% and 4.7%, respectively, for this composite outcome. The study dropout was around 45%.

In the Danish PREvention of Cancer by Intervention with Selenium (DK PRECISE) study, healthy participants were randomised to receive 100, 200 and 300 µg/day selenium as Se-yeast intended for 5 years (sample size around 120 individuals per group). Median plasma baseline concentration was 85 ng/g (equivalent to around 87 µg/L corresponding to an estimated selenium intake of around 50 µg/day). The authors reported that 25 individuals stopped the study early mainly because of 'hair loss, skin reactions, and grooved nails' and that 'these were equally associated with selenium and placebo and were independent of selenium dose' (Winther et al., 2015). The study flow chart documents 3, 2, 1 and 2 'adverse events' and 3, 0, 2 and 2 'adverse effects' in the groups receiving the placebo, 100, 200 or 300 µg/day selenium, respectively, during the first 6 months of intervention; and 2, 11, 10 and 4 'adverse events' and 3, 5, 6 and 4 'adverse effects' from 6 months after the initiation of the trial until its conclusion. However, no definition of 'adverse events'/'adverse effects' and no description of the method used for their monitoring are provided in the article. The % drop-out during the trial was 28%, 27%, 27% and 24% in the respective groups.

For the Selenium and Celecoxib (Sel/Cel) trial in the US, in which participants with a history of colorectal adenoma received 200 µg/day selenium as Se-yeast or a placebo for a median duration of 3 years, Thompson et al. (2016) reported a hazard ratio (HR) of 0.86 (95% CI 0.53, 1.39) for developing 'brittle hair and/or nails' in the selenium group (30 events/908 participants) compared with the placebo group (35 events/912 participants). The method to monitor these events is not described in the article. Median baseline plasma selenium concentrations were around 135 µg/L (corresponding to an estimated selenium intake of around 126 µg/day).

<sup>17</sup> National Cancer Institute Common Toxicity Criteria (version 2): Alopecia: Grade 0: normal, Grade 1: mild hair loss; Grade 2: pronounced hair loss; Nail changes: Grade 0: normal, Grade 1: discoloration or ridging (koilonychia) or pitting, Grade 2: partial or complete loss of nail(s) or pain in nailbeds; Fatigue, Grade 0: none, Grade 1: increased fatigue over baseline, but not altering normal activities; Grade 2: moderate (e.g., decrease in performance status by 1 ECOG level or 20% Karnofsky or Lansky) or causing difficulty performing some activities; Nausea: Grade 0: none, Grade 1: able to eat, Grade 2: oral intake significantly decreased, Grade 3: no significant intake, requiring IV fluids.

<sup>18</sup> Criteria defined in the study protocol (provided by the authors): Halitosis (bad breath): Grade 1: mildly altered from baseline, Grade 2: moderately altered from baseline; Dermatitis: Grade 1: faint erythema or dry desquamation, Grade 2: moderate to brisk erythema or a patchy moist desquamation, mostly confined to skin folds and creases; moderate edema, Grade 3: moist desquamation other than skin folds and creases; may include bleeding induced by minor trauma or abrasion, Grade 4: skin necrosis or ulceration of full thickness dermis; may include spontaneous bleeding.

Finally, the intervention study by Fairris et al. (1989) involved psoriasis patients in the US, who consumed 600 µg/day selenium as Se-yeast supplement (n = 22), a combination of 600 µg/day selenium as Se-yeast and 600 IU of vitamin E (n = 23) or a placebo (n = 24) for 12 weeks. The patients were followed up at weeks 2, 4, 8 and 12 of supplementation and again 12 weeks after supplementation stopped. On each occasion, the following symptoms were sought by direct questioning: 'garlic breath', 'nausea', 'vomiting', 'loss of nails' and 'alopecia'. The authors report that no signs and symptoms of selenium toxicity occurred in the study, but results are not shown in the publication.

The Panel notes that one RCT shows an increased risk of alopecia and other features of selenium toxicity at a total dietary selenium intake of around 330 µg/day compared with an intake of around 130 µg/day. This finding was not corroborated in three other RCTs. However, they had a much smaller sample size and no or partial reporting on how the reported signs and symptoms were defined and monitored.

### Cross-sectional studies

In addition to the cross-sectional study by Yang et al. (1989a), three cross-sectional studies investigated signs and symptoms of selenium toxicity in populations living in seleniferous areas, in Brazil, India and the US. In addition, one cross-sectional study investigated signs and symptoms of selenium toxicity in schoolchildren enrolled in a public health programme in which Brazil nuts, which naturally have a high selenium content, were distributed to pre-school children.

Lemire et al. (2012) reported on a cross-sectional study in 407 individuals (aged 15–87 years) living in the Brazilian Amazonas who had a large variation in selenium intake, as reflected in plasma selenium concentrations that were between 50 and 950 µg/L (median 135 µg/L). Individuals were classified according to their plasma selenium levels, i.e. < 328 µg/L (n = 360), ≥ 328 to < 520 µg/L (n = 15) and ≥ 520 µg/L (n = 11). A trained nurse performed an examination of the clinical dermal signs of selenium toxicity (hair, body hair, fingernails, toenails and skin) and garlic odour breath. Individual signs on fingernails and toenails specific for selenosis (e.g. longitudinal or transversal streaks, darkening, discoloration, symmetric thickening and stratifying) were detected in up to 8 individuals (2.2%) of those with plasma selenium levels < 328 µg/L and in up to 2 individuals (7.7%) of those with levels ≥ 328 µg/L. In the groups with levels ≥ 328 µg/L, the effect was limited to darkening of toenails and to longitudinal streaks on fingernails, while other symptoms did not occur in this groups. Dry and brittle hair, sparse head hair and body hair occurred respectively in 2 (0.6%), 21 (6%) and 163 (45%) individuals with the lowest plasma selenium levels, and in 0, 1 (4%) and 13 (50%) individuals in the groups with higher selenium levels. The Panel notes that the higher intake groups were small and may have not allowed the detection of individuals with specific symptoms.

In the study by Chawla et al. (2020), 680 adult residents living in a seleniferous area in Punjab, India, were examined for signs of selenosis, including: 'pallor', 'hair abnormalities', 'nail abnormalities', 'garlic odour', 'oedema' and 'dermatitis'. For 238 individuals, serum selenium concentrations were available. Nail and hair abnormalities occurred in more than half of the population under investigation and at median serum concentrations of around 250 µg/L compared with around 155 µg/L in those without abnormalities, but there was a wide overlap in serum selenium concentration between individuals with and without abnormalities. There was an increased risk of hair and nail abnormalities as well as garlic odour, but not pallor and dermatitis, at serum selenium concentrations above the study population median of 171 µg/L (odds ratio (OR)) adjusted for age, sex and socio-economic status: nail abnormalities OR 2.1 (95% CI 1.2, 3.5); hair abnormalities OR 1.6 (0.9, 2.7); garlic odour OR 3.45 (0.59, 20.34); pallor OR 0.57 (0.13, 2.50); dermatitis OR 0.81 (0.21, 3.19).

A cross-sectional study in children living in the Brazilian Amazonas (Martens et al., 2015) included 41 children from a public preschool (age range around 2–6.5 years) who had received as part of a public health programme 15 to 30 g of Brazil nuts 3 days per week and a control group of 88 children who had not received Brazil nut-enriched meals. Children who had received Brazil nuts consumed on average 155 µg/day selenium, an intake that is above the UL of 60 and 90 µg/day for 1- to 3- and 4- to 6-year-old children, and those who had not consumed the nuts around 44 µg/day, based on the analysis of duplicate food portions. The paper reports that, upon clinical examination of the children by a doctor, 'no signs of selenosis were observed in either group'.

### Case reports

A case of selenosis in a 55-year-old woman has been reported by Senthilkumaran et al. (2012). The woman had consumed 10–15 paradise nuts per day for 20 days and her serum selenium concentration

was 512 µg/L. She presented with headaches, dizziness, vomiting, abdominal pain, massive alopecia and greyish discoloration of the fingernails. Two months after the end of the exposure her hair restarted to grow.

### Conclusions

The Panel notes that signs and symptoms of selenium toxicity have been observed at average intakes below those that have been reported by Yang et al. (1989a) to be associated with selenosis and which have been used by the SCF (2000a) to establish the NOAEL. However, the number of studies available is limited and there seems to be a wide variability in the susceptibility of individuals to selenium toxicity. Nail and hair changes were visible at a median serum concentration of 250 µg/L in one cross-sectional study among residents living in a seleniferous area in India (Chawla et al., 2020). Another cross-sectional study among individuals living in the Brazilian Amazonas reports on signs of selenium toxicity at plasma selenium levels < 328 µg/L in 2.2% of individuals; such signs were not consistently present in groups with higher plasma levels, but these included less than 15 participants (Lemire et al., 2012). A case report describes overt selenosis at serum selenium concentration of 512 µg/L (Senthilkumaran et al., 2012). Finally, there is evidence from a large RCT (SELECT; Lippman et al., 2009) in around 8,700 men (age ≥ 50 years) that average selenium intakes of 330 µg/day for a median of 5.5 years (around 130 µg/day from background diet plus 200 µg/day from supplements) increase the risk of developing features of selenium toxicity, such as alopecia and dermatitis. This finding was not corroborated in three other smaller RCTs at similar or higher levels of selenium intake (Algotar et al., 2013b; Winther et al., 2015; Thompson et al., 2016); however, the latter provide limited information on the method used to identify adverse events and may have lacked sufficient power to detect such effects (sample size in intervention arms between 22 and 900 participants).

The Panel considers that available studies provide evidence that signs and symptoms of selenium toxicity occur at selenium exposures below the previously identified NOAEL of 850 µg/day; thus, the NOAEL needs to be revisited.

None of the studies published after Yang et al. (1989a) and investigating selenium toxicity at selenium exposures below 850 µg/day allow the derivation of a NOAEL.

There are indications from the SELECT (Lippman et al., 2009), a large RCT, that the risk of developing features of selenium toxicity is increased when individuals with baseline selenium intake around 130 µg/day are supplemented with 200 µg/day.

The Panel considers that, from available evidence from intervention and observational studies, a LOAEL of 330 µg/day can be identified from the SELECT.

### **3.5.2.3. Identification of biomarkers of effect**

In line with the protocol and the Guidance on ULs (EFSA NDA Panel, 2022), a biologically based model for establishing ULs was investigated. Markers that could be indicative of when selenium homeostasis is becoming overwhelmed and key tissues and organs are becoming functionally and structurally affected, as the systemic load of the nutrient increases, were explored. Fundamental to this are the recognition of the components of homeostasis and adaptation, and of early evidence of adaptation failing. In that context, excretion of selenium metabolites, markers of liver dysfunction or damage, and haematological parameters have been examined as potential markers of excess selenium intake through the systematic review of the evidence. The selection of these markers have been identified *a priori* in the protocol, based on expert knowledge (Annex A).

#### *Excretion of selenium metabolites*

The excretion of DMSe in breath and TMSe in urine has been proposed to reflect processes that aim at minimising selenium accumulation in the body outside the regulated pool (Burk and Hill, 2015). Notably, as described in Section 3.2, TMSe excretion is influenced by a polymorphism in the INMT gene, which characterises individuals as eliminators or non-eliminators of TMSe, and eliminators may excrete TMSe in urine at usual dietary selenium intakes (Lajin and Francesconi, 2016).

#### TMSe excretion in urine

A total of nine eligible studies, i.e. seven intervention studies (Sun et al., 1987; Robinson et al., 1997; Janghorbani et al., 1999; Kuehnelt et al., 2005; Kuehnelt et al., 2007; Jäger et al., 2016a,b) and two cross-sectional studies (Yang et al., 1989b; Kuehnelt et al., 2015) have been identified.

Yang et al. (1989b) reported a positive linear relationship between TMSe excretion and 24-h total urinary selenium excretion (log–log scale) in 37 males living in a seleniferous area in China (TMSe-

eliminator status not determined). Janghorbani et al. (1999) observed a non-linear relationship between TMSe as a fraction of total urine selenium and urinary selenium excretion with increasing selenium supplementation, in 10 adult males (TMSe-eliminator status not determined) living in a seleniferous area in China with daily selenium intakes of 197 to 1,230 µg who were moved to a low selenium area and reduced their selenium dietary intake to 43 µg/day.

In the intervention studies in which selenium was administered at doses of 50 µg selenate (Jäger et al., 2016a), 200 µg selenite or 100 µg Se-yeast (Jäger et al., 2016b), TMSe non-eliminators did not excrete TMSe in detectable amounts, while TMSe-eliminators all excreted TMSe regardless of supplementation. In the cross-sectional study by Kuehnelt et al. (2015), Andean women (mean ± SD whole blood selenium 180 ± 20 µg/L) characterised as TMSe non-eliminators (TMSe excretion < 4% of total urinary selenium), excreted on average 0.35% of total urinary selenium as TMSe, versus 11% in eliminators. In a Bangladeshi women population (mean whole blood selenium 114 µg/L (SD not reported)), TMSe non-eliminators excreted on average 0.4%–1% of total urinary selenium as TMSe, while eliminators excreted 13%–24% (Kuehnelt et al., 2015).

In three intervention studies in which TMSe-eliminator status was not characterised, the following results were obtained. In the first trial, at doses of 1,000 µg selenium provided as selenite, L-SeMet, or DL-SeMet, no TMSe in urine was detected (Kuehnelt et al., 2005). In the second, urinary excretion of TMSe as a fraction of total urinary selenium metabolites was below 0.5% for supplementation doses of 197, 3,395 and 5,592 µg selenium as selenite (Sun et al., 1987). In the third, only one out of five cancer patients excreted TMSe in significant amounts after supplementation (8,000 µg/day selenium as SeMet for 7 days plus 4,000 µg/day for 21 days) (Kuehnelt et al., 2007). A notable observation from two studies (Robinson et al., 1997; Kuehnelt et al., 2007) was that metabolites other than TMSe became more prominent in urine with increasing selenium intakes.

The Panel notes that the available data do not allow a threshold to be determined below or above which TMSe concentrations in urine could be used as an indicator of selenium overload either in TMSe-eliminators or in non-eliminators.

#### DMSe exhalation in breath

Five eligible studies, i.e. three intervention studies (Serwin et al., 2003; Reid et al., 2004; Kremer et al., 2005) and two cross-sectional studies (Lemire et al., 2012; Chawla et al., 2020), investigated DMSe exhalation in breath. As described in Section 3.2 DMSe exhalation in breath, leading to a garlic odour in breath, may occur when the capacity of the lungs to convert DMSe into TMSe is exceeded. It is affected by the same polymorphism in the INMT gene that also affects TMSe production.

In the RCT by Reid et al. (2004), men with biopsy-proven prostate cancer were randomised to consume either 1,600 µg/day (n = 8) or 3,200 µg/day (n = 16) Se-yeast (amount of selenium in Se-yeast not reported) for an average of about 12 months. Supplementation was stopped when plasma selenium had reached 1,000 µg/L. Selenium toxicity symptoms were monitored throughout the study and plasma selenium levels at the time when symptoms were reported were documented. Garlic breath was observed in six individuals in the 3,200-µg group and none in the 1,600-µg group. It appeared on average at a plasma selenium level of around 155 µg/L (SD 222; read from graph).

Kremer et al. (2005) analysed breath samples of a healthy male volunteer using cryotrapping–cryofocussing–gas chromatography–inductively coupled plasma–time of flight mass spectrometry. Following the ingestion of 300 µg <sup>77</sup>Se given as selenite, isotopically labelled selenium in DMSe appeared in breath 15 min after ingestion with the highest concentration reached after 90 min (1.4 ng/L). After 20 days, labelled selenium was still excreted in breath.

In an RCT (Serwin et al., 2003), 22 patients with active plaque psoriasis received either 200 µg/day selenium as SeMet or placebo for 4 weeks. Every 2 weeks patients were asked to report symptoms of selenium toxicity, including garlic breath. None of the patients reported the development of garlic odour in breath.

Lemire et al. (2012) reported on a cross-sectional study in 407 individuals living in the Brazilian Amazonas with a large variation in selenium intake. Individuals were classified by plasma selenium levels, i.e. < 328 µg/L (n = 360), ≥ 328 to < 520 µg/L (n = 15) and ≥ 520 µg/L (n = 11). Garlic breath occurred in around 16% of individuals in the group with plasma selenium concentrations < 328 µg/L, in 20% of individuals in the group with plasma selenium concentrations ≥ 328 to < 520 µg/L and in 10% of individuals in the group with the highest plasma concentrations.

In the cross-sectional study by Chawla et al. (2020), described above, garlic odour occurred in eight of 238 individuals. Those individuals had median serum selenium concentrations of 404 µg/L (IQR 212–600 µg/L), while individuals with no detectable garlic odour had concentrations of 165 µg/L

(111–392 µg/L). In two individuals, garlic odour was noticeable at serum selenium concentrations below the median of 171 µg/L.

The Panel notes that DMSe production is affected by the same polymorphism that also affects TMSe excretion. Contrary to TMSe, DMSe is not exhaled in breath to a significant extent if a certain threshold of selenium intake is not exceeded, at least not to an extent that a change in breath odour is noticeable. This threshold is likely to have a large interindividual variability, in particular owing to the polymorphism that influences DMSe production. In addition, in most of the studies, garlic odour was self-reported and not assessed in a standardised manner.

#### Other selenium metabolites

The metabolome of selenium includes selenosugars (Figure 3, Section 3.2), which are one of the forms in which of selenium is excreted in urine. There is indication from animal experiments that hexose conjugation of selenium may occur as an early parallel feature of homeostasis rather than as a pathway recruited for selenium excretion when methylation becomes less effective (Katarzyna et al., 2020).

The Panel, however, notes that selenosugars have not been explored yet in humans as candidate markers of actual or potential excess selenium intake.

#### *Markers of liver function*

The liver is one of the target organs for selenium toxicity. In hepatocyte models, early features involve increased accumulation of selenides with oxidative damage (Section 3.5.1). Markers of liver dysfunction and damage have been observed in livestock and animal models. In rodents, liver cirrhosis is a common effect of chronic selenium excess exposure. Although less commonly observed in domestic animals (horses, cattle and swine), focal necrosis of the liver can be observed in advanced cases of chronic selenosis in these animals (ATSDR, 2013; Alexander, 2022).

In its previous assessment, the SCF (2000a) noted hepatic effects in humans manifested by an increased prothrombin time, attributed to impaired synthesis of coagulation factors in the liver, which was observed at dietary intakes at and above 850 µg/day selenium in the cross-sectional study in seleniferous areas of China reported by Yang et al. (1989a). The SCF (2000a) further noted that in a study by Longnecker et al. (1991) in areas of high selenium intake in the US, the concentration of the liver enzyme ALT in serum, although within the reference range, showed a correlation with selenium intake, but this was not considered to be clinically significant; no effect on prothrombin time was seen in that study. The SCF (2000a) noted that the US population studied covered a lower range of selenium intake than the Chinese study and, considering mean body weights, it is also likely that the intake per kg body weight was greater in the Chinese study, in comparison with the US study. No other evidence of adverse effects of selenium intake on liver was reported in the SCF assessment (SCF, 2000a).

For the present assessment, data were collected to systematically investigate human evidence of an effect of 'high' selenium dietary intake on liver function.

A total of 11 pertinent human studies were retrieved, i.e. two intervention studies (Välimäki et al., 1991; Reid et al., 2004) and nine cross-sectional studies (Yang et al., 1989a; Longnecker et al., 1991; Ruhl and Everhart, 2003; Petrovski et al., 2012; Yang et al., 2016; Loomba et al., 2020; Wu et al., 2020; Isobe et al., 2021; Wang et al., 2021).

In an intervention study in which high doses of Se-yeast (i.e. 1,600 µg/day selenium (n = 8) and 3,200 µg/day selenium (n = 16)) were administered to patients with a diagnosis of prostate cancer without other active treatment for 1 year, markers of liver function remained within the normal range, i.e. alkaline phosphatase (ALP) (43.5–111.2 U/L), ALT (11.9–27.3 U/L), aspartate aminotransferase (AST) (13.3–29.1 U/L), albumin (3.8–4.7 g/dL) and total bilirubin (< 1.2 mg/dL); however, ALP and bilirubin levels were increased at 6 and 12 months of intervention in the 3,200 µg/day group (i.e. ALP 84 vs 65 U/L and bilirubin 0.59 vs 0.38 mg/dl at 12 months intervention) (Reid et al., 2004). In the other intervention study, in a group of 8 healthy individuals who received 200 µg/day selenium as Se-yeast, no changes were observed in the same markers of liver function, as well as in prothrombin time; an increase in bilirubin was observed in controls (from 9.1 ± 1.2 to 12.2 ± 1.4 µmol/L) but this was within the normal range (Välimäki et al., 1991).

In some cross-sectional studies, positive correlations between markers of selenium exposure and ALT activity were observed. These studies had sample sizes between 93 and 8,550 individuals. Longnecker et al. (1991) observed an increase in ALT activity at dietary selenium intake 68–724 µg/day ( $\beta$  19.7; 95% CI 8.65, 29.9;  $p < 0.05$ ). Yang et al. (2016) investigated exposure levels of plasma

selenium < 182 µg/L (quantile; Q1) vs > 247 µg/L (Q4) and observed elevated ALT (Q1 median (interquartile range; IQR): 14 (10–20) U/L vs Q4: 17 (12–23) U/L;  $p < 0.001$ ). Wang et al. (2021) reported a 9.25 (95% CI 2.23, 16.76) percent higher ALT activity in quintile 5 (143–298 µg/L serum selenium) than in quintile 1 (58–115 µg/L). Isobe et al. (2021) reported a positive correlation between selenium exposure and log ALT activity ( $r = 0.122$ ,  $p < 0.001$ ) in a population with mean  $\pm$  SD serum selenium concentrations of  $159 \pm 28$  µg/L, Ruhl and Everhart (2003) observed a slight increase in risk of having elevated ALT activity across deciles of serum selenium concentrations (overall range 39–425 µg/L) (OR 1.05; 95% CI 0.99, 1.12). A positive association between serum selenium concentrations and ALT activity was reported. For each 100 U/L higher ALT activity serum selenium concentrations were 0.007 µmol/L (95% CI 0.039, 0.195 µmol/L) higher (Petrovski et al., 2012). No correlation between selenium exposure and ALT activity was observed by Loomba et al. (2020) at serum selenium concentrations of 112–401 µg/L ( $r = 0.043$ ; 95% CI  $-0.085$ , 0.169). Loomba et al. (2020) did not observe correlations between hair and nail selenium concentrations and ALT. Most of the studies did not report sufficient details to establish whether the extent of increase in ALT activity was of biological relevance. In the study by Longnecker et al. (1991) in ranchers living in seleniferous areas of the US and corresponding controls it is reported that even though ALT was increased in those with higher selenium exposure, ALT levels were not outside the reference range. This observation is consistent with the results of the intervention studies.

Correlations between other markers of liver function and selenium exposure were less consistent. Yang et al. (1989a) observed a prolonged prothrombin time (defined as > 14 s) in 84 individuals in whom this was measured, in 45% of the population with whole blood selenium concentration > 1,000 µg/L, compared to only 2.7% individuals with the same observation with lower whole blood selenium concentrations. Longnecker et al. (1991) reported no relationship between dietary selenium intake and prothrombin time ( $\beta \times 1,000$  1.18; 95% CI  $-165$ , 173), and gamma-glutamyl transferase (GGT) activity ( $\beta$  2.36; 95% CI  $-27.5$ , 31.5) and an inverse association with ALP activity ( $\beta$   $-28.3$ ; 95% CI  $-59.0$ , 2.4). Loomba et al. (2020) reported no correlation between serum selenium and ALP activity ( $r = 0.07$ ; 95% CI  $-0.06$ , 0.19), as well as AST activity ( $r = 0.09$ ; 95% CI  $-0.04$ , 0.22) and albumin concentrations ( $r = 0.04$ ; 95% CI  $-0.09$ , 0.16). In other studies, a positive correlation was observed between selenium exposure and AST activity (Yang et al., 2016; Isobe et al., 2021). Isobe et al. (2021) found a relationship between selenoprotein P concentrations and log AST ( $r = 0.14$ ,  $p < 0.001$ ) and Yang et al. (2016) between plasma selenium quartiles (Q1 < 181.6 µg/L, Q4 > 247.4 µg/L) and AST (median (IQR): Q1 20 (16–24), Q2 21(17–25), Q3 21 (18–26), Q4 22 (19–27) U/L,  $p$  for trend < 0.001). A positive association was also found for selenium exposure and GGT (Yang et al., 2016; Isobe et al., 2021). Isobe et al. (2021) reported a correlation between selenoprotein P and log GGT of 0.2,  $p < 0.001$ . Yang et al. (2016) found a significant  $p$  for trend between serum selenium quartiles and GGT (median (IQR): Q1 19 (13–31), Q2 20 (14–32), Q3 21 (14–34), Q4 22 (15–40) U/L,  $p$  for trend < 0.001). Petrovski et al. (2012) found no association between serum selenium in individuals without chronic liver disease and some markers of liver function (selenium concentrations per 100 Unit difference in the marker of liver function (GGT 0.004; 95% CI  $-0.019$ , 0.026 µmol/L; ALP  $-0.008$ ; 95% CI  $-0.028$ , 0.013 µmol/L and albumin 0.059; 95% CI  $-0.042$ , 0.159 µmol/L). A negative association was observed for AST ( $-0.0121$ ; 95% CI  $-0.235$ ,  $-0.007$  µmol/L) and the AST/ALT ratio ( $-0.095$ ; 95% CI  $-0.123$ ,  $-0.069$  µmol/L). Finally, Wu et al. (2020) reported a positive linear relationship between quintiles of dietary selenium intake (Q1  $\leq 21.3$  µg/1,000 kcal, Q5  $\geq 31$  µg/1,000 kcal) and non-alcoholic fatty liver disease (NAFLD), diagnosed based on imaging or histological evidence of hepatic steatosis, in the absence of specific aetiologies and no heavy alcohol consumption (prevalence of NAFLD Q1 31.6%, Q2 35.3%, Q3 37.2%, Q4 37.6%, Q5 42.3%,  $p < 0.001$ ). Markers of liver function were not measured in this study.

The Panel notes that animal models indicate that the liver is one of the target organs for selenium toxicity and that data in humans provide indications that excess selenium intake may affect liver function. However, the Panel considers that available data in humans are limited and insufficient to inform the identification of a reference point that could be used to establish an UL for selenium.

#### *Haematological parameters*

Six eligible studies that reported on the relationship between selenium exposure and haematological parameters were retrieved, i.e. two intervention studies (Fairris et al., 1989; Hawkes et al., 2001) and four cross-sectional studies (Yang et al., 1989a; Longnecker et al., 1991; Larvie et al., 2019; Loomba et al., 2020).

In the cross-sectional study by Yang et al. (1989a), an increase in WBC counts was observed in individuals with increasing selenium consumption up to around 1,400 µg/day through their habitual diet (low selenium group, 25 men (mean selenium intakes around 60–70 µg/day): mean ± SE WBC counts  $8,216 \pm 469/\text{mm}^3$ , medium selenium group, 23 men (mean selenium intakes around 200 µg/day):  $9,104 \pm 695/\text{mm}^3$ , high selenium group, 28 men (mean selenium intakes around 1,200–1,400 µg/day):  $10,004 \pm 403/\text{mm}^3$ ).

A decrease in WBC counts by 5% was observed in a group of 5 men who consumed a diet containing about 300 µg/day selenium (baseline vs end mean ± SD  $6,100 \pm 1,300$  vs  $5,800 \pm 1,400/\text{mm}^3$ ) for 99 days compared to 6 men who consumed a diet containing about 15 µg/day selenium and in whom WBC counts increased by 10% ( $4,100 \pm 750$  vs  $4,500 \pm 760/\text{mm}^3$ ) (Hawkes et al., 2001) while in another intervention study involving 69 psoriasis patients, 600 µg/day selenium supplementation for 12 weeks did not affect WBC counts (results not shown in the publication) (Fairris et al., 1989).

In two other studies in a seleniferous area of India (median (IQR) serum selenium concentration 171 (111–400) µg/L among 238 individuals) (Loomba et al., 2020) and in the US (median (range) serum selenium concentration 2.33 (1.56–4.60) µmol/L among 142 individuals) (Longnecker et al., 1991), no relationship was found between selenium intake and WBC counts. The correlation coefficients (95% CI) between serum selenium concentrations and WBC counts in the study by Loomba et al. (2020) was 0.08 (–0.04, 0.21). Longnecker et al. (1991) reported a regression coefficient (95% CI) of –10.2 (–42.5, 22.0) between dietary selenium intake (range 68–724 µg/day) and WBC counts.

No relevant findings were reported for other haematological parameters (haemoglobin concentrations, haematocrit, RBC and platelet counts) in these studies.

### Conclusion

Overall, the Panel considers that there is no valid marker that is predictive of a risk of selenium excess and potential toxicity, or biomarker of effect, which can be used to establish an UL for selenium.

### 3.5.3. Hypertension

This section and the followings follow the approach for hazard identification that is outlined for sQ2 (Section 2.2.2.3).

For the risk of hypertension, incidence of hypertension is included in the standalone main LoE and changes in systolic blood pressure (SBP) and/or diastolic blood pressure (DBP) are included in the standalone surrogate LoE.

#### 3.5.3.1. Intervention studies

No eligible intervention studies were retrieved which assessed the effect of selenium supplementation on the incidence of hypertension.

*LoE2. Standalone surrogate: Changes in systolic blood pressure and/or diastolic blood pressure*

#### Preliminary UA

One eligible RCT was retrieved, which involved healthy adult males and females in Spain (Navas-Carretero et al., 2011) and aimed at investigating in normo- and overweight adults the effect of integrating selenium-enriched chicken in the diet on body composition, lipid profile, glucose metabolism and antioxidant status. The intervention group received a controlled diet with selenium-enriched chicken (22 µg/day selenium supplementation; n = 11) and the control group received non-enriched chicken (n = 13) for 10 weeks. No effect of the intervention was found on blood pressure levels (Appendix D.2.1).

The Panel notes the limited BoE from intervention studies. No comprehensive UA is performed.

#### 3.5.3.2. Observational studies

*LoE1. Standalone main: Incidence of hypertension and LoE2. Standalone surrogate: Changes in systolic blood pressure and/or diastolic blood pressure*

The relationship between dietary selenium intake and risk of hypertension was investigated in three prospective cohort studies (Flemish Study on Environment, Genes and Health Outcomes (FLEMENGHO)

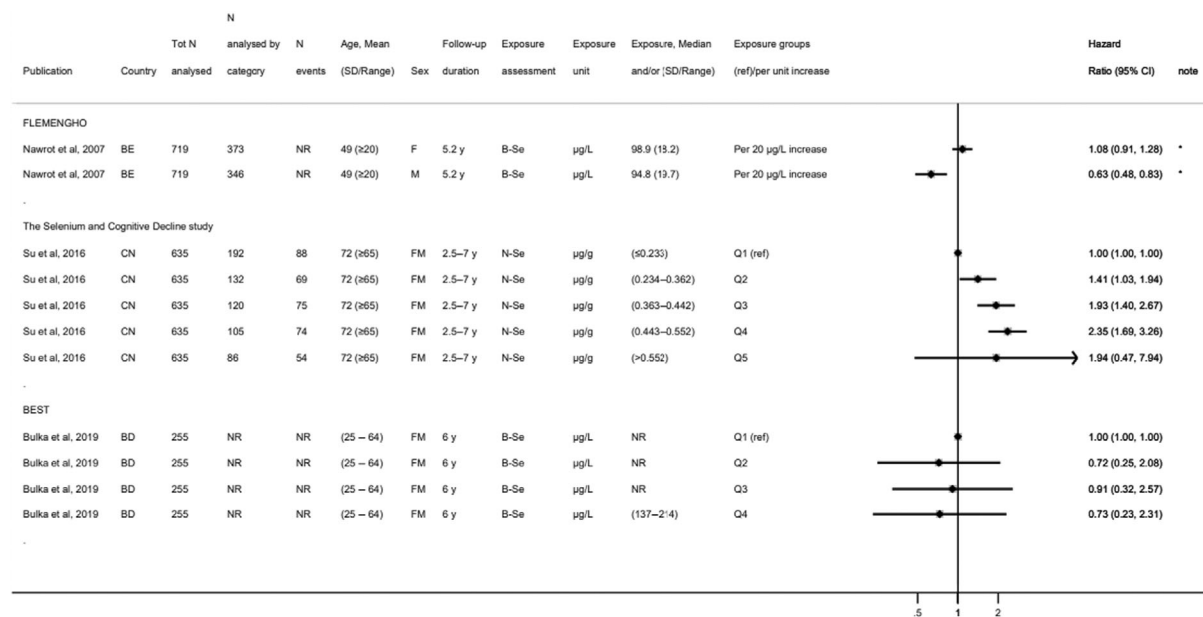

Nawrot et al., 2007; The Selenium and Cognitive Decline study Su et al., 2016; Bangladesh Vitamin E and Selenium Trial (BEST) Bulka et al., 2019). Bulka et al. (2019) and Su et al. (2016) defined hypertension cases as SBP  $\geq 140$ , DBP  $\geq 90$  mmHg, and/or use of antihypertensive medication, and/or self-reported physician-diagnosed hypertension, while Nawrot et al. (2007) defined 'high blood pressure' cases as SBP  $\geq 130$  or DBP  $\geq 85$  mmHg or use of antihypertensive medication. Three additional prospective cohort studies (Programming Research in Obesity, Growth Environment and Social Stress (PROGRESS) Kupsco et al., 2019; Prospective Urban and Rural Epidemiology (PURE) Swart et al., 2019; RHEA, Howe et al., 2021) reported on the relationship of dietary selenium intake with blood pressure levels.

**Preliminary UA**

Two studies investigated the association between exposure to various metals, including selenium, in pregnant women and blood pressure in their child (PROGRESS (544 mother-child pairs in Mexico; children aged 4–6 years at follow up), RHEA (176 mother-child pairs in Greece; children aged 11 years at follow up)). Exposure was assessed as selenium concentrations in maternal whole blood in PROGRESS and maternal urine in RHEA.

The four other prospective cohort studies involved adult males and females. The size of the cohorts ranged between 255 participants (BEST) and 719 participants (FLEMENGHO), and the length of follow-up ranged between 2.5 years (Selenium and Cognitive Decline study) and 10 years (PURE). Cohorts were located in Belgium, China, Bangladesh and South Africa. Exposure was assessed in whole blood (BEST, PROGRESS), serum (PURE) or nail (Selenium and Cognitive Decline study).

The evidence table is in Appendix D.2.2. Key study characteristics, together with the risk estimates and related CIs, are plotted in Figures 8 and 9 for incidence of hypertension and change in blood pressure, respectively.

\*Denotes hypertension definition different from other studies.

BD: Bangladesh; BE: Belgium; BEST Bangladesh Vitamin E and Selenium Trial; B-Se: blood selenium; CI: confidence interval; CN: China; FLEMENGHO: Flemish Study on Environment Genes and Health Outcomes; FM: females and males; N-Se: nail selenium; NR: not reported; P/S-Se: plasma/serum selenium, Q: quantile; SD: standard deviation; y: years.

**Figure 8:** Observational studies investigating the effect of selenium on the incidence of hypertension

\*Denotes estimated annual changes in blood pressure; \*\*denotes mother–child pair studies where exposure was analysed in the mothers and outcome in their child; the age of children is shown.

BD: Bangladesh; BP: blood pressure; B-Se: blood selenium; CI: confidence interval; FM: females and males; GR: Greece; MX: Mexico; SD: standard deviation; U-Se: urinary selenium; ZA: South Africa; y: years.

**Figure 9:** Observational studies investigating the effect of selenium on continuous measures of blood pressure

The Panel notes that available observational studies are small and heterogeneous in terms of population characteristics (age, country) and biomarkers of selenium exposure.

Inconsistent results were found in the two mother–child pair studies investigating prenatal exposure to various metals, including selenium, and blood pressure in the child (Kupsco et al., 2019; Howe et al., 2021) (Figure 8).

Among the prospective cohorts of adults, one study reported a positive association between nail selenium concentrations and incidence of hypertension in an elderly Chinese population (Su et al., 2016). This is not supported by the other available studies (Nawrot et al., 2007; Bulka et al., 2019; Swart et al., 2019) (Figures 8 and 9).

The Panel considers that the available BoE from observational studies does not suggest a positive relationship between dietary intake of selenium and risk of hypertension over the range of exposure investigated in these studies. No comprehensive UA is performed.

### 3.5.3.3. Overall conclusions on hypertension

The Panel considers that the available BoE does not suggest a positive relationship between dietary intake of selenium and risk of hypertension.

### 3.5.4. Alzheimer's dementia

Incidence of Alzheimer's dementia is included in the standalone main LoE.

#### 3.5.4.1. Intervention studies

*LoE1. Standalone main: Incidence of Alzheimer's dementia*

##### Preliminary UA

When developing the protocol for this assessment (Annex A), the Panel noted one prospective cohort study in Italy, in which higher amounts of selenate, but not of other selenium species or of overall selenium, in cerebrospinal fluid in 56 subjects with mild cognitive impairment were associated with an increased risk of developing Alzheimer's dementia (Vinceti et al., 2017a).

One eligible study was identified as the result of the literature search, which reported on an observational follow-up of an intervention study.

The Prevention of Alzheimer's Disease by Vitamin E and Selenium (PREADVISE) trial, ancillary to the SELECT (Kryscio et al., 2017) began as a double-blind RCT recruiting 7,540 non-demented individuals in the US and transitioned into an observational cohort study upon cessation of the intervention (4,271 participants of the original sample agreed to remain in the study). The study included groups which received selenium supplementation (200 µg/day) or a placebo for a median duration of 5.5 years and aimed at determining the effect of the intervention on dementia. A HR for dementia incidence of 0.83 (95% CI 0.61, 1.13) was estimated for the selenium arm compared to placebo (see evidence table in Appendix D.3.1).

The Panel considers that the available BoE from RCTs does not suggest a positive relationship between dietary intake of selenium and risk of Alzheimer's dementia at the intake level investigated. No comprehensive UA is performed.

#### **3.5.4.2. Observational studies**

No eligible observational study was retrieved. The study by Vinceti et al. (2017a) described above was not included in the current risk assessment, because selenium in cerebrospinal fluid was not among the eligible biomarkers of exposure.

#### **3.5.4.3. Overall conclusions on Alzheimer's dementia**

The Panel considers that the available BoE does not suggest a positive relationship between dietary selenium intake and risk of Alzheimer's dementia.

### **3.5.5. Amyotrophic lateral sclerosis**

The incidence of ALS is included in the standalone main LoE.

#### **3.5.5.1. Intervention studies**

No eligible intervention study was retrieved.

#### **3.5.5.2. Observational studies**

*LoE1. Standalone main: Incidence of amyotrophic lateral sclerosis*

##### Preliminary UA

Two prospective cohort studies investigated the association between selenium exposure and the risk of ALS. The evidence table is in Appendix D.4.1.

One prospective cohort study (Rivalta cohort in Italy) investigated the risk for ALS associated with high exposure to selenium through contaminated water. 'Exposed' individuals consumed water with a selenium content of 8–10 µg/L while the 'unexposed' cohort consumed water with selenium content < 1 µg/L. Over a total follow-up of 29 years, the incidence rate ratio (IRR) was 2.8 (95% CI 1.3, 6) for the exposed vs unexposed cohorts, with higher IRR observed in women (5.1; 95% CI 1.8, 14.3) than men (1.7; 95% CI 0.5, 5.4) (Vinceti et al., 2019).

One NCC within the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort (France, Germany, Greece, Italy, the Netherlands, Spain, UK) investigated the association between blood selenium concentration and ALS mortality over a median follow up of 8.1 years. An OR of 1.21 (95% CI 0.65, 2.25) was estimated, comparing the highest (> 123 ng/g) vs lowest (≤ 104 ng/g) tertiles of selenium in RBCs (Peters et al., 2021).

The Panel notes the limited BoE from observational studies. The Panel considers that the available BoE is insufficient to conclude on a positive relationship between dietary intake of selenium and risk of ALS. No comprehensive UA is performed.

#### **3.5.5.3. Overall conclusions on amyotrophic lateral sclerosis**

The Panel considers that the available BoE is insufficient to conclude on a positive relationship between dietary intake of selenium and risk of ALS.

### **3.5.6. Functional neuropsychological development in children**

For the impairment of functional neuropsychological development in children, measures of functional neuropsychological development are included in the standalone main LoE.

### 3.5.6.1. Intervention studies

No eligible intervention study was retrieved.

### 3.5.6.2. Observational studies

#### *LoE1. Standalone main: measures of neuropsychological development*

A total of 11 eligible prospective observational studies reported in 13 publications were retrieved. All studies investigated the association between prenatal selenium exposure and functional neurodevelopmental outcomes in children (Skröder et al., 2015; Kippler et al., 2016; Polanska et al., 2017; Skröder et al., 2017; Tatsuta et al., 2017; Varsi et al., 2017; Amorós et al., 2018a,b; Močenić et al., 2019; Calamandrei et al., 2020; Castriotta et al., 2020; Doherty et al., 2020; Li et al., 2020a). Two studies also assessed selenium biomarkers of exposure in children after birth (Skröder et al., 2017; Doherty et al., 2020).

#### Preliminary UA

The study size varied from 114 to 1,408 mother–child pairs. Cohorts were located in Europe (Croatia, Spain, Greece, Italy, Norway, Poland, Slovenia), Asia (Bangladesh, China, Japan) and in the US. Maternal selenium exposure was assessed during pregnancy (mostly at 1st or 3rd trimester) or at delivery, and children’s functional neurodevelopment was assessed at different ages ranging from 6 months to 10 years. Maternal selenium exposure during pregnancy was assessed through selenium concentrations in RBCs, serum/plasma, urine and toenails, and at delivery through maternal whole blood or cord blood content. The neurodevelopment tests used included different editions (I–III) of the Bayley Scales of Infant Development (BSID), the McCarthy Scales of Children’s Abilities (MSCA), the Kyoto Scale of Psychological Development (KSPD), the Ages and Stages Questionnaire (ASQ), the Wechsler Preschool and Primary Scale of Intelligence (WPPSI) and Wechsler Intelligence Scale for Children (WISC), the Social Responsiveness Scale 2nd edition (SRS-2), and the Behaviour Assessment System for Children 2nd edition (BASC-2), according to the developmental stage of the children involved in the studies. The evidence table is in Appendix D.5.1. Data on these outcomes are not plotted due to lack of comparability across studies.

In the birth cohort of the Spanish Childhood and Environment Project, an inverted U-shaped relationship was found between maternal selenium status measured through plasma selenium during the 1st trimester of pregnancy and some domains of child neuropsychological development assessed at both 1 year of age (children’s mental and psychomotor development scales of BSDI version II) and 5 years of age (verbal and global memory scales of the MSCA test) (Amorós et al., 2018a).

In the Northern Adriatic Cohort II in Italy (Castriotta et al., 2020), an inverted U-shaped relationship was observed between cord blood selenium concentrations and the cognitive development of children at 40 months of age, assessed by the BSID version III. In a dichotomous analysis, children who had low and high selenium concentrations in cord blood at birth had higher odds of falling in the first quintile of cognitive composite compared with those who had medium concentrations.

In a mother–child cohort in China (Li et al., 2020a), an inverted U-shaped relationship between maternal urinary selenium excretion during the last month of gestation and mental and psychomotor development (BSDI version I) at 2 years was reported in girls, but not in boys.

The other studies reported no or positive associations between measures of selenium exposure and measures of neurodevelopment in children (Skröder et al., 2015; Kippler et al., 2016; Polanska et al., 2016; Skröder et al., 2017; Tatsuta et al., 2017; Varsi et al., 2017; Močenić et al., 2019; Calamandrei et al., 2020; Castriotta et al., 2020; Doherty et al., 2020; Li et al., 2020a). The Panel notes that, in most studies, non-linearity was either not explored (Polanska et al., 2017; Tatsuta et al., 2017; Varsi et al., 2017; Močenić et al., 2019; Calamandrei et al., 2020; Castriotta et al., 2020; Doherty et al., 2020) or not observed (Skröder et al., 2015; Kippler et al., 2016).

The Panel notes that available observational studies are heterogeneous in terms of population characteristics (child age at assessment, country), selenium exposure assessments and methods used to assess children’s neurodevelopment, which hampers comparisons between studies. Findings are inconsistent across studies and domains of cognitive and motor functions. However, some data suggest that there might be a relationship between ‘higher’ maternal selenium status and decreased functional neuropsychological development in the offspring. The Panel notes that these data are limited and subject to uncertainties related to the observational nature of these findings and further research is necessary.

The Panel considers that the available BoE from observational studies is insufficient to conclude on a relationship between 'high' dietary intake of selenium and impaired functional neuropsychological development in children. No comprehensive UA is performed.

### 3.5.6.3. Overall conclusions on functional neuropsychological development in children

The Panel considers that the available BoE is insufficient to conclude on a relationship between high dietary intake of selenium and impaired functional neuropsychological development in children.

### 3.5.7. Thyroid diseases

Incidence of thyroid diseases such as hypo- or hyperthyroidism or thyroid cancer, are included in the standalone main LoE. Measures of thyroid hormones are included in the standalone surrogate LoE.

#### 3.5.7.1. Intervention studies

No eligible intervention studies were retrieved which assessed the effect of selenium supplementation on the incidence of thyroid disease.

*LoE2. Standalone surrogate: changes in thyroid hormones*

Nine eligible intervention studies were identified that investigated the relationship between dietary selenium intake and thyroid function as measured by changes in thyroid hormone concentrations. The supplemental doses ranged from 10 to 400 µg/day. Eight studies lasted less than 1 year (13 to 48 weeks) (Olivieri et al., 1995; Duffield and Thomson, 1999; Hawkes and Keim, 2003; Thomson et al., 2005; Hawkes et al., 2008; Rayman et al., 2008b; Thomson et al., 2009; Carvalho et al., 2015) and one study lasted 5 years (Winther et al., 2015).

#### Preliminary UA

The study size ranged from 12 to 501 participants. The studies included adult males and females, except for two studies that included only males (Hawkes and Keim, 2003; Hawkes et al., 2008). Most studies selected apparently healthy individuals and one study selected subjects treated for dyslipidaemia and hypertension (Carvalho et al., 2015). The studies were conducted in Brazil, Denmark, Italy, the UK, the US and New Zealand. Mean/median plasma selenium concentrations at baseline were between 62 and 118 µg/L across trials. The outcomes assessed included plasma levels of the thyroid hormones triiodothyronine (T3), thyroxine (T4) and thyroid-stimulating hormone (TSH), as well as free triiodothyronine (FT3), free thyroxine (FT4) and T3:T4 ratio.

The evidence table is in Appendix D.6.1 Key study characteristics, together with the effect estimates and related CIs, are plotted in Figure 10.

\*Denotes depletion study.

BR: Brazil; CI: confidence interval; DK: Denmark; FM: females and males; IT: Italy; N: number; NR: not reported; NZ: New Zealand; PRECISE: PREvention of Cancer by Intervention with Selenium SD: standard deviation; Suppl-I: inorganic selenium supplement; Suppl-O: organic selenium supplement; T3: triiodothyronine; T4: thyroxine; TSH: thyroid-stimulating hormone, UK: United Kingdom.

**Figure 10:** Intervention studies investigating the effects of selenium supplementation vs placebo on thyroid hormone concentrations (standardised mean differences), sorted by study duration

Among studies lasting less than 1 year, the direction of the changes in T4, FT4, T3, FT3, TSH, and T3:T4 ratio is inconsistent (dose: 40 to 300 µg/day; duration: 13 to 48 weeks) (Figure 10). In the largest and longest trial using 100, 200 or 300 µg/day for 5 years, Winther et al. (2015) reported a decrease of  $-0.035$  mIU/L ( $p = 0.611$ ) in TSH and  $-0.21$  pmol/L ( $p = 0.12$ ) in FT4 per 100 µg/day increase using a binary analysis (i.e. active treatment vs placebo as a binary covariate in the regression model); using a dose-analysis (i.e. dose as a continuous covariate in the regression model), a decrease in TSH of  $-0.066$  mIU/L ( $p = 0.010$ ) and in FT4 of  $-0.11$  pmol/L ( $p = 0.015$ ) was estimated. The Panel considers that the variations in thyroid hormones observed in this study are not biologically relevant.

The Panel considers that the available BoE from RCTs does not suggest a positive relationship between selenium intake and thyroid diseases at the intake levels investigated. No comprehensive UA is performed.

### 3.5.7.2. Observational studies

*LoE1. Standalone main: incidence of thyroid diseases*

#### Preliminary UA

One eligible prospective observational study was identified, which investigated the relationship between dietary selenium intake assessed with FFQ and thyroid cancer incidence in a cohort of 566,398 men and women of the National Institutes of Health-American Association of Retired Persons (NIH-AARP) Diet and Health Study in the US (O'Grady et al., 2014). After 10 years of follow-up, a HR of 1.35 (95% CI 0.99, 1.84) was estimated when comparing the 5th to the 1st quintile of selenium intake (see evidence table in Appendix D.6.2).

The Panel notes the limited BoE from observational studies. No comprehensive UA is performed.

### 3.5.7.3. Overall conclusions on thyroid diseases

The Panel considers that the available BoE does not suggest a positive relationship between selenium intake and thyroid diseases.

## 3.5.8. Prostate cancer

Incidence of prostate cancer is included in the standalone main LoE.

### 3.5.8.1. Intervention studies

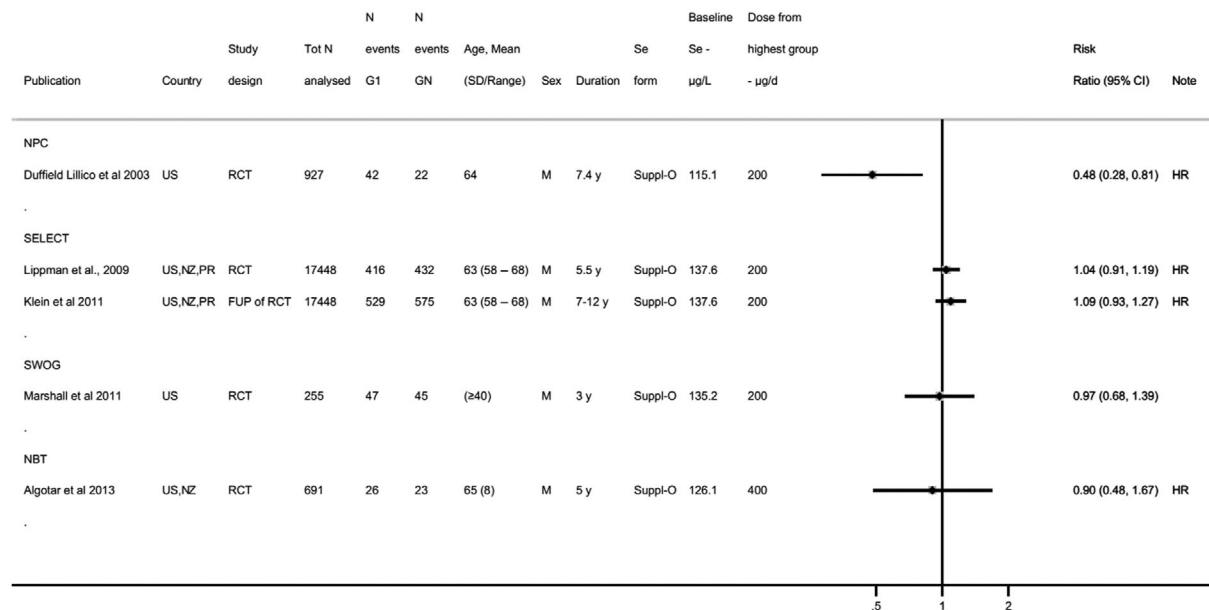

*LoE1. Standalone main: incidence of prostate cancer*

Four intervention studies investigated the effect of selenium supplementation vs placebo on incidence of prostate cancer (NBT, Algotar et al., 2013b; Nutritional Prevention of Cancer (NPC) trial, Duffield-Lillico et al., 2003a; SELECT, Lippman et al., 2009; Southwest Oncology Group (SWOG) trial, Marshall et al., 2011). The supplemental intake of selenium ranged from 200 to 400 µg/day and the mean study intervention period ranged from 3 to 12 years. For the SELECT, results for an additional observational follow-up period of 3 years after cessation of the intervention were also reported (Klein et al., 2011).

#### Preliminary UA

The study size ranged between 255 (Marshall et al., 2011) and 17,448 participants (SELECT, Lippman et al., 2009); one trial was in healthy men (SELECT), two trials included men at 'high' risk of prostate cancer (NBT, SWOG), and one trial involved men with confirmed history of non-melanoma skin cancer (NPC). Incidence of prostate cancer was the primary outcome in the SELECT, the NBT and the SWOG trial, while in the NPC trial it was added as a secondary endpoint during the course of intervention. Two studies were conducted in the US (SWOG, NPC), one in the US and New Zealand (NBT) and one study in the US, New Zealand and Puerto Rico (SELECT). Mean/median plasma selenium concentration at baseline ranged between 115 µg/L (NPC) and 138 µg/L (SWOG).

The evidence table is in Appendix D.7.1. Key study characteristics, together with the effect estimates and related CIs, are plotted in Figure 11.

CI: confidence interval; duration: duration of the intervention and follow-up phase for studies with an observational period (i.e. Klein et al., 2011); FUP: follow-up; GN: highest dose group from each study; HR: hazard ratio; M: males; NBT: Negative Biopsy Trial; NPC: Nutritional Prevention of Cancer; NZ: New Zealand; PR: Porto Rico; RCT: randomised controlled trial; SD: standard deviation; SELECT: Selenium and Vitamin E Cancer Prevention Trial; Suppl-O: organic selenium supplement; SWOG: Southwest Oncology Group; US: United States; y: years.

Notes: For Algotar et al. (2013b), HR adjusted for age at baseline, race, baseline PSA, and baseline plasma Se concentration; for Duffield-Lilloco et al. (2003a), HR adjusted for age and smoking.

**Figure 11:** Intervention studies investigating the effects of selenium supplementation vs placebo on incidence of prostate cancer, sorted by supplemental dose

The NBT, NPC and SWOG trials found no indication of an increased risk of prostate cancer in the groups which received selenium supplementation (dose: 200 to 400 µg/day; mean duration: 3 to 7.4 years) (Figure 10). In the largest trial, i.e. the SELECT, a HR of 1.04 (99% CI 0.87, 1.24) was estimated when comparing the selenium group (200 µg/day) to the control group after a median of 5.5 years of supplementation. After 3 years of follow-up upon cessation of the intervention, the HR was 1.09 (99% CI 0.93, 1.27) (Klein et al., 2011) (Figure 10 and evidence table in Appendix D.7.1). Making use of data collected through the SELECT and applying a case-cohort study design, authors observed a non-statistically significant increase in the risk of high-grade prostate cancer among men in the highest quintiles of baseline toenail selenium compared to the lowest quintile (Q4 ≥ 0.9– < 1.0 µg selenium/g toenail, HR: 1.52 (95% CI 0.71, 3.25); Q5 ≥ 1.0 µg selenium/g toenail, HR: 1.74 (95% CI 0.81, 3.72)) (Kristal et al., 2014).

The Panel considers that the available BoE from RCTs does not suggest a positive relationship between dietary intake of selenium and risk of prostate cancer at the doses investigated in these studies. No comprehensive UA is performed.

### 3.5.8.2. Observational studies

#### LoE1. Standalone main: incidence of prostate cancer

Fifteen eligible prospective observational studies investigated the relationship between selenium exposure and incidence of prostate cancer (EPIC, Allen et al., 2008; Seattle firms, Coates et al., 1988; Mobile Clinic Health Examination Survey (MCHES), Knekt et al., 1990; Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC), Hartman et al., 1998; Health Professional Follow-Up Study (HPFS), Yoshizawa et al., 1998; CLUE II, Helzlsouer et al., 2000; Honolulu Heart Program (HHP), Nomura et al., 2000; Carotene and Retinol Efficacy Trial (CARET), Goodman et al., 2001; Physician's Health Study (PHS), Li et al., 2004; Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCOCS), Peters et al., 2007; Prostate Cancer Prevention Trial (PCPT), Kristal et al., 2010; Uppsala Longitudinal Study of Adult Men (ULSAM), Grundmark et al., 2011; Netherlands Cohort Study, Geysels et al., 2013; The Multiethnic Cohort (MEC), Park et al., 2015; Diet, Cancer and Health cohort, Outzen et al., 2021).

### Preliminary UA

The cohort size ranged between 37 (Seattle firms) and 75,216 (MEC) participants. The length of follow-up ranged from 2.5 to 26.5 years. Cohorts were located in Europe (Germany, Denmark, Spain, Finland, Greece, Italy, the Netherlands, Sweden, the UK) and in the US and Canada.

Plasma or serum selenium concentrations were used as measure of selenium exposure in seven studies (MCHES, HHP, CARET, PHS, PLCOCS, EPIC, ULSAM), one study used plasma selenoprotein P concentration (Diet, Cancer and Health cohort), four studies used toenail selenium (HPFS, CLUE II, Netherlands Cohort Study and the Diet, Cancer and Health cohort). Total dietary intake was assessed through a diet history questionnaire or a semi-quantitative FFQ (SFFQ) in two studies (ATBC, MEC) and supplemental intake of selenium was estimated through a questionnaire in one other (PCPT).

The evidence table is in Appendix [D.7.2](#). Key study characteristics, together with the risk estimates and related CIs, are plotted in Figures [12](#) and [13](#).

Tolerable upper intake level for selenium

\*Denotes imputed standard error.

CI: confidence interval; CA: Canada; CARET: Carotene and Retinol Efficacy Trial; DE: Germany; DK: Denmark; EPIC: European Prospective Investigation into Cancer and Nutrition; ES: Spain; FI: Finland; GR: Greece; IT: Italy; M: males; MCHES: Mobile Clinic Health Examination Survey; N: number; NL: The Netherlands; N: number NR: not reported; OR: odds ratio; P/S-Se: plasma/serum Se; Q: quantile; RR: risk ratio; SD: standard deviation; SE: Sweden; UK: United Kingdom; ULSAM: Uppsala Longitudinal Study of Adult Men; US: United States; y: years.

**Figure 12:** Observational studies on plasma/serum selenium concentrations and incidence of prostate cancer

ATBC: Alpha-Tocopherol, Beta-Carotene Cancer Prevention; C: category; CA: Canada; CI: confidence interval; d: day; DK: Denmark; FI: Finland; HPFS: Health Professionals Follow-Up Study; M: males; MEC: Multiethnic Cohort; N: number; NL: Netherlands; N-Se: nail selenium; NR: not reported; OR: odds ratio; P/S-Se: plasma/serum selenium; PCPT: Prostate Cancer Prevention Trial; Q: quantile; RR: risk ratio; SFFQ: semiquantitative food frequency questionnaire; Suppl-Q: supplement use questionnaire; US: United States, y: years. Note: For Kristal et al., 2010 stratified results plotted for incidence of prostate cancer for Gleason scores 2–7 (stratified results for Gleason scores 8–10 available in evidence table in Appendix D.7.2).

**Figure 13:** Observational studies on measures of selenium intake other than plasma/serum selenium and incidence of prostate cancer

Overall, prospective observational studies investigating the association between plasma/serum selenium concentration (Figures 12) or other measures of selenium exposure (Figure 13) do not support a positive association with the risk of prostate cancer.

The Panel considers that the available BoE from observational studies does not suggest a positive relationship between dietary selenium intake and risk of prostate cancer over the range of exposure investigated in these studies. No comprehensive UA is performed.

### 3.5.8.3. Overall conclusions on prostate cancer

The Panel considers that the available BoE does not suggest a positive relationship between dietary selenium intake and risk of prostate cancer.

### 3.5.9. Skin cancer

For the risk of skin cancer, incidence of any type of skin cancer (i.e. melanoma skin cancer, squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) skin cancer) is included in the standalone main LoE.

#### 3.5.9.1. Intervention studies

##### *LoE1. Standalone main: incidence of skin cancer*

Three RCTs, reported in five publications, investigated the effect of selenium supplementation vs placebo on incidence of skin cancer (NPC, Reid et al., 2008; NPC, Duffield-Lillico et al., 2002; NPC, Duffield-Lillico et al., 2003b; Sel/Cel, Thompson et al., 2016; NBT, Algotar et al., 2013b). The NPC and NBT trials measured the incidence of melanoma skin cancer, SCC and BCC skin cancer. The Sel/Cel trial reports on incidence of SCC only. Three publications are available from the NPC trial: two report the effect of 200 µg/day vs placebo based on the data collected in the main trial conducted in several study sites (Duffield-Lillico et al., 2002, 2003b); one reports the results of an adjunct trial conducted in one of the study sites, in which an additional group of participants was randomised to receive a supplemental dose of 400 µg/day or a placebo (Reid et al., 2008). Across trials, the supplemental doses of selenium ranged from 200 to 400 µg/day and the mean study intervention period ranged from 2.75 to 7.9 years.

##### Preliminary UA

The study size ranged from 423 (NPC adjunct trial) to 1,820 participants (Sel/Cel). The studies included adult males and females (Sel/Cel and NPC) or males only (NBT). One trial was conducted in patients with a history of non-melanoma skin cancer (NPC), one in subjects with a history of colorectal adenomas (Sel/Cel) and one in men at high risk for prostate cancer (NBT). In the NPC trial, incidence of non-melanoma skin cancers (i.e. BCC and SCC) was the primary outcome and incidence of melanoma skin cancer was a secondary outcome, while in the NBT and Sel/Cel trials they were assessed as part of the evaluation of adverse events/toxicity outcomes. The studies were conducted mainly in US, and New Zealand. Mean/median plasma selenium concentration at baseline were between 114 and 127 µg/L across trials.

The evidence table is in Appendix D.8.1. Key study characteristics, together with the effect estimates and related CIs, are plotted in Figure 14.

\*Denotes estimated risk ratios and standard errors; \*\*denotes incidence rates instead of N events.

BCC: basal cell carcinoma; CI: confidence interval; FM: females and males; GN: highest dose group from each study; HR: hazard ratio; N: number; NBT: Negative Biopsy Trial; NPC: Nutritional Prevention of Cancer; NZ: New Zealand; SCC: squamous cell carcinoma; SD: standard deviation; Sel/Cel: Selenium and Celecoxib; Suppl-O: organic Se supplement; US: United States; y: years.

Note: Participants in the NPC trial were at high risk of non-melanoma skin cancer at baseline having been diagnosed with 1 or more SCC or 2 or more BCC within the year prior to randomization.

**Figure 14:** Intervention studies investigating the effect of selenium supplementation vs placebo on incidence of skin cancer, sorted by duration

In the NPC trial, an increased incidence of SCC (HR 1.25; 95% CI 1.03, 1.51) was found in the group of subjects who received 200  $\mu\text{g/day}$  selenium for 7.9 years compared to the control group (Duffield-Lillico et al., 2003b). In a subgroup analysis according to baseline plasma selenium concentrations, an increased incidence of SCC was found in the second tertile (105.6–122.0 ng/mL; HR 1.49; 95% CI 1.05, 2.12) and third tertile ( $\geq 122.4$  ng/mL; HR 1.59; 95% CI 1.11, 2.30) (Duffield-Lillico et al., 2003b). In the adjunct study of the NPC trial, the HR for SCC was 1.05 (95% CI 0.72, 1.53) comparing the group of participants who received 400  $\mu\text{g/day}$  selenium for 5.2 years to the control group (Reid et al., 2008). In the Sel/Cell trial, the HR for SCC was 1.34 (95% CI 0.76, 2.37) when comparing the intervention group (200  $\mu\text{g/day}$  selenium for 2.75 years) to the control group (Thompson et al., 2016). In the NBT trial, 17 cases of SCC were identified in the control group compared to 10 and 2 cases in the groups which received 200 or 400  $\mu\text{g/day}$  selenium for 5 years, respectively (Algotar et al., 2013b). The Panel notes that an increased incidence of SCC was observed in the NPC trial among participants with plasma selenium  $\geq 105.6$  ng/mL who received a supplemental intake of 200  $\mu\text{g/day}$  selenium. However, the Panel notes the available data on an effect of selenium supplementation on the risk of SCC are limited. In addition, the Panel notes the paucity of data on the risk of BCC or melanoma in the selenium supplementation trials described above.

The Panel considers that the available BoE is insufficient to conclude on a positive relationship between selenium exposure and risk of skin cancer at the doses investigated in these studies. No comprehensive UA is performed.

### 3.5.9.2. Observational studies

#### LoE1. Standalone main: incidence of skin cancer

Six prospective observational cohorts, reported in seven publications, investigated the relationship between selenium exposure and incidence of skin cancer (Nurses' Health Study (NHS) and HPFS, Matthews et al., 2019; Skin Cancer Prevention (SCP) study, Karagas et al., 1997; VITamins And Lifestyle (VITAL) cohort, Asgari et al., 2009; Nambour Skin Cancer (NSC) study, van der Pols et al., 2009; Heinen et al., 2007; MCHES, Knekt et al., 1990; Knekt et al., 1991). The incidence of SCC

and BCC were investigated in five cohorts (NHS and HPFS, SCP study, NSC study and MCHES) and four cohorts (NHS and HPFS, NSC study and MCHES), respectively. The incidence of melanoma was investigated in three cohorts (NHS and HPFS, VITAL) and one NCC (within the MCHES cohort).

#### Preliminary UA

The size of the cohorts ranged between 392 participants (SCP study) and 69,671 participants (VITAL), while the NCC included 10 cases of melanoma and 18 matched controls (MCHES; Knekt et al., 1991). The length of follow-up ranged from 5 years in the SCP study and VITAL cohort, to 28 years in the NHS cohort. Cohorts were located in Finland, US and Australia. All cohorts involved adult males and females; the MCHES cohort also included adolescents from 15 years of age.

The SCP study was an RCT designed to investigate the effect of  $\beta$ -carotene supplementation in preventing non-melanoma skin cancer in people who had a history of BCC or SCC; Karagas et al. (1997) reported the association between baseline plasma selenium and incidence of a new SCC among all trial participants. The NSC study was an RCT which investigated the effect of  $\beta$ -carotene supplementation or use of sunscreen in preventing non-melanoma skin cancer; the association between baseline plasma selenium and incidence of SCC and BCC among the participants involved in the control group was investigated (van der Pols et al., 2009). In the NSC study, the associations between estimates of dietary selenium intake and incidence of BCC and SCC were also investigated among a subset of participants who completed an SFFQ at the end of the trial and were further followed-up for 8 years after the end of the intervention phase (Heinen et al., 2007). In the other cohorts, selenium exposure was assessed as toenail selenium in the NHS and HPFS cohorts, as 10-year average selenium supplement intake in the VITAL cohort, and as serum selenium in MCHES.

The evidence table is in Appendix D.8.2. Key study characteristics, together with the risk estimates and related CIs, are plotted in Figure 15.

Tolerable upper intake level for selenium

\*Denotes imputed standard error.

AU: Australia; BCC: basal cell carcinoma; C: category; CI: confidence interval; d: day; FI: Finland; FM: females and males; HPFS: Health Professionals Follow-Up Study; MCHES: Mobile Clinic Health Examination Survey; N: number; NCC: nested case-control study; NHS: Nurses' Health Study; NR: not reported; NSC: Nambour Skin Cancer; N-Se: nail selenium; OR: odds ratio; P/S-Se: plasma/serum selenium; Q: quantile; RR: risk ratio; SD: standard deviation; SCC: squamous cell carcinoma; SCP: Skin Cancer Prevention; SFFQ: semiquantitative food frequency questionnaire; Suppl-Q: supplement use questionnaire; UK: United Kingdom; VITAL: VITamins And Lifestyle.

Notes: Knekt et al. (1991) and Karagas et al. (1997) are NCCs; Karagas et al. (1997) enrolled participants with at least one BCC or SCC cancer previously removed.

Figure 15: Observational studies on selenium exposure and incidence of skin cancer

The Panel notes the heterogeneity of the exposure-endpoint relationships investigated across studies. Overall, available prospective observational studies do not support an increased risk of skin cancer (SCC, BCC or melanoma) associated with increased selenium exposure, as assessed by plasma or nail selenium concentrations or as estimated by dietary questionnaires.

The Panel considers that the available BoE from observational studies does not suggest a positive relationship between selenium intake and risk of skin cancer over the range of exposure investigated in these studies. No comprehensive UA is performed.

### 3.5.9.3. Overall conclusions on skin cancer

The Panel considers that the available BoE is insufficient to conclude on a positive relationship between dietary selenium exposure and risk of skin cancer.

### 3.5.10. Type 2 diabetes mellitus

Incidence of T2DM is included in the standalone main LoE for the risk of T2DM.

Measures of glucose homeostasis have been grouped in LoEs which follow the natural history of T2DM, i.e. from those that are expected to be impaired first to those expected to be impaired later in time:

- a) Measures of insulin sensitivity obtained either in steady-state conditions (during an euglycaemic hyperinsulinaemic clamp) or in non-steady state conditions (e.g. during an intravenous glucose tolerance test (IVGTT) with frequent sampling/minimal model assessment).
- b) Indices of insulin sensitivity/resistance and indices of insulin secretion/beta cell function, either derived from the fasting state (e.g. homeostasis model assessment for insulin resistance (HOMA-IR), homeostasis model assessment of  $\beta$ -cell function (HOMA- $\beta$ ) or from an oral glucose tolerance test (OGTT)) (e.g. Matsuda index of insulin sensitivity).
- c) Measures of glucose tolerance, either derived from the fasting state (fasting blood glucose (FBG) and fasting insulin (FI)) or from an OGTT, including glucose and insulin at 120 min and areas under the curve (AUCs) for glucose and insulin.
- d) Measures of blood glucose control, including fructosamine, glycated albumin and glycated haemoglobin (HbA1c).

LoE (c) is considered standalone surrogate because cut-off values for fasting glucose and for glucose at 120 min during an OGTT are used for the diagnosis of diabetes. Within this LoE, measures of fasting insulin and insulin at 120 min during an OGTT will be considered as complementary. In contrast, LoEs (a), (b) and (d) are considered complementary because, on their own, they cannot answer the sQ about the risk of T2DM.

#### 3.5.10.1. Intervention studies

*LoE1. Standalone main: incidence of type 2 diabetes mellitus*

Five RCTs, which investigated effects of selenium supplementation vs placebo, reported data on incident cases of T2DM (NPC, Stranges et al., 2007; SELECT, Lippman et al., 2009; NBT, Algotar et al., 2013a; Eastern Cooperative Oncology Group (ECOG), Karp et al., 2013; Sel/Cel, Thompson et al., 2016). The supplemental intake of selenium ranged from 200 (five study arms) to 400  $\mu\text{g}$  (one study arm) per day and the mean study intervention period ranged from 2.8 to 7.7 years. For the SELECT, results after an additional observational follow-up period of 3 years after cessation of the intervention were also reported (Klein et al., 2011). The SELECT was a 4-arm trial with groups receiving either selenium supplementation alone, vitamin E alone, the combination of the two, or a placebo; only the results for the arms receiving selenium or placebo are considered below.

In addition, in a publication describing the effect of selenium supplementation on changes in HbA1c in the context of the 5-year PRECISE pilot trial (DK PRECISE) authors reported the overall number of study participants receiving medication for T2DM 2 years after the initiation of the intervention. The trial included three arms of selenium supplementation (100, 200 or 300  $\mu\text{g}/\text{day}$ ) vs placebo (Stranges et al., 2019). As the number of incident T2DM cases by study group was not provided in the publication, authors were contacted to obtain the data. In their answer, authors also provided data for the UK PRECISE trial, a pilot RCT which used 100, 200 or 300  $\mu\text{g}/\text{day}$  vs placebo for 6 months (Rayman et al., 2012).

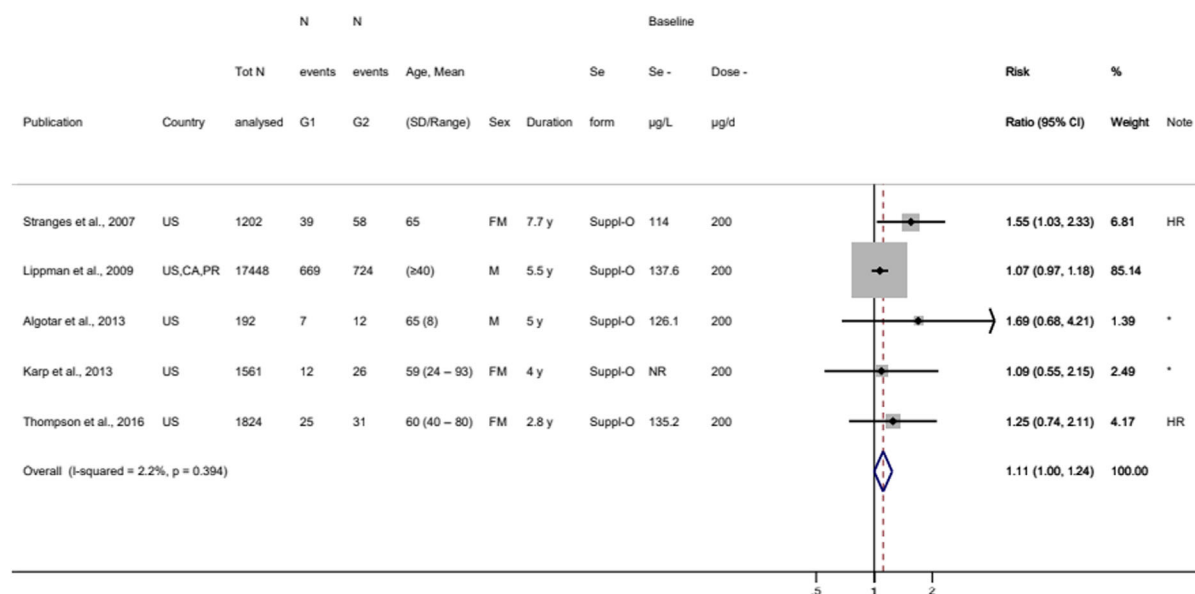

Preliminary UA

The study size ranged between 192 participants (NBT) and 17,448 participants (SELECT). Three trials involved healthy individuals (SELECT; DK PRECISE; UK PRECISE), one trial recruited men at 'high' risk of prostate cancer (NBT), one trial involved men with confirmed history of non-melanoma skin cancer (NPC), one trial included subjects with resected non-small-cell lung cancer (ECOG), and one trial selected subjects with a history of colorectal adenomas (Sel/Cel). Three studies were conducted in the US (NPC, ECOG, Sel/Cel), one in the US and New Zealand (NBT), one study in the US, New Zealand and Puerto Rico (SELECT), with mean/median plasma selenium concentration at baseline between 114 and 137 µg/L. The DK PRECISE and UK PRECISE were conducted in Denmark and UK respectively, with mean plasma selenium concentration at baseline of 88 µg/L in both trials.

Cases of T2DM were recorded from the start of the intervention among the secondary outcomes of the study in two trials (NPC, NBT). In three trials, cases of T2DM were monitored among safety endpoints, either from the start of the intervention (Sel/Cel; DK PRECISE; UK PRECISE) or added during the course of intervention (SELECT, ECOG). Three studies reported estimates of RRs (NPC, SELECT, Sel/Cel), while two studies only reported the number of T2DM cases in each study arm (NBT, ECOG). For DK PRECISE and UK PRECISE, the number of incident T2DM cases in each study arm was obtained from the authors through personal communication.

The evidence table is in Appendix D.9.1. Key study characteristics, together with the effect estimates and related CIs, are plotted in Figure 16. A random-effect meta-analysis of the eligible RCTs was conducted. For each study, the effect estimate corresponded to the RR in the group receiving 200 µg/day selenium compared to the control group. For the NBT trial, in which a dose of 400 µg/day selenium was also tested, the RR was the same in both treatment groups.

In view of the specific characteristics of the DK PRECISE (mean plasma selenium concentration at baseline of 88 µg/L) and UK PRECISE (6 months follow up), the Panel considered that these trials could not be combined with the other trials and therefore, these data were not included in the meta-analysis (number of T2DM cases available in Appendix D.9.1).

\*Denotes estimated risk ratios and standard errors.

CA: Canada; CI: confidence interval; d: day; FM: females and males; G: group; HR: hazard ratio; N: number; PR: Puerto Rico; SD: standard deviation; Suppl-O: organic selenium supplement; US: United States; y: years.

Note: In Karp et al. (2013): the ratio of participants assigned to G1 and G2 was 1:2: i.e. 521 individuals in the control group and 1:040 individuals in treatment group.

**Figure 16:** Intervention studies investigating the effect of selenium supplementation vs placebo on the incidence of T2DM

A higher number of T2DM cases in the selenium supplementation groups than in the control groups was found in the five studies included in the meta-analysis. The pooled effect (RR) is 1.11 (95% CI

1.00, 1.24), with low statistical heterogeneity identified across studies ( $I^2 = 2.2\%$ ,  $p = 0.394$ ). The Panel notes that the SELECT is the major determinant of the pooled effect estimate (85% weight in the estimation of the overall effect).

The Panel notes that in the NPC trial, in a stratified analysis by tertile of baseline plasma selenium concentrations, the HRs were 1.13 (95% CI 0.58, 2.18) in the first tertile ( $\leq 105.2$  ng/mL), 1.36 (95% CI 0.60, 3.09) in the second tertile (95% CI 105.3, 121.6 ng/mL) and 2.70 (95% CI 1.30, 5.61) in the third tertile ( $> 121.6$  ng/mL). HRs were 1.04 (95% CI 0.60, 1.80) and 2.50 (95% CI 1.32, 4.77) for the subgroups with baseline plasma selenium concentrations below or above the median value of 113.4 ng/mL (Stranges et al., 2007). No indication of a modification of the association by age ( $\leq 65$  years vs  $> 65$  years), sex (men vs women), smoking status (never, former, current), or body mass index (BMI) ( $\leq 23.71$ , 23.72–26.76,  $> 26.76$  kg/m<sup>2</sup>) was found.

In the Sel/Cel trial, a HR of 2.21 (95% CI 1.04, 4.67) was found in the group aged  $\geq 63$  years vs 0.59 (95% CI 0.25, 1.35) in the group aged  $< 63$  years.

In the SELECT, after an additional observational follow-up period of 3 years after cessation of the intervention, the HR was 1.04 (99% CI 0.93, 1.17) (Klein et al., 2011).

Overall, the Panel considers that the available BoE suggests a positive relationship between the intake of selenium and incidence of T2DM.

#### *LoE2. Standalone surrogate: measures of glucose tolerance*

Ten eligible RCTs reported on the effect of selenium supplementation on measures of glucose tolerance. FBG concentrations were measured in nine trials, among which seven also reported measures of FI concentration (Navas-Carretero et al., 2011; Jamilian et al., 2015; Karamali et al., 2015; Hosseinzadeh et al., 2016; Mesdaghinia et al., 2017; Raygan et al., 2018; Tamtaji et al., 2019), while two studies did not (Hawkes et al., 2008; Richie et al., 2014). The supplemental intake of selenium ranged from 30 to 300  $\mu\text{g/day}$  and the mean/median study intervention period ranged from 8 to 48 weeks. One study reported the results of an OGTT conducted in a subset of the initial study sample of the Sel/Cel trial mentioned above, in which participants received 200  $\mu\text{g/day}$  selenium for 2.9 years (Jacobs et al., 2019).

#### Preliminary UA

The size of the studies reporting on FBG (with or without FI) ranged between 24 and 70 participants; three trials were in healthy adults (Hawkes et al., 2008; Navas-Carretero et al., 2011; Richie et al., 2014), one trial involved pregnant women (Mesdaghinia et al., 2017), two trials in women with polycystic ovary syndrome (Jamilian et al., 2015; Hosseinzadeh et al., 2016), one trial among patients with cervical intraepithelial neoplasia grade 1 (Karamali et al., 2015), one trial in patients with congestive heart failure (Raygan et al., 2018), and one trial in patients with Alzheimer's dementia (Tamtaji et al., 2019). The study which conducted an OGTT involved 175 individuals with a history of colorectal adenomas (Sel/Cel, Jacobs et al., 2019). Six studies were conducted in Iran, one in Spain, and three in the US. Median/mean plasma selenium concentrations at baseline were reported for two studies based in the US and were approx. 140  $\mu\text{g/L}$  (Richie et al., 2014; Jacobs et al., 2019). Mean whole blood selenium concentration was 144  $\mu\text{g/L}$  in the study conducted in Spain (Navas-Carretero et al., 2011). An average selenium intake of approx. 32  $\mu\text{g/day}$  at baseline was estimated in one study in Iran, using six 24-h recalls (Hosseinzadeh et al., 2016).

Measures of glucose tolerance were investigated as the primary outcome in three trials (Jamilian et al., 2015; Hosseinzadeh et al., 2016; Raygan et al., 2018) and as secondary outcome in five trials (Richie et al., 2014; Karamali et al., 2015; Mesdaghinia et al., 2017; Jacobs et al., 2019; Tamtaji et al., 2019). Two trials measured FBG among other blood parameters (including markers of antioxidant or inflammatory status, blood lipids) (Hawkes et al., 2008; Navas-Carretero et al., 2011).

The evidence table is in Appendix D.9.2. Key study characteristics, together with the effect estimates and related CIs for fasting blood glucose and fasting insulin are plotted in Figures 17 and 18, respectively. A random-effect meta-analysis of the eligible RCTs was conducted. For each study, the effect estimate corresponds to the differences between the group receiving the highest daily selenium dose compared to the control group.

CI: confidence interval; d: day; ES: Spain; FM: females and males; IR: Iran; N: number; NR: not reported; SD: standard deviation; Se: selenium; Suppl-O: organic selenium supplement; US: United States; wks: weeks.

Notes: Baseline selenium intake estimated with six 24-h recalls in Hosseinzadeh et al. (2016) (in  $\mu\text{g/day}$ ). Baseline selenium measured in whole blood in Navas-Carretero et al. (2011) (in  $\mu\text{g/L}$ ).

**Figure 17:** Intervention studies investigating the effect of selenium supplementation vs placebo on fasting glucose

CI: confidence interval; d: day; ES: Spain; FM: females and males; IR: Iran; N: number; NR: not reported; SD: standard deviation; Se: selenium; Suppl-O: organic selenium supplement; wks: weeks.

Notes: Baseline selenium intake estimated with six 24-h recalls in Hosseinzadeh et al. (2016) (in  $\mu\text{g/day}$ ). Baseline selenium measured in whole blood in Navas-Carretero et al. (2011) (in  $\mu\text{g/L}$ ).

**Figure 18:** Intervention studies investigating the effect of selenium supplementation vs placebo on fasting insulin

Lower FBG concentrations were found in the intervention groups compared to control group in seven out of nine trials (Figure 17). In those trials which also measured FI, the pattern of change was consistent, with lower FI concentrations found in six out of seven trials (Figure 18).

However, the Panel notes that three of these articles are currently under investigation after concerns were raised to the Editors-in-Chief of the Scientific Journals about their integrity (Karamali et al., 2015; Mesdaghinia et al., 2017; Raygan et al., 2018), according to information available on the respective Journal websites. Forest plots excluding studies from this research group are presented in Figure 19.

a. Fasting glucose

b. Fasting insulin

CI: confidence interval; d: day; ES: Spain; FM: females and males; IR: Iran; N: number; NR: not reported; SD: standard deviation; Se: selenium; Suppl-O: organic selenium supplement; US: United States; wks: weeks.

Notes: Baseline selenium intake estimated with six 24-h recalls in Hosseinzadeh et al. (2016) (in  $\mu\text{g/day}$ ). Baseline selenium measured in whole blood in Navas-Carretero et al. (2011) (in  $\mu\text{g/L}$ ).

**Figure 19:** Intervention studies investigating the effect of selenium supplementation vs placebo on fasting glucose and fasting insulin, excluding: Karamali et al. (2015), Mesdaghinia et al. (2017), Raygan et al. (2018), Tamtaji et al. (2019) and Jamilian et al. (2015)

Jacobs et al. (2019) conducted a 3-h modified OGTT among a subsample of participants from the Sel/Cel study (200 µg/day vs placebo for 2.9 years). A convenience sample was selected among the participants who remained in the trial near the end of follow up. A total of 96 in the control group and 79 in the selenium group accepted to perform the test. At 120 min after oral administration of 75 g glucose, there was no difference in blood glucose concentration between the two groups (mean ± SD: 132.2 ± 49.8 mg/dL in the control group vs 129.4 ± 41.4 in the selenium group,  $p = 0.70$ ) (Appendix D.9.2).

The Panel considers that the available BoE does not suggest an adverse effect of high selenium intake on measures of glucose tolerance.

#### Comprehensive UA.

The Panel selected incidence of T2DM as the key endpoint for the comprehensive UA.

**Risk of bias appraisal.** Four RCTs were at low RoB (tier 1) and one RCT was at moderate RoB (tier 2) (Table 6).

**Table 6:** Outcome of the risk of bias appraisal of the RCTs on incidence of T2DM

| Reference              | Study name | Exposure | Outcome | Randomization | Allocation concealment | Blinding | Attrition/exclusion from analysis | Other threats | Tier |
|------------------------|------------|----------|---------|---------------|------------------------|----------|-----------------------------------|---------------|------|
| Stranges et al. (2007) | NPC        | +        | +       | +             | +                      | +        | +                                 | +             | 1    |
| Lippman et al. (2009)  | SELECT     | +        | +       | +             | NR                     | +        | +                                 | +             | 1    |
| Algotar et al. (2013b) | NBT        | +        | +       | +             | -                      | +        | -                                 | -             | 2    |
| Karp et al. (2013)     | ECOG       | +        | +       | +             | +                      | +        | NR                                | -             | 1    |
| Thompson et al. (2016) | Sel/Cel    | +        | +       | +             | +                      | NR       | +                                 | +             | 1    |

+: low RoB; -: high RoB; NR: not reported.

The reasons for judging certain items as high RoB are outlined in the following.

With respect to allocation concealment for the NBT study described by Algotar et al. (2013a), it is reported that randomisation codes were held by unblinded personnel. As it was unclear what the exact tasks of these individuals were, a high RoB rating was attributed to this item. Study drop-out percentages were 34.1%, 41.9% and 40.8% for the placebo group, the 200 µg/day selenium group and the 400 µg/day selenium group, respectively. This high drop-out rate was considered to have introduced a high RoB. The judgement related to the item on other threats to internal validity was based on the fact that no risk estimates were provided in the publications. In addition, it was unclear why self-reports of T2DM were not confirmed with the available data on plasma glucose concentrations. For the ECOG trial described by Karp et al. (2013), the assessment of T2DM only started 7 years after the start of the study and 2 years before the end of the study. This is the reason why the question on other threats to internal validity was rated as high RoB.

In a sensitivity analysis excluding the NBT and ECOG trials, considering the RoB appraisal and the fact that these studies only reported number of T2DM cases by group rather than risk estimates, the pooled effect estimate (RR) for the effect of selenium supplementation vs placebo on incidence of T2DM was 1.18 (95% CI 0.95, 1.48;  $I^2 = 38.2%$ ,  $p = 0.198$ ).

**Publication bias.** Funnel plots and Egger's regression results provide weak support ( $p = 0.137$ ; intercept 0.97, 95% CI 0.56, 2.51) for a publication bias, i.e. there is weak support that results of some studies with no effect of selenium supplementation on T2DM or an effect in the opposite direction may have not been published (Figure 20).

The Panel notes the low number of studies and thus the low power of the test and related risk for false-negatives. Therefore, the Panel considers the results of the tests as inconclusive.

The Panel notes that the reporting of adverse effects in supplementation studies is often incomplete, particularly for those which are not pre-planned in the study protocol.

**Figure 20:** Funnel plot of the RCTs on incidence of T2DM

**Dose–response relationship.** Eligible studies were similar regarding the baseline selenium status of the participants (mean/median plasma concentration between 114 and 137  $\mu\text{g/L}$ ) and all used a supplementation dose of 200  $\mu\text{g/day}$  (corresponding to a total selenium intake between 270 and 340  $\mu\text{g/day}$ ). Only the NBT trial used two doses of selenium, i.e. 200 and 400  $\mu\text{g/day}$ . The number of T2DM cases identified during the intervention was 7 in the control group, 12 in the group receiving 200  $\mu\text{g/day}$  and 12 in the group receiving 400  $\mu\text{g/day}$ .

The Panel considers that the data from RCTs are not suitable to characterise a dose–response relationship between selenium intake and incidence of T2DM.

*LoE3. Complementary: Indices of insulin sensitivity/resistance and indices of insulin secretion/ $\beta$ -cell function*

Among the RCTs which reported on measures of glucose tolerance, seven studies also assessed changes in the HOMA2-IR (Navas-Carretero et al., 2011; Jamilian et al., 2015; Karamali et al., 2015; Hosseinzadeh et al., 2016; Mesdaghinia et al., 2017; Raygan et al., 2018; Tamtaji et al., 2019), among which four also HOMA2- $\beta$ . A statistically significant decrease in HOMA2-IR was found in six trials (30–200  $\mu\text{g/day}$  selenium for 8–26 weeks, Navas-Carretero et al., 2011; Jamilian et al., 2015; Karamali et al., 2015; Mesdaghinia et al., 2017; Raygan et al., 2018; Tamtaji et al., 2019), with a consistent decrease in HOMA2- $\beta$  in the three trials reporting this parameter (Jamilian et al., 2015; Karamali et al., 2015; Mesdaghinia et al., 2017). In contrast, a statistically significant increase in HOMA2-IR was found in one trial (200  $\mu\text{g/day}$  for 12 weeks; Hosseinzadeh et al., 2016) (Appendix D.9.2).

However, the Panel notes that three of these articles are currently under investigation after concerns were raised to the Editors-in Chief of the Scientific Journals about their integrity (Karamali et al., 2015; Mesdaghinia et al., 2017; Raygan et al., 2018), according to information available on the respective Journal websites. Forest plots excluding studies from this research group are presented in Figure 19.

*LoE4. Complementary: Measures of blood glucose control*

The DK PRECISE reported HbA1c measurements at baseline and after 6 months and 2 years of selenium supplementation with 100  $\mu\text{g/day}$  ( $n = 124$ , group 1), 200  $\mu\text{g/day}$  ( $n = 122$ , group 2), or 300  $\mu\text{g/day}$  ( $n = 119$ , group 3) vs placebo ( $n = 126$ ). After 2 years, HbA1c had decreased in all groups, with no difference between active treatment and placebo (mean (95% CI) in control group:  $-1.8$  ( $-3.1, -0.6$ ); group 1:  $-2.7$  ( $-4.0, -1.4$ ); group 2:  $-1.7$  ( $-3.0, -0.3$ ); group 3:  $-2.8$  ( $-4.1, -1.5$ )) (Stranges et al., 2019). Six participants were using diabetes medications at baseline, six at 6 months, and 14 at 2 years. The exclusion from analysis of participants once they had received diabetes medications did not alter the results on HbA1c.

**Consistency across LoEs.** The increased risk of T2DM observed following selenium supplementation is not supported by the results of studies reporting on measures of glucose tolerance (LoE2, standalone surrogate), indices of insulin sensitivity/resistance (LoE3, complementary) or measures of blood glucose control (LoE4, complementary).

## Outcome of the comprehensive analysis of the uncertainties

**Table 7:** Comprehensive analysis of the uncertainties in the BoE from intervention studies

| What is the level of certainty that the intake of selenium is positively and causally associated with the risk of T2DM? |   |   |
|---|---|---|
| BoE   | <b>LoE1. Standalone main. Endpoint:</b> incidence of T2DM<br>5 RCTs, 22,227 participants (92% males). Pooled mean effect estimate, RR (95% CI) = 1.11 (1.00, 1.24) (Figure 16).   | Initial certainty:<br><b>High (&gt; 75%–100% probability)</b> |
| Domain  | Rationale   | Evaluation  |
| RoB   | 4 studies in tier 1 (low RoB), 1 study in tier 2 (moderate RoB) (Table 6).<br><u>Key questions:</u> <ul style="list-style-type: none"> <li>• Randomisation: low</li> <li>• Exposure assessment: low</li> <li>• Outcome assessment: low</li> </ul> Mostly low RoB for blinding; mixed low/high RoB or not reported for attrition/exclusion from analysis; mixed low/high RoB for other threats to internal validity  | Not serious   |
| Unexplained inconsistency   | Point estimates are in the same direction.<br>Low statistical heterogeneity ( $I^2 = 2.2\%$ for the meta-estimate).<br>RR estimates substantially higher in smaller studies; yet, 95% CI largely overlap.   | Not serious   |
| Indirectness  | No concern regarding the directness of the endpoint (incidence of the disease).<br><br>Regarding the study populations: all trials were conducted in populations with average baseline plasma selenium higher than those typically observed in European populations; mean age was $\geq 63$ years in the 5 trials; men are overrepresented as compared to women in the overall body of evidence; three trials were designed for the secondary prevention of cancer, i.e. recruited people with a history of non-melanoma skin cancer, non-small-cell lung cancer and colorectal adenomas, respectively, while the largest trial involved men from the general population. Overall, no source of concern was identified given the relevance of the study populations for the target population | Not serious   |
| Imprecision   | Low, based on the 95% CI of the meta-estimate   | Not serious   |
| Publication bias  | Weak support for publication bias based on funnel plot and Egger test. Given the low number of studies and thus the low power of the test and related risk for false-negatives, the results of the tests are considered inconclusive.<br>Funding sources were public (n = 4), or not reported (n = 1).  | Undetected  |
| Upgrading factors   | <u>Dose–response:</u> cannot be characterised based on the available BoE<br><u>Consistency across LoEs:</u> the increased risk of T2DM observed following selenium supplementation is not supported by the results of the surrogate and complementary LoEs<br><br><u>Magnitude:</u> effect size is insufficient to consider upgrading   | None identified   |
| <b>Final certainty</b>  | Started 'high'. No serious concern identified regarding RoB, unexplained inconsistency, imprecision, indirectness and no publication bias detected. However, the level of certainty was downgraded one level considering the limitations related to the design and conduct of the studies (T2DM not the primary outcome) and the inconsistent results from the surrogate and complementary LoEs.  | <b>Moderate (&gt; 50%–75% probability)</b>                    |

BoE: body of evidence; CI: confidence interval; LoE: line of evidence; RoB: risk of bias; RR: risk ratio; T2DM: type 2 diabetes mellitus.

**Conclusions from intervention studies.** The level of certainty in a positive and causal relationship between the intake of selenium and risk of T2DM is moderate (rationale in Table 7).

### 3.5.10.2. Observational studies

#### *LoE1. Standalone main: incidence of type 2 diabetes mellitus*

Ten cohorts investigated the relationship between selenium exposure and incidence of T2DM. Seven were PCs (Hortega study, Galan-Chilet et al. 2017; ULSAM, Gao et al., 2014; NHS and HPFS, Park et al., 2012; HORMones and Diet in the ETiology of Breast Cancer (ORDET), Stranges et al., 2010; Moli-Sani, Vinceti et al., 2021; China Stroke Primary Prevention Trial (CSPPT), Zhang et al., 2019), three were NCCs (Dongfeng-Tongji cohort (DFJT), Yuan et al., 2018; Jinchang cohort, Cheng et al., 2022; ORDET, Cabral et al., 2021) and one was a case-cohort study (EPIC-Potsdam, Cabral et al., 2021). Two analyses of the ORDET cohort were available, using a FFQ (Stranges et al., 2010) and toenail selenium concentration (Vinceti et al., 2015b) to characterise selenium exposure, respectively. The CSPPT study used a population involved in an RCT designed to investigate the effect of enalapril and/or folic acid treatment in preventing stroke (Zhang et al., 2019).

#### Preliminary UA

The size of the PCs ranged between 1,234 participants (Hortega) and 21,335 participants (Moli-Sani), while the NCCs and case-cohort studies included between 621 participants (ORDET) and 2,741 participants (EPIC-Potsdam). The length of follow-up ranged from 4.5 years in the CSPPT study to 26 years in the NHS cohort. Five cohorts were located in Europe (Spain, Sweden, Italy, Germany), one in the US and three in China. All cohorts involved adult males and females.

Selenium exposure was assessed as plasma/serum selenium concentrations in the Hortega, ULSAM, DFJT, EPIC-Postdam and CSPPT studies, as dietary selenium intake estimates based on FFQs in the Moli-Sani study and one of analyses of the ORDET study and as toenail selenium concentrations in the NHS and HPFS cohorts and the other analysis of the ORDET study.

The evidence table is in Appendix [D.9.3](#). Key study characteristics, together with the risk estimates and related CIs, are plotted in Figures [21](#) and [22](#).

Tolerable upper intake level for selenium

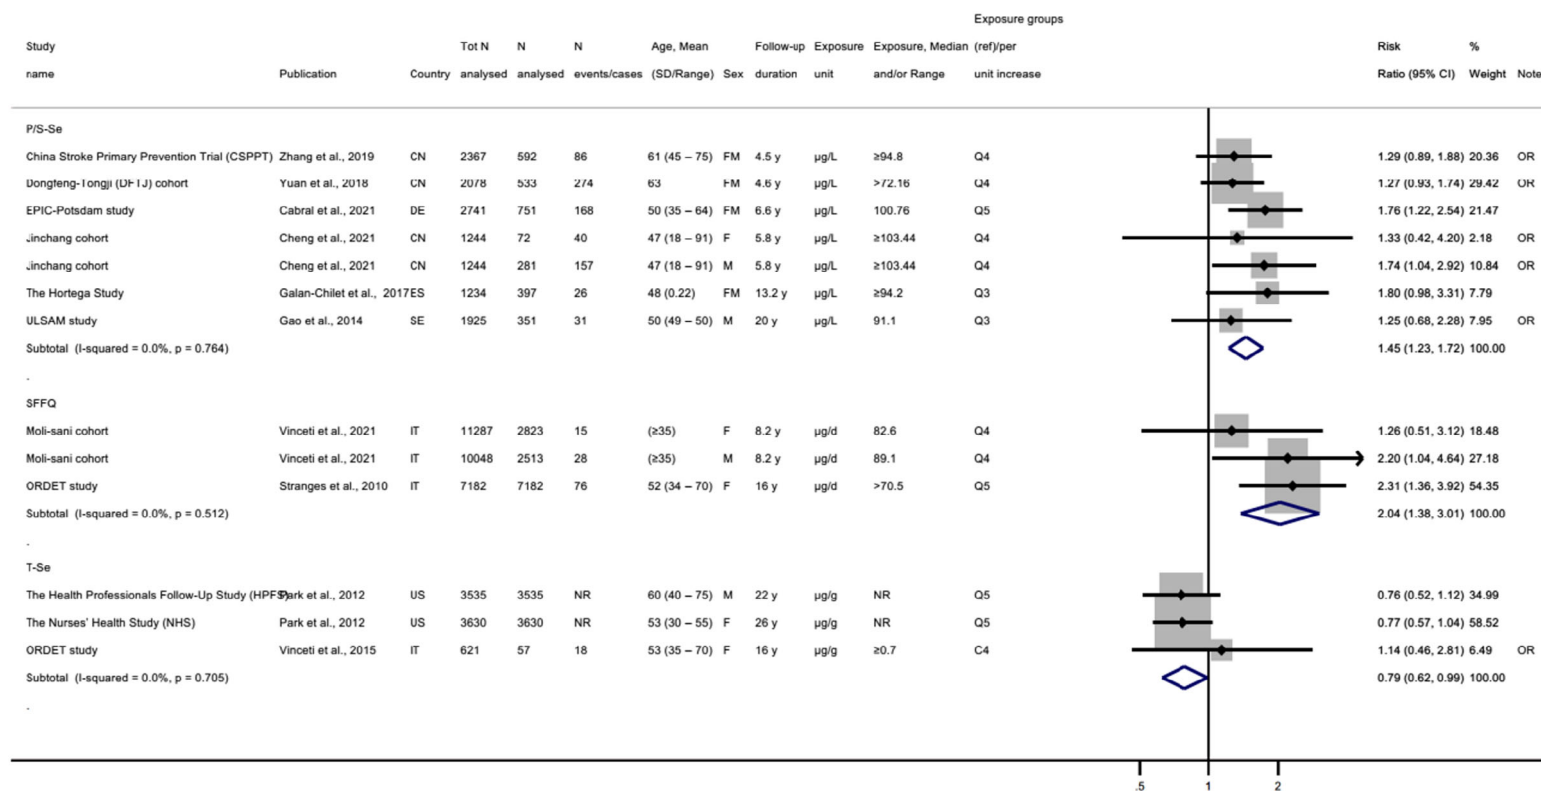

C: category; CI: confidence interval; CN: China; d: day; DE: Germany; EPIC: European Prospective Investigation into Cancer and Nutrition; ES: Spain; IT: Italy; N: number; NR: not reported; FM: females and males; SD: standard deviation; SE: Sweden; OR: Odds Ratio; ORDET: HORMones and Diet in the Etiology of Breast Cancer; P/S-Se: plasma/serum selenium; Q: quantile; ref: reference; SFFQ: semiquantitative food frequency questionnaire; T-Se: toenail selenium; ULSAM: Uppsala Longitudinal Study of Adult Men; US: United States; y: years.

Note: For Stranges et al., 2010: N analysed refers to total number of participants.

**Figure 21:** Observational studies on selenium exposure and incidence of T2DM, most adjusted RRs from PCs and NCCs

C: category; CI: confidence interval; CN: China; d: day; DE: Germany; EPIC: European Prospective Investigation into Cancer and Nutrition; ES: Spain; FM: females and males; IT: Italy; N: number; NR: not reported; ORDET: HORMones and Diet in the Etiology of Breast Cancer; P/S-Se: plasma/serum selenium; SD: standard deviation; SE: Sweden; SFFQ: food frequency questionnaire; T-Se: toenail selenium; OR: Odds Ratio; ULSAM: Uppsala Longitudinal Study of Adult Men; US: United States; y: years.  
 Note: For Stranges et al., 2010: N analysed refers to total number of participants.

**Figure 22:** Observational studies on selenium exposure and incidence of T2DM, most adjusted highest vs lowest RRs from PCs and NCCs

Eight observational studies found a positive association between selenium exposure and risk of T2DM, while two did not (Park et al., 2012; Vinceti et al., 2015b). These two studies used toenail selenium concentrations as a marker of exposure.

Overall, the Panel considers that the available BoE suggests a positive relationship between the intake of selenium and incidence of T2DM.

#### *LoE2. Standalone surrogate: measures of glucose tolerance*

One PC conducted in 76 healthy Japanese adults (Oo et al., 2018) reported a positive association between baseline serum selenoprotein P concentration and FBG after 4 years of follow-up ( $\beta = 0.237$ ,  $p = 0.033$ ), independently from age and baseline insulinogenic index,<sup>19</sup> BMI and HBA1c levels. Baseline serum selenium concentration and glutathione peroxidase 3 activities were not associated with FBG at follow-up.

The Panel notes the limited BoE from observational studies on measures of glucose tolerance (Appendix D.9.4).

#### Comprehensive UA

The Panel selected incidence of T2DM as the key endpoint for the comprehensive UA.

**Risk of bias appraisal.** All eligible observational studies were at low RoB (tier 1) (Table 8).

**Table 8:** Outcome of the risk of bias appraisal of the observational studies on incidence of T2DM

| Reference                  | Study name      | Exposure | Outcome | Confounding | Attrition/exclusion from analysis | Comparison Groups | Tier |
|----------------------------|-----------------|----------|---------|-------------|-----------------------------------|-------------------|------|
| Cabral et al. (2021)       | EPIC Potsdam    | +        | +       | ++          | ++                                | ++                | 1    |

++: Definitely low RoB; +: probably low RoB.

**Dose–response relationship.** A dose–response meta-analysis modelling the relationship between selenium exposure and risk of T2DM was performed using restricted cubic splines. The method and results are summarised below. The technical statistical report and all related references are in Annex B.

The NHS, the HPFS and one of the analyses of the ORDET study could not be included in the analysis as they used toenail selenium concentrations as markers of exposure. Upon request for additional data from the study authors of EPIC-Potsdam and ORDET, risk estimates by quintiles of exposure and not standardised for energy intake, respectively, were included in the dose–response meta-analysis. For three estimates of two studies (Stranges et al., 2010; Vinceti et al., 2018a and for males and females in Vinceti et al., 2021), in which selenium intake had been assessed with FFQs, exposure was converted to estimated mean plasma concentrations using the equation from the dose–response reported in Section 3.3.2.

Thirty non-referent most adjusted RRs from 10 study-specific analyses (5 PCs and 3 NCCs) were included ( $I^2 = 0\%$ ;  $p = 0.771$ ) in the dose–response analysis. The predicted pooled RR of T2DM was

<sup>19</sup> Calculated as the ratio of the increment of plasma insulin ( $\mu\text{U/mL}$ ) to the increment in glucose ( $\text{mg/L}$ ) during the first 30 min of OGTT.

1.10 (95% CI 1.07, 1.14) for an increase in selenium plasma concentrations of 10 µg/L in the linear model ( $p$  for linear trend < 0.0001) and 1.53 (95% CI 1.13, 2.06) at 100 µg/L in the non-linear model (restricted cubic splines with three knots at fixed percentiles, 10%, 50%, and 90%, of the distribution;  $p$  for non-linearity = 0.157).

A subgroup analysis on the three 'intake' estimates from the ORDET and the Moli-sani studies provided strong evidence of departure from linearity ( $p$  = 0.009; RR at 92 µg/L inflection point: 1.17 (95% CI 1.09, 1.26)); the subgroup of studies that reported on plasma selenium concentrations showed no support for non-linearity ( $p$  = 0.831). The inclusion of the two studies for which the conversion was necessary (Stranges et al., 2010; Vinceti et al., 2018a) was found to have little impact on the relative risk (RR) estimate but improved its precision (Annex B).

A sensitivity analysis excluding females' study-specific trends confirmed no evidence of departure from linearity ( $p$  = 0.568), while in a sensitivity analysis excluding Cheng et al. (2022) (Jinchang cohort; in which it had been observed that the risk of developing T2DM differed between men and women) and with a choice of four knots (Harrell: 5%, 35%, 65%, 95%) the data supported a departure from linearity ( $p$  = 0.039; RR at 94 µg/L inflection point: 1.12 (95% CI 1.06, 1.18)) (Annex B).

Overall, the dose–response meta-analysis could not consistently identify departures from non-linearity between plasma selenium concentrations and risk of T2DM over the range of plasma selenium concentrations investigated.

The Panel considers that a linear positive dose–response between plasma selenium concentration and incidence of T2DM over a range of plasma selenium concentrations which largely corresponds to selenium intake levels achieved through the natural selenium content of food, is not biologically plausible. A major limitation of the analysis relates to the lack of data points in the higher range of plasma selenium concentrations (> 120 µg/L). The Panel notes that the baseline mean/median plasma concentrations in the trials described in Section 3.5.10.1 were between 114 and 137 µg/L, which is at or above the plasma selenium concentrations found in observational studies included in this assessment.

There are uncertainties associated with this dose–response relationship:

- The observed association could also be due to confounding factors. For example, other dietary factors in foods that contain selenium could contribute to the risk of T2DM. Key potential confounders (i.e. age, sex, BMI) were adjusted for in all eligible cohorts. Nevertheless, unmeasured confounding cannot be excluded.
- Factors other than dietary selenium intake affect plasma selenium concentrations (Section 3.3 and Appendix A). It cannot be excluded that metabolic disturbances (e.g. an increase in oxidative stress), occurring before T2DM is diagnosed, could affect plasma selenium concentrations. In the ORDET cohort where the association with incidence of T2DM was investigated using both plasma and toenail Se concentrations, a positive association was found with plasma selenium concentrations, while no association was found with toenail selenium concentrations. Similarly, no association was found between toenail selenium concentrations and incidence of T2DM in the NHS and HPFS cohorts.

**Publication bias.** Publication bias in the subset of studies included in the dose–response modelling was investigated through a funnel plot (Figure 23) and Egger's regression. No support for a 'small-study effect' (larger effects in PCs where RRs are more imprecise) was found ( $p$  = 0.444; intercept 0.88, 95% CI –1.76, 3.53).

**Figure 23:** Funnel plot of the observational studies on incidence of T2DM included in the dose–response analysis

*LoE4. Complementary: Measures of blood glucose control*

In a cohort of 2,774 adult men and women in Germany (Monitoring of Trends and Determinants in Cardiovascular Diseases (MONICA)/Cooperative Health Research in the Region of Augsburg (KORA) cohort), no association was found between the intake of selenium from food supplements (assessed through interviews at baseline) and HbA1c levels after 10 years of follow-up (Schwab et al., 2015). In a population of 548 mother–child pairs in Mexico (PROGRESS cohort), no association was found between blood selenium concentrations during the 2nd trimester of pregnancy and HbA1c levels measured in children at 4–6 years of age (Kupsco et al., 2019).

The Panel notes the limited BoE from observational studies on these endpoints.

**Consistency across LoEs.** The Panel considers that this cannot be assessed given the limited BoE available on LoE2 and LoE4.

**Outcome of the comprehensive analysis of the uncertainties**

**Table 9:** Comprehensive analysis of the uncertainties in the BoE from observational studies

| What is the level of certainty that the intake of <b>selenium</b> is positively and causally associated with the risk of T2DM? |  |  |
|--|--|--|
| BoE  | LoE1. Standalone main. Endpoint: incidence of T2DM<br>10 observational studies, 47,271 participants (42.6% males). Pooled mean effect estimate, RR (95% CI) = 1.45 (1.23, 1.72) for six studies which used plasma/serum Se (7 study-specific analyses: CSPPT, DFTJ, EPIC-Postdam, Jinchang males, Jinchang females, Hortega, ULSAM); pooled mean effect estimate, RR (95% CI) = 2.04 (1.38, 3.01) for two studies which used a FFQ (3 study-specific analyses: ORDET, Moli-Sani males, Moli-Sani females); pooled mean effect estimate, RR (95% CI) = 0.79 (0.62, 0.99) for two studies which used toenail selenium (3 study-specific analyses: HPFS, NHS, ORDET). | Initial certainty:<br><b>Moderate (&gt; 50%–75% probability)</b> |

**Conclusions from observational studies.** The level of certainty in a positive and causal relationship between the intake of selenium and risk of T2DM is low (rationale in Table 9).

### 3.5.10.3. Mode of action

Several possible mechanisms by which selenium could be involved in the development of T2DM have been proposed in the literature.

As discussed in Section 3.5.1, endoplasmic reticulum stress and increased ROS production have been suggested to play a role in the development of T2DM (Zachariah et al., 2021). It has also been suggested that selenium may on the one hand stimulate biosynthesis and secretion of insulin in pancreatic beta-cells and on the other may lead to a reduced insulin sensitivity in target cells. It has been put forward that both purported mechanisms could be mediated through the upregulation of selenoproteins involved in the antioxidant network, in particular, glutathione peroxidases and thioredoxin reductases. An upregulation of the antioxidant defence system may lead to a reduction in hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) concentrations in the target cells. As H<sub>2</sub>O<sub>2</sub> is essential for insulin signalling in target cells, its reduction may lead to an impairment of the insulin signalling cascade. The effect on an increased insulin secretion has been proposed to be also due to a modulation of H<sub>2</sub>O<sub>2</sub> concentrations in the β-cells where H<sub>2</sub>O<sub>2</sub> is essential for insulin biosynthesis (Steinbrenner, 2013; Steinbrenner et al., 2022). Mice with a global overexpression of glutathione peroxidase 1, which were fed a selenium-adequate diet from 8 to 24 weeks of age, developed hyperglycaemia, hyperinsulinaemia, mild insulin resistance and obesity. The insulin-induced activation of the insulin receptor was attenuated (McClung et al., 2004). An overexpression of β-cell specific glutathione peroxidase 1, reversed hyperglycaemia in *db/db* mice, increased β-cell volume and insulin granulation (Harmon et al., 2009). Glutathione peroxidase 1 knock-out mice were protected from high-fat-diet-induced insulin resistance and showed improved insulin signalling in muscle cells, but not hepatocytes (Loh et al., 2009). In another study, glutathione peroxidase 1 knock-out mice had lower fasting plasma

insulin concentrations, glucose-stimulated insulin secretion and lower  $\beta$ -cell mass as compared with the wild type (Wang et al., 2011). An involvement of selenoprotein P, the transport protein in blood, in the upregulation of the expression of glutathione peroxidase has been also suggested. It has been observed that the treatment of mice with purified human selenoprotein P induced glucose intolerance and insulin resistance, while selenoprotein P knock-out was associated with improved glucose tolerance and insulin resistance. Also, *in vitro* studies seem to suggest an involvement of selenoprotein P in a potential adverse effect on the insulin signalling cascade (Misu et al., 2010).

The Panel notes that even though there is evidence that oxidative stress and the concomitant upregulation of the antioxidant networks may play a role in the pathogenesis of T2DM, convincing evidence lacks that this antioxidant network is upregulated as a sole response to excess selenium intakes, in particular considering that selenoprotein concentrations in humans reach a plateau beyond a certain selenium intake. Taking this into account, it has been speculated that additional selenium species beyond selenoproteins, i.e. low molecular weight selenometabolites might have specific actions on signalling and metabolic pathways (Steinbrenner et al., 2022).

The Panel considers that potential mechanisms by which excess intake of selenium may increase the risk of T2DM are not firmly established.

#### **3.5.10.4. Overall conclusions on type 2 diabetes mellitus**

There is evidence from RCTs for a positive and causal relationship between the intake of selenium and risk of T2DM (moderate level of certainty). The available BoE from observational studies and information regarding the mode of action cannot be used to modify the level of certainty in this conclusion.

#### **3.5.11. All-cause mortality**

All-cause mortality rate is included in the standalone main LoE.

##### **3.5.11.1. Intervention studies**

*LoE1. Standalone main: All-cause mortality rate*

The effect of selenium supplementation vs placebo on all-cause mortality was investigated in five intervention studies (NBT, Clark et al., 1996; NPC, Clark et al., 1996; SWOG, Marshall et al., 2011; DK-PRECISE, Rayman et al., 2018; SELECT, Lippman et al., 2009). The supplemental doses of selenium ranged from 200 to 400  $\mu\text{g}/\text{day}$  and the mean study intervention period ranged from 3 up to 12 years. The SELECT (Klein et al., 2011) and DK-PRECISE (Rayman et al., 2018) also reported results for an additional observational follow-up period of 3 and 10 years after cessation of the intervention, respectively.

The study size ranged between 437 and 17,448 participants; one trial included healthy men and women with relatively low selenium status (DK-PRECISE), one trial included healthy men (SWOG), two trials included men at risk of prostate cancer (NBT, SELECT), and one trial involved men and women with confirmed history of non-melanoma skin cancer (NPC). Number of deaths by study arm was recorded as part of the evaluation of adverse events/toxicity in the five trials. Mean plasma selenium concentration at baseline were between 87 (DK-PRECISE) and 138  $\mu\text{g}/\text{L}$  (SWOG) across trials.

An overview of eligible studies is provided in the evidence table presented in Appendix D.10.1. Key study characteristics, together with the effect estimates and related CIs, are plotted in Figure 24.

\*Denotes estimated risk ratio and standard error.

CI: confidence interval; d: day; duration: duration of the intervention and follow-up phase for studies with an observational period (i.e. Klein et al., 2011; Rayman et al., 2018); DK: Denmark; FM: females and males; FUP: follow-up; GN: highest dose group from each study; HR: hazard ratio; NBT: Negative Biopsy Trial; NZ: New Zealand; PR: Puerto Rico; PRECISE: PREvention of Cancer by Intervention with Selenium; RCT: randomised controlled trial; SD: standard deviation; Se: selenium; SELECT: Selenium and Vitamin E Cancer Prevention Trial; Suppl-O: organic selenium supplements; SWOG: Southwest Oncology Group; US: United States; y: years.

**Figure 24:** Intervention studies investigating the effect of selenium supplementation vs placebo on all-cause mortality, sorted by supplemental dose

There is no indication for an increased mortality risk in the groups which received selenium supplementation in the NPC trial, the NBT, the SWOG trial and the SELECT (dose: 200 to 400 µg/day; duration: 3 to 12 years) (Figure 24). In the DK-PRECISE, the HR comparing 300 µg/day selenium to placebo was 1.62 (95% CI 0.66, 3.96) after 5 years of treatment and 1.59 (95% CI 1.02, 2.46) after an additional 10 year of observational follow-up (Figure 22). Mortality rates in the groups receiving 100 and 200 µg/day selenium were similar to the control group (Rayman et al., 2018) (see evidence table in Appendix D.10.1). The Panel notes the excess mortality with selenium supplementation of 300 µg/day for 5 years in the DK-PRECISE.

Overall, the Panel considers that the available BoE from RCTs does not suggest a positive relationship between selenium supplementation and all-cause mortality.

### 3.5.11.2. Observational studies

#### LoE1. Standalone main: All-cause mortality rate

Sixteen prospective observational cohorts investigated the relationship between selenium exposure and all-cause mortality (Virtamo et al., 1985; Kilander et al., 2001; Wei et al., 2004; Akbaraly et al., 2005; Ray et al., 2006; González et al., 2007; Lauretani et al., 2008; Eaton et al., 2010; Bates et al., 2011; Alehagen et al., 2016; Henríquez-Sánchez et al., 2016; Sun et al., 2016; Vinceti et al., 2016a; Giovannini et al., 2018; Schomburg et al., 2019; Li et al., 2020b).

The size of the cohorts ranged between 215 participants (Asturias cohort) and 73,854 participants (SWHS). The length of follow-up ranged from 4 (Prevención con Dieta Mediterránea (PREDIMED) and Asturias cohorts) to 27 years (Reggio Emilia cohort). Cohorts were located in Europe (Spain, Finland, France, Italy, Sweden, UK), China, and the US. Most cohorts involved adult males and females, while one cohort involved females only, two cohorts involved males only.

Twelve studies assessed exposure as plasma or serum selenium (Virtamo et al., 1985; Kilander et al., 2001; Wei et al., 2004; Akbaraly et al., 2005; Ray et al., 2006; González et al., 2007; Lauretani et al., 2008; Eaton et al., 2010; Bates et al., 2011; Alehagen et al., 2016; Giovannini et al., 2018; Li et al., 2020b), one study assessed plasma selenoprotein P concentration (Schomburg

et al., 2019), two studies assessed dietary intake of selenium through a SFFQ (Henríquez-Sánchez et al., 2016; Sun et al., 2016), and one study investigated selenium exposure through drinking water (Vinceti et al., 2016a). The evidence table is in Appendix D.10.2. Key study characteristics, together with the risk estimates and related CIs, are plotted in Figures 25 and 26.

Tolerable upper intake level for selenium

\*Denotes Q1 vs Q2-Q3-Q4.

C: category; CI: confidence interval; CN: China; ES: Spain; EVA: Étude du Vieillissement Artériel; FI: Finland; FM: females and males; FR: France; iSIRENTE: Invecchiamento e Longevità nel Sirente; InCHIANTI: Invecchiare in Chianti; IT: Italy; N: number; NHANES: National Health and Nutrition Examination Survey; NR: not reported; P/S-Se: plasma/serum selenium; Q: quantile; ref: reference; RR: risk ratio; SD: standard deviation; SE: Sweden; Se: selenium; SES: cohort in the south-east of Sweden; UK: United Kingdom; US: United States; WHAS: Women's Health and Aging Studies; y: years.

**Figure 26:** Observational studies on measures of selenium exposure other than plasma/serum selenium and all-cause mortality

Overall, prospective observational studies investigating the association between plasma/serum selenium concentration (Figure 25) or other measures of selenium exposure (Figure 26) do not support a positive association with all-cause mortality.

The Panel considers that the available BoE from observational studies does not suggest a positive relationship between dietary selenium intake and all-cause mortality over the range of exposure investigated in these studies.

### 3.5.11.3. Overall conclusions on all-cause mortality

The Panel considers that the available BoE does not suggest a positive relationship between dietary selenium intake and all-cause mortality.

## 3.6. Hazard characterisation

### 3.6.1. Selection of a critical effect and reference point

The Panel considers that the progression of the effects of excess selenium on keratinised epithelia or integuments (hair, skin, nails) as seen in selenosis is a consequence of altered protein metabolism. Alopecia is an early observable feature and a well-established adverse effect of excess selenium exposure (Sections 3.5.2.1 and 3.5.2.2). Thus, based on considerations of causality and biological relevance, the Panel selects alopecia as the critical endpoint on which to base a UL for selenium (Section 3.6.2).

There are indications from one RCT, the SELECT (Lippman et al., 2009), that at average selenium intakes of 330 µg/day (around 130 µg/day from the background diet plus 200 µg/day from supplements), the risk of developing alopecia is increased as compared to un-supplemented individuals with similar background selenium intakes. This was accompanied by an increased risk of other features of selenium toxicity, such as dermatitis (Section 3.5.2.2). The Panel notes uncertainties related to the self-reporting of adverse events in that study; signs and symptoms of selenosis were, however, recorded among the pre-planned adverse events monitored in the study using standardised criteria. Strengths of this study also lie in its controlled setting regarding selenium intake (fixed supplemental dose, high level of compliance among participants), its large sample size and its long duration. The Panel uses the LOAEL of 330 µg/day identified from the SELECT as a RP for the derivation of an UL for selenium.

### 3.6.2. Derivation of a tolerable upper intake level

#### 3.6.2.1. Adults

The Panel notes that men aged  $\geq 50$  years, recruited from the general population in the US, were involved in the SELECT. There is no indication from the literature that younger men may be more susceptible to selenium toxicity. The Panel considers that the results from the SELECT can be generalised to the European male adult population and that the LOAEL of 330 µg/day derived from that study is applicable to this population group.

The Panel considers that the large number (~8,700 individuals per arm) and characteristics of the participants involved in the SELECT adequately account for inter-individual variability among adult men. No UF is required to account for this source of uncertainty.

The following uncertainties need to be accounted for:

- The use of a LOAEL as the RP for the derivation of the UL. Data are lacking to characterise the steepness of the dose–response curve. However, when compared to controls, an excess of less than 1% of the selenium supplemented participants exhibited alopecia in the SELECT, possibly indicating that the NOAEL might not be far from the LOAEL.
- The lack of data in women. However, the Panel notes that there is no indication from the literature that women may be more susceptible than men to selenium toxicity.

Taking this into account and considering that alopecia is an early sign of selenium toxicity, is of mild nature and likely to be reversible, the Panel considers that an UF of 1.3 is sufficient to cover for the uncertainties. After rounding to the closest 5 µg, it results in an UL of 255 µg/day for adult men and women, which is judged by the Panel to be protective for adverse effects of excess selenium intake based on available data. The choice of an UF of 1.3 is based on expert judgement and is a pragmatic choice which allows to extrapolate the value for adults to infants and children (Sections 3.6.2.3 and

3.6.2.4). The application of a higher UF would result in ULs for younger age groups very close to background intakes of selenium observed in European countries (Sections 3.4.2 and 3.4.3). The Panel notes that no adverse effects related to selenium excess intake have been reported with the current background intake of selenium (intake from food, excluding food supplements) in European countries.

The Panel further notes that the UL value is lower than the mean selenium intake levels which have been associated with an increased number of T2DM cases in intervention studies (Section 3.5.10).

The UL covers selenium intake from all dietary sources based on available evidence, including the forms currently authorised for addition to food<sup>10</sup> and use in food supplements<sup>20</sup> (i.e. sodium selenate, sodium hydrogen selenite, sodium selenite, L-selenomethionine and selenium-enriched yeast).

### 3.6.2.2. Pregnant and lactating women

There is no indication for a specific risk or increased susceptibility to adverse effects of excessive selenium intake during pregnancy or lactation from populations living in seleniferous areas.

In line with what was previously proposed by the SCF (2000a), the Panel considers that the UL for women also applies during pregnancy and lactation.

### 3.6.2.3. Children and adolescents

There are no data to support a derivation of a UL for children. On the other hand, there is no indication from the literature that children may be more susceptible than adults to selenium toxicity. The Panel considers that it is appropriate to extrapolate the UL from adults to children based on allometric scaling (body weight<sup>0.75</sup>) as it is the preferred method to adjust for metabolic differences between age groups, using reference body weights (EFSA NDA Panel, 2022).

ULs are established for the age categories proposed by the Panel in its guidance on establishing ULs (EFSA NDA Panel, 2022). Values are rounded to the closest 5 µg (Table 10).

**Table 10:** UL for children and adolescents aged 1 year to 17 years

| Age range   | Reference bw males and females (kg) <sup>(a)</sup> | UL males and females (µg/day) |
|-------------|--|-------------------------------|
| 1–3 years   | 11.9   | 70                            |
| 4–6 years   | 19.0   | 95                            |
| 7–10 years  | 28.7   | 130                           |
| 11–14 years | 44.6   | 180                           |
| 15–17 years | 60.3   | 230                           |

bw: body weight; UL: Tolerable Upper Intake Level.

(a): The median weight for age at the mid-age of each age category used as reference weight. Sources: WHO Multicentre Growth Reference Study Group (2006) for children aged 1–3 years; van Buuren et al. (2012) for children and adolescents aged 4–17 years.

### 3.6.2.4. Infants

There are no data to support a derivation of an UL for infants. On the other hand, there is no indication from the literature that infants may be more susceptible than adults to selenium toxicity. The Panel considers that it is appropriate to extrapolate the UL from adults to infants aged ≥ 4 months based on allometric scaling (body weight<sup>0.75</sup>) as it is the preferred method to adjust for metabolic differences between age groups, using reference body weights (EFSA NDA Panel, 2022).

ULs established for infants aged 4–6 months and 7–11 months, respectively. Values are rounded to the closest 5 µg.

The Panel notes that breast milk concentration reflects maternal selenium intake and that there are large variations in breast milk selenium concentrations between countries or regions within a country (EFSA NDA Panel, 2014). In European countries, selenium concentrations in mature breast milk of 50 µg/L or above have been measured (Miklavcic et al., 2013; Krachler et al., 2000) corresponding to 40 µg per day or more based on an average consumption of 800 mL/day breast milk, which indicates that the UL established for infants aged 4 to 6 months can be considered sufficiently protective (Table 11).

<sup>20</sup> Directive 2002/46/EC of the European Parliament and of the Council of 10 June 2002 on the approximation of the laws of the Member States relating to food supplements. *OJ L 183*, 12.7.2002, pp. 51–57.

**Table 11:** UL for infants aged 4 to 11 months

| Age range   | Reference bw males and females (kg) <sup>(a)</sup> | UL males and females (µg/day) |
|-------------|--|-------------------------------|
| 4–6 months  | 7.2  | 45                            |
| 7–11 months | 8.6  | 55                            |

bw: body weight; UL: Tolerable Upper Intake Level.

<sup>(a)</sup>: The averages of the median weights-for-age for boys and girls at 5 and 9 months, respectively, were used as reference weights (WHO Multicentre Growth Reference Study Group, 2006).

### 3.7. Risk characterisation

The ULs apply to the general European population and relate to selenium intake from all dietary sources.

Among adults, mean and high consumers (P95) selenium intake estimates, excluding supplements, are below the UL of 255 µg/day, across countries and age groups (Sections 3.4.2 and 3.4.3). The Panel considers that it is unlikely that adult consumers exceed the UL for selenium, except for regular users of food supplements containing high daily doses of selenium or regular consumers of Brazil nuts (Section 3.4.1).

Based on EFSA intake estimates, mean and high consumers' (P95) selenium intakes, excluding supplements, are below the ULs for infants and children, including adolescents, across all surveys (Section 3.4.2). Considering national reports published after EFSA's intake assessment (Section 3.4.3, Annex D), the Panel notes that high consumers (P95) intakes estimated for some groups of the Spanish and French surveys exceed the ULs. The Panel notes that no risk has been reported with the current levels of selenium intake in EU countries from food (excluding food supplements) in toddlers and children. The Panel, however, considers that selenium-containing supplements in toddlers and children should be used with caution based on individual needs, upon consultation with a healthcare provider.

With respect to infants, the Panel also notes that exclusively formula-fed infants being fed a formula with the currently highest permitted concentration of selenium as per Delegated Regulation (EU) 2016/127<sup>21</sup> (i.e. 8.6 µg/100 kcal), will consume on average 43 µg/day selenium, using mean formula intakes in the first half year of life of 500 kcal/day as a basis. High consumers can reach formula intakes of around 1,000 mL (EFSA Scientific Committee, 2017b) (or 700 kcal/day using as a basis the maximum energy content of a formula as permitted by Delegated Regulation (EU) 2016/127). The Panel notes that in these high consumers, the selenium intake would be 60 µg/day. Therefore, infants from 4–6 months and infants from 7–11 months for whom formula with the highest permitted concentration of selenium is predominant in the diet may exceed the UL of 45 µg/day and 55 µg/day, respectively, when such a formula is consumed on a regular basis.

### Conclusions

The following ULs are established:

| Age group       | UL males and females (µg/day) |
|-----------------|-------------------------------|
| 4–6 months      | 45                            |
| 7–11 months     | 55                            |
| 1–3 years       | 70                            |
| 4–6 years       | 95                            |
| 7–10 years      | 130                           |
| 11–14 years     | 180                           |
| 15–17 years     | 230                           |
| Adults          | 255                           |
| Pregnant women  | 255                           |
| Lactating women | 255                           |

UL, Tolerable Upper Intake Level.

<sup>21</sup> Commission Delegated Regulation (EU) 2016/127 of 25 September 2015 supplementing Regulation (EU) No 609/2013 of the European Parliament and of the Council as regards the specific compositional and information requirements for infant formula and follow-on formula and as regards requirements on information relating to infant and young child feeding. OJ L 25, 2.2.2016, pp. 1–29.

## Recommendations for research

- Biomarkers of exposure and effect that can be used for the risk assessment of selenium are limited. The identification and validation of biomarkers would allow a more refined hazard characterisation (i.e. dose–response assessment and characterisation of critical levels). Further investigation of homeostatic and adaptive responses to excess selenium intakes and of the mechanistic pathways involved in adverse effects of selenium is recommended, also with the aim of validating biomarkers (EFSA NDA Panel, 2022).
- Further investigation of the relationship between excess selenium intake and the risk of diseases such as T2DM is needed to ascertain further the causality of reported associations (e.g. strengthening the understanding of underlying mode of actions).
- Further investigation of age and sex susceptibility to selenium toxicity is needed. Genetic traits that may influence individual susceptibility (e.g. TMS<sub>e</sub> eliminators vs non eliminators) also requires further investigation.
- Additional research is needed regarding potential differences in the toxicity profile of the various dietary forms of selenium (e.g. organic vs inorganic Se).
- Data on the consumption of selenium-containing fortified and enriched foods, and food supplements in EU populations are scarce. For the intake assessment of selenium and risk characterisation, there is a need to generate more data on selenium intake from food supplements and fortified/enriched foods among users of those products. Improved food composition databases, which include analytical results representative of the food supply of the survey population (using appropriate sampling methods), are also needed to enhance estimations of selenium intake.

## Appendix A – Characteristics of selenium biomarkers as measures of selenium intake

| Biomarker   | Description   | Influencing factors   | Characteristics  | Sensitivity as biomarker of selenium intake <sup>(b)</sup>   |
|---|---|---|--|--|
| <b>Serum/plasma<sup>(a)</sup><br/>Se concentrations</b> | Non-cellular Se; organic (mainly selenoproteins (selenoprotein P, glutathione peroxidase 3, thioredoxin reductases)); albumin-bound SeMet; selenosugars (Ward-Deitrich et al., 2021) and inorganic selenium (Vinceti et al., 2015a; Filippini et al., 2018) | <ul style="list-style-type: none"> <li>- Sex, age (Sheehan and Halls, 1999; Muntau et al., 2002)</li> <li>- Smoking status (Swanson et al., 1990; Alfthan and Neve, 1996; Kocyyigit et al., 2001; Arnund et al., 2006; Filippini et al., 2018)</li> <li>- Inflammation, disease (Miller et al., 1983; Nichol et al., 1998; Combs et al., 2012)</li> <li>- Chemical nature of dietary Se</li> <li>- <i>GPX1</i> 679 genotype (Combs et al., 2012)</li> </ul> | <ul style="list-style-type: none"> <li>- Varies across geographical locations (Fordyce, 2013; Stoffaneller and Morse, 2015; Ibrahim et al., 2019)</li> <li>- Responds to Se supplementation over wide range of supplemental intake (15–700 µg/d); dose-dependent (Ashton et al., 2009)</li> <li>- Higher response to organic Se, especially in non-deficient populations (Thomson et al., 1982; Burk et al., 2006; Combs, 2015)</li> <li>- Suitable for speciation analysis</li> </ul> | <ul style="list-style-type: none"> <li>- Can detect changes in intake over short/medium-term</li> <li>- Can distinguish 'high' from 'low' consumers</li> <li>- Low responsiveness to inorganic Se intake in Se-replete populations (Neve, 1995)</li> <li>- Population-specific equations to predict dietary Se intake (Longnecker et al., 1996; Burk et al., 2006; Combs, 2015)</li> </ul> |
| <b>RBC Se concentrations</b>                            | Mainly glutathione peroxidase 1 and Hb-bound Se   | <ul style="list-style-type: none"> <li>- Age (Lloyd et al., 1983)</li> <li>- Chemical nature of dietary Se (Neve, 1995)</li> <li>- Unaffected by inflammatory responses (Stefanowicz et al., 2013)</li> </ul>   | <ul style="list-style-type: none"> <li>- Responds to Se supplementation, more slowly than serum/plasma (Neve, 1995; Ashton et al., 2009)</li> </ul>  | <ul style="list-style-type: none"> <li>- Can detect changes in intake over medium/long-term</li> <li>- Can distinguish 'high' from 'low' consumers</li> </ul>  |
| <b>Whole blood Se concentrations</b>                    | Cellular and non-cellular circulating Se  | <ul style="list-style-type: none"> <li>- Age (Lloyd et al., 1983)</li> <li>- Smoking status (Lloyd et al., 1983)</li> <li>- Disease (Muecke et al., 2009; Muecke et al., 2018)</li> <li>- Chemical nature of dietary Se</li> </ul>  | <ul style="list-style-type: none"> <li>- Varies across geographical locations (Fordyce, 2013)</li> <li>- Responds to Se supplementation over wide range of supplemental intake (15–200<sup>(c)</sup> µg/d); dose-dependent (Neve, 1995; Ashton et al., 2009)</li> <li>- Suitable for speciation analysis</li> </ul>  | <ul style="list-style-type: none"> <li>- Can detect changes in intake over medium/long-term</li> <li>- Can distinguish 'high' from 'low' consumers</li> <li>- Population-specific to predict dietary Se intake (Yang et al., 1989b)</li> </ul>   |
| <b>Urine Se concentrations</b>                          | Primary route of Se elimination, mainly as selenosugars 1 and 3, trimethylselenonium ion (TMSe) and selenate and Se-methylselenoneine   | <ul style="list-style-type: none"> <li>- Sex</li> <li>- Chemical nature of dietary Se (Burk et al., 2006)</li> <li>- Se status</li> <li>- Kidney function (Oster and Prellwitz, 1990)</li> <li>- Physical activity (Rodriguez Rodriguez et al., 1995)</li> <li>- <i>GPX1</i> 679 genotype (Combs et al., 2012)</li> </ul>   | <ul style="list-style-type: none"> <li>- Varies across geographical locations (Fordyce, 2013)</li> <li>- Responds to Se supplementation over wide range of supplemental intake (100–700 µg/d); dose-dependent (Yang et al., 1989b; Burk et al., 2006; Combs et al., 2012)</li> <li>- Correlates with plasma Se over a wide range (Yang et al., 1989b; Sanz Alaejos and Diaz Romero, 1993)</li> </ul>   | <ul style="list-style-type: none"> <li>- Can detect changes in intake over short term</li> <li>- Can distinguish 'high' from 'low' consumers'</li> <li>- Population-specific to predict dietary Se intake (Yang et al., 1989b; Sanz Alaejos and Diaz Romero, 1993; Longnecker et al., 1996; Combs, 2015)</li> </ul>  |

| Biomarker  | Description   | Influencing factors   | Characteristics   | Sensitivity as biomarker of selenium intake <sup>(b)</sup>   |
|--|---|---|---|--|
|  |   | - TMSe eliminators vs non-eliminators (Kuehnelt et al., 2015; Lajin et al., 2016a)  | - Suitable for speciation analysis  |  |
| <b>(Toe)nail/hair Se concentrations</b>                                      | Deposition of Se  | <ul style="list-style-type: none"> <li>- Age (Hunter et al., 1990)</li> <li>- Smoking (Swanson et al., 1990; van den Brandt et al., 1993; Virtanen et al., 1996; Xun et al., 2011)</li> <li>- Chemical nature of dietary Se (i.e. toenail Se content might not reflect inorganic Se exposure (Filippini et al., 2017))</li> <li>- Growth rate (Slotnick and Nriagu, 2006)</li> <li>- External exposure (e.g. Se-containing shampoos)</li> </ul> | <ul style="list-style-type: none"> <li>- Varies across geographical locations (Morris et al., 1983; Hunter et al., 1990; Fordyce, 2013)</li> <li>- Responds slowly to Se supplementation (weeks to months) (Gallagher et al., 1984; Longnecker et al., 1993)</li> <li>- Correlation with Se intake (Hunter et al., 1990; Swanson et al., 1990) and blood/plasma Se (Yang et al., 1989a; Satia et al., 2006) over a wide range shown in some studies. Other studies found no or low association with Se intake (Hunter et al., 1990; Al-Saleh and Billedo, 2006; Satia et al., 2006; Vinceti et al., 2012) or blood selenium (Satia et al., 2006; Vinceti et al., 2012; Chawla et al., 2020).</li> </ul> | <ul style="list-style-type: none"> <li>- Can detect changes in intake over medium/long-term</li> <li>- Can distinguish 'high' from 'low' consumers</li> <li>- Requires standardised procedures for sample collections and treatments as prone to contamination (Slotnick and Nriagu, 2006)</li> <li>- Population-specific to predict dietary Se intake based on toenail content (Longnecker et al., 1996)</li> </ul> |
| <b>Plasma selenoprotein P concentrations</b>                                 | 20%–70% of total plasma Se; mostly secreted in the liver (Saito, 2021)  | <ul style="list-style-type: none"> <li>- Inflammation; oxidative stress (Saito, 2020; Vinceti et al., 2022); insulin levels and glucose metabolism (Speckmann et al., 2008; Mao and Teng, 2013; Schomburg, 2022)</li> <li>- Se status</li> <li>- Selenoprotein P polymorphisms (Meplan et al., 2007)</li> </ul>   | <ul style="list-style-type: none"> <li>- Responds rapidly to Se supplementation in populations with 'low Se' intake/status (Duffield et al., 1999; Hurst et al., 2010)</li> <li>- Correlates with plasma/serum Se up to 80–90 µg/L (Hurst et al., 2013)</li> </ul>  | <ul style="list-style-type: none"> <li>- Responsive in population with Se status in the lowest range</li> <li>- Plateau (i.e. maximum expression) in the higher range of Se intake (&gt; ca. 60–70 µg/day)</li> </ul>  |

AAS: Atomic absorption spectrometer; d: day; ELISA: enzyme-linked immunosorbent assay; GF: graphite-furnace; Hb: haemoglobin; HG: Hydride-generation; ICP-MS: Inductively coupled plasma mass spectrometry; RBC: red blood cell; Se: selenium.

(a): Serum and plasma selenium concentrations are considered equivalent.

(b): Short term: hours/days; Medium term: weeks; Long term: months.

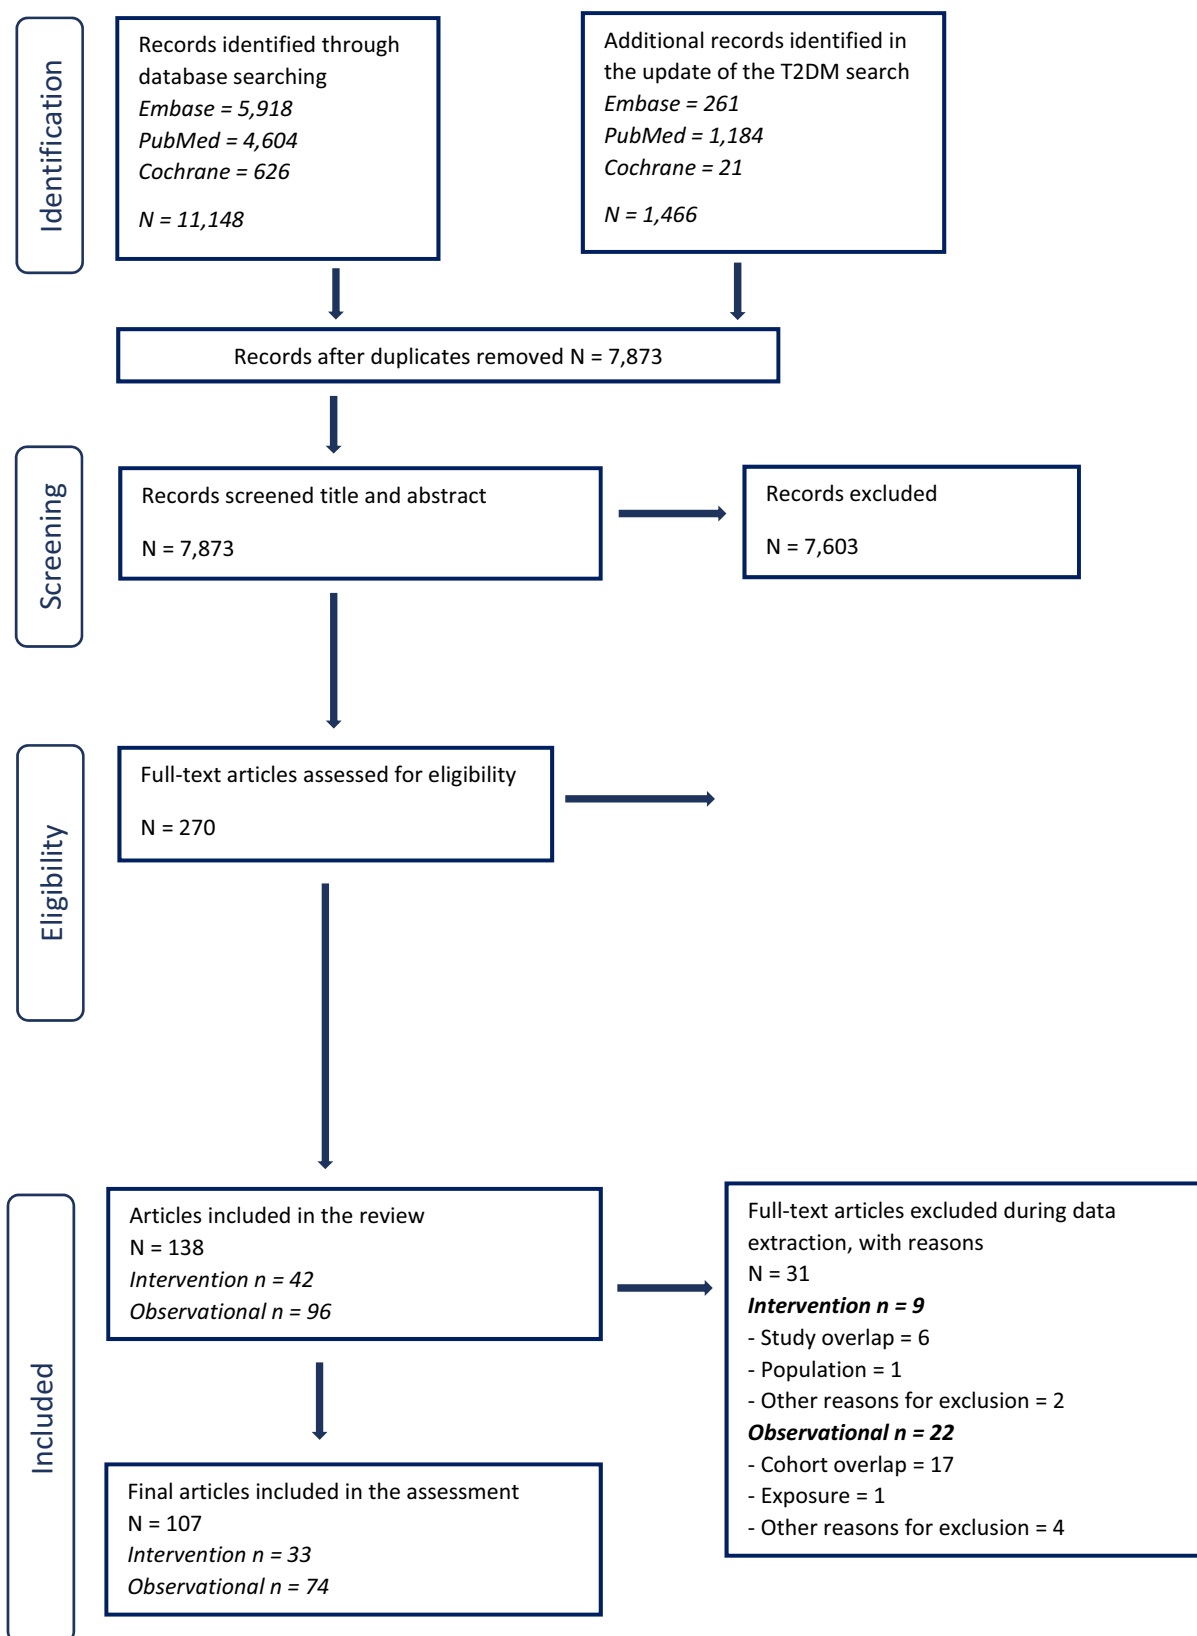

(c): Highest dose tested in available supplementation trials reporting on blood Se concentration.

### Appendix B – Flow charts for the selection of human studies

Note: 26 articles identified from the search for sQ1 were included in the dose–response plasma-intake modelling.

**Figure B.1:** Flow chart for the selection of studies addressing sQ1

Note: 17 studies identified through the search addressing sQ2 were included in the dose–response analysis for plasma-intake.

**Figure B.2:** Flow chart for the selection of studies addressing sQ2

## Appendix C – RoB appraisal

### C.1. Criteria used to appraise RoB in eligible studies

#### C.1.1. Human controlled trials

| Question  | Rating | Explanation for expert judgement  |
|---|--------|---|
| <b>1. Was administered dose or exposure level adequately randomised?</b><br><br><b>Key question</b> | +      | There is direct or indirect evidence that subjects were allocated to any study group (or intervention sequence for cross-over studies) including controls using a method with a random component (including authors state that allocation was random, without description of the method used). Acceptable methods of randomisation include: referring to a random number table, using a computer random number generator, coin tossing, shuffling cards or envelopes, throwing dice, or drawing of lots. Restricted randomisation (e.g., blocked randomisation) to ensure particular allocation ratios will be considered low risk of bias. Similarly, stratified randomisation and minimisation approaches that attempt to minimise imbalance between groups on important prognostic factors (e.g., body weight) will be considered acceptable |
|   |        | There is indirect evidence that subjects were allocated to study groups (or intervention sequence for cross-over studies) using a method with a random component (i.e., authors state that allocation was random, without description of the method used)<br><b>OR</b><br>it is deemed that allocation without a clearly random component during the study would not appreciably bias results (e.g. cross-over studies with no or unlikely carry-over effects)  |
|   | NR     | There is insufficient information provided about how subjects (or clusters) were allocated to study groups  |
|   | –      | There is indirect evidence that subjects were allocated to study groups using a method with a non-random component<br><b>NOTE:</b> <i>Non-random allocation methods may be systematic but have the potential to allow participants or researchers to anticipate the allocation to study groups. Such "quasi-random" methods include alternation, assignment based on date of birth, case record number, or date of presentation to study.</i><br>NR: There is insufficient information provided about how subjects were allocated to study groups (or intervention sequence for cross-over studies)   |
|   |        | There is direct evidence that subjects were allocated to study groups (or intervention sequence for cross-over studies) using a non-random method including judgement of the clinician, preference of the participant, the results of a laboratory test or a series of tests, or availability of the intervention.  |
| <b>2. Was allocation to study groups adequately concealed?</b>                                      | +      | There is direct evidence that at the time of recruitment the research personnel and subjects did not know what study group subjects were allocated to, and it is unlikely that they could have broken the blinding of allocation until after assignment was complete and irrevocable. Acceptable methods used to ensure allocation concealment include central allocation (including telephone, web-based and pharmacy-controlled randomisation); sequentially numbered drug containers of identical appearance; sequentially numbered, opaque, sealed envelopes; or equivalent methods   |
|   |        | There is indirect evidence that the research personnel and subjects did not know what study group subjects were allocated to and it is unlikely that they could have broken the blinding of allocation until after recruitment was complete and irrevocable<br><b>OR</b><br>It is deemed that lack of adequate allocation concealment would not appreciably bias results (e.g. cross-over studies where all subjects receive all the study treatments)  |

| Question  | Rating | Explanation for expert judgement   |
|---|--------|--|
|   | NR     | There is insufficient information provided about allocation to study groups.   |
|   | –      | <p>There is indirect evidence that at the time of recruitment it was possible for the research personnel and subjects to know what study group subjects were allocated to (or treatment sequence for cross-over studies), or it is likely that they could have broken the blinding of allocation before recruitment was complete and irrevocable</p> <p><b>NOTE:</b> <i>Inadequate methods include using an open random allocation schedule (e.g., a list of random numbers); assignment envelopes used without appropriate safeguards (e.g., if envelopes were unsealed or nonopaque or not sequentially numbered); alternation or rotation; date of birth; case record number; or any other explicitly unconcealed procedure.</i></p> <p>There is direct evidence that at the time of recruitment it was possible for the research personnel and subjects to know what study group subjects were allocated to, or it is likely that they could have broken the blinding of allocation before recruitment was complete and irrevocable</p>  |
| <b>3. Were the research personnel and human subjects blinded to the study group during the study?</b> | +      | <p>There is direct evidence that the subjects and research personnel were adequately blinded to study group, <b>AND</b> it is unlikely that they could have broken the blinding during the study. Methods used to ensure blinding include central allocation; sequentially numbered drug containers of identical appearance; sequentially numbered, opaque, sealed envelopes; or equivalent methods</p> <p>There is indirect evidence that the research personnel and subjects were adequately blinded to study group, <b>AND</b> it is unlikely that they could have broken the blinding during the study</p> <p><b>OR</b></p> <p>it is deemed that lack of adequate blinding during the study would not appreciably bias results (this would depend on the outcome).</p>   |
|   | NR     | There is insufficient information provided about blinding to study group during the study  |
|   | –      | <p>There is indirect evidence that it was possible for research personnel or subjects to infer the study group</p> <p><b>NOTE:</b> <i>Inadequate methods include using an open random allocation schedule (e.g., a list of random numbers), assignment envelopes used without appropriate safeguards, alternation or rotation; date of birth; case record number; or any other explicitly unconcealed procedure</i></p> <p>There is direct evidence for lack of adequate blinding of the study group including no blinding or incomplete blinding of research personnel and subjects. For some treatments, such as behavioural interventions, allocation to study groups cannot be concealed</p>   |
| <b>4. Were outcome data complete without attrition or exclusion from analysis?</b>                    | +      | <p>There is direct evidence that there was no loss of subjects during the study and outcome data were complete,</p> <p><b>OR</b></p> <p>loss of subjects (i.e., incomplete outcome data) was adequately addressed<sup>(a)</sup> and reasons were documented when human subjects were removed from a study or analyses. Review authors should be confident that the participants included in the analysis are exactly those who were randomised into the trial. Acceptable handling of subject attrition includes: very little missing outcome data (e.g. &lt; 10% in each group); reasons for missing subjects unlikely to be related to outcome; missing outcome data balanced in numbers across study groups, with similar reasons for missing data across groups,</p> <p><b>OR</b></p> <p>analyses (such as intention-to-treat analysis) in which missing data have been imputed using appropriate methods (insuring that the characteristics of subjects lost to follow up or with unavailable records are described in identical way and are not significantly different from those of the study participants).</p> |

| Question  | Rating | Explanation for expert judgement  |
|---|--------|---|
|   |        | <p><b>NOTE:</b> <i>Participants randomised but subsequently found not to be eligible need not always be considered as having missing outcome data.</i></p> <p>There is indirect evidence that loss of subjects (i.e., incomplete outcome data) was adequately addressed and reasons were documented when human subjects were removed from a study,</p> <p><b>OR</b></p> <p>it is deemed that the proportion lost to follow-up would not appreciably bias results (e.g. &lt; 20% in each group). This would include reports of no statistical differences in characteristics of subjects lost to follow up or with unavailable records from those of the study participants. Generally, the higher the ratio of participants with missing data to participants with events, the greater potential there is for bias. For studies with a long duration of follow-up, some withdrawals for such reasons are inevitable.</p>  |
|   | NR     | There is insufficient information provided about numbers of subjects lost to follow-up  |
|   | –      | <p>There is indirect evidence that loss of subjects (i.e., incomplete outcome data) was unacceptably large (e.g. &gt; 20% in each group) and not adequately addressed.</p> <p>There is direct evidence that loss of subjects (i.e., incomplete outcome data) was unacceptably large and not adequately addressed.</p> <p>Unacceptable handling of subject attrition includes: reason for missing outcome data likely to be related to true outcome, with either imbalance in numbers or reasons for missing data across study groups; or potentially inappropriate application of imputation.</p>   |
| <p><b>5. Can we be confident in the exposure characterisation?</b></p> <p><b>Key question</b></p> | +      | <p>There is direct evidence that the exposure was adequately assessed, i.e. the sugar content of the intervention (and control) foods and/or beverages was measured during the study by e.g. food analysis <b>AND</b> there is direct evidence that the exposure was consistently administered (i.e., with the same method and time-frame) across treatment groups (e.g., administration of study foods or diets was supervised; compliance was assessed)</p> <p>There is indirect evidence that the exposure was adequately assessed, i.e. the sugar content of the intervention (and control) foods and/or beverages was not measured but rather e.g. calculated from food composition tables, provided by the food manufacturer, calculated from the ingredients list;</p> <p><b>AND</b> there is indirect evidence that exposure was consistently administered (i.e., with the same method and time-frame) across treatment groups (e.g. administration of study foods or diets was not supervised <b>but</b> study products were provided by the investigators and compliance was assessed using food records, return of unconsumed foods, or a similar method).</p> |
|   | NR     | There is insufficient information provided about the validity of the exposure assessment method   |
|   | –      | <p>There is indirect evidence that the exposure was assessed using poorly validated methods (e.g. study products or diets were not provided by the investigators and compliance was not checked)</p> <p>There is direct evidence that the exposure was assessed using poorly validated methods</p> <p><b>OR</b></p> <p>There is direct evidence of poor compliance with the intervention</p>  |
| <p><b>6. Can we be confident in the outcome assessment?</b></p> <p><b>Key question</b></p>        | +      | <p>There is direct evidence that the outcome was assessed using well-established methods (e.g., the “gold standard”). Such methods will depend on the outcome, but may include: objectively measured with diagnostic methods, measured by trained interviewers, obtained from registries</p> <p><b>AND</b> subjects had been followed for the same length of time in all study groups,</p>  |

| Question   | Rating | Explanation for expert judgement   |
|--|--------|--|
|  |        | <p><b>AND</b> there is direct evidence that the outcome assessors (including study subjects, if outcomes were self-reported) were adequately blinded to the study group, and it is unlikely that they could have broken the blinding prior to reporting outcomes.</p> <p>There is indirect evidence that the outcome was assessed using acceptable methods (i.e., deemed valid and reliable but not the gold standard). Such methods will depend on the outcome, but may include: proxy reporting of outcomes, mining data collected for other purposes <b>AND</b> subjects had been followed for the same length of time on average in all study groups (or if not, this has been accounted for using appropriate statistical approaches), <b>OR</b> it is deemed that the outcome assessment methods used would not appreciably bias results (e.g. when there is no information about the method but standard measurements are most likely, e.g. blood lipids, body weight in a research setting), <b>AND</b></p> <p>there is indirect evidence that the outcome assessors (including study subjects, if outcomes were self-reported) were adequately blinded to the study group, and it is unlikely that they could have broken the blinding prior to reporting outcomes, <b>OR</b> it is deemed that lack of adequate blinding of outcome assessors would not appreciably bias results, which is more likely to apply to objective outcome measures.</p> |
|  | NR     | <p>There is insufficient information provided about blinding of outcome assessors <b>OR</b> there is no information about the outcome assessment method</p>  |
|  | –      | <p>There is indirect evidence that the outcome assessment method is an insensitive instrument (e.g., a questionnaire used to assess outcomes with no information on validation), <b>OR</b></p> <p>the length of follow up differed by study group, <b>OR</b></p> <p>there is indirect evidence that it was possible for outcome assessors (including study subjects if outcomes were self-reported) to infer the study group prior to reporting outcomes <b>AND</b> it is deemed that the outcome assessment methods used could appreciably bias results</p> <p>There is direct evidence that the outcome assessment method is an insensitive instrument, <b>OR</b></p> <p>the length of follow up differed by study group, <b>OR</b></p> <p>there is direct evidence for lack of adequate blinding of outcome assessors (including study subjects if outcomes were self-reported), including no blinding or incomplete blinding <b>AND</b> it is deemed that the outcome assessment method could have biased the results</p>  |
| <p><b>7. Were there no other potential threats to internal validity (e.g. statistical methods were appropriate and researchers adhered to the study protocol)?</b></p> | +      | <p>There is direct evidence that variables, other than the exposure and outcome, did not differ between groups during the course of the intervention in a way that could bias results/For cross-over trials: there is direct evidence of no carry-over effects, <b>AND</b></p> <p>there is no evidence of differences in baseline characteristics between groups.</p> <p>There is indirect evidence that variables, other than the exposure and outcome, did not differ between groups during the course of the intervention in a way that could bias results/For cross-over trials: there is indirect evidence of no carry-over effects (e.g. presence of a sufficient washout period) <b>AND</b> there is no evidence of differences in baseline characteristics between groups, <b>OR</b></p> <p>there is evidence that reported variables differed between groups at baseline/For cross-over trials: no washout period <b>AND</b> it is deemed that</p>  |

| Question | Rating | Explanation for expert judgement   |
|----------|--------|--|
|          |        | these differences (or absence of washout for cross-over trials) would not appreciably bias results (no concern or adequately addressed by analysis)  |
|          | NR     | There is no information about baseline characteristics by group (for parallel studies)   |
|          | –      | <p>There is no information on variables, other than the exposure and outcome, which could bias the results would have differed between groups during the course of the intervention/ For cross-over trials: no washout period</p> <p><b>AND</b><br/>there is indirect evidence that variables, other than the exposure and outcome, may have differed between groups during the course of the intervention in a way that could bias results/ For cross-over trials: indirect evidence of carry-over effects</p> <p>There is evidence that variables, other than the exposure and outcome, differed between groups during the intervention/For cross-over trials: direct evidence of carry-over effects</p> <p><b>AND</b> It is deemed that these differences appreciably biased results (there is concern e.g. not adequately addressed by analysis)</p> <p><b>OR</b><br/>there is evidence that reported variables differed between groups at baseline</p> <p><b>AND</b> it is deemed that these differences appreciably biased results (e.g. not adequately addressed by analysis)</p> |

+: Low RoB; NR: not reported; –: high RoB.

(a): This will depend on the context in which the assessment is performed. For safety assessments the interest lies in particular in the population group who followed the protocol and consumed the intervention accordingly (PP population), while for efficacy assessments the intention-to-treat population is of greater importance. This item needs to be judged on a case-by-case basis as also other types of information supplied in the publication could be used in the assessment (e.g. considerations on the type of missingness of the data or sensitivity analyses presented in the publication).

### C.1.2. Prospective observational studies

| Question  | Rating | Explanation for expert judgement  |
|---|--------|---|
| <p><b>1. Did the study design or analysis account for important confounding?</b></p> <p><b>Key question</b></p> | ++     | <p>There is direct evidence that appropriate adjustments or explicit considerations were made for primary covariates and confounders in the final analyses through the use of statistical models to reduce research-specific bias including standardisation, matching, adjustment in multivariate model, stratification, propensity scoring, or other methods that were appropriately justified. Acceptable consideration of appropriate adjustment factors includes cases when the factor is not included in the final adjustment model because the author conducted analyses that indicated it did not need to be included,</p> <p><b>AND</b> there is direct evidence that primary covariates and confounders were assessed using valid and reliable measurements,</p> <p><b>AND</b> there is direct evidence that other exposures anticipated to bias results were not present or were appropriately measured and adjusted for.</p> <p><i>Note: This applies to:</i></p> <ul style="list-style-type: none"> <li>• Studies which characterised exposure through serum/plasma selenium and accounted for age, sex and BMI as potential confounders</li> <li>• Studies which characterised exposure through dietary questionnaire (e.g. FFQ) and accounted for age, sex, BMI as potential confounders, and total energy intake (the latter, for the purpose of reducing measurement errors)</li> </ul> |
|   | +      | There is indirect evidence that appropriate adjustments were made, OR it is deemed that not considering or only considering a partial list of covariates or confounders in the final analyses would not appreciably bias results.   |

| Question  | Rating | Explanation for expert judgement  |
|---|--------|---|
|   |        | <p><b>AND</b> there is evidence (direct or indirect) that primary covariates and confounders were assessed using valid and reliable measurements, OR it is deemed that the measures used would not appreciably bias results (i.e., the authors justified the validity of the measures from previously published research),</p> <p><b>AND</b> there is evidence (direct or indirect) that other co-exposures anticipated to bias results were not present or were appropriately adjusted for, OR it is deemed that co-exposures present would not appreciably bias results.</p> <p><i>Note: This applies to studies which characterised exposure through dietary questionnaire (e.g. FFQ) and accounted for age, sex, BMI as potential confounders, but did not control for total energy intake</i></p>  |
|   | NR     | <p>There is insufficient information provided about the distribution of known confounders,</p> <p><b>OR</b> there is indirect evidence that primary covariates and confounders were assessed using measurements of unknown validity,</p> <p><b>OR</b> there is insufficient information provided about the measurement techniques used to assess primary covariates and confounders,</p> <p><b>OR</b> there is insufficient information provided about co-exposures in occupational studies or studies of contaminated sites where high exposures to other chemical exposures would have been reasonably anticipated</p>  |
|   | –      | <p>There is indirect evidence that the distribution of potential confounders differed between the groups and was not appropriately adjusted for in the final analyses</p> <p><b>OR</b> there is indirect evidence that primary covariates and confounders were assessed using measurements of unknown validity,</p> <p><b>OR</b> there is indirect evidence that there was an unbalanced provision of additional co-exposures across the primary study groups, which were not appropriately adjusted for</p>  |
|   | – –    | <p>There is direct evidence that the distribution of primary covariates and known confounders differed between the groups, confounding was demonstrated, and was not appropriately adjusted for in the final analyses,</p> <p><b>OR</b> there is direct evidence that primary covariates and confounders were assessed using non valid measurements,</p> <p><b>OR</b> there is direct evidence that there was an unbalanced provision of additional co-exposures across the primary study groups, which were not appropriately adjusted for.</p>  |
| <p><b>2. Were outcome data complete without attrition or exclusion from analysis?</b></p> | ++     | <p>There is direct evidence that loss of subjects (i.e., incomplete outcome data) was adequately addressed and reasons were documented when subjects were removed from a study.</p> <p>Acceptable handling of subject attrition includes:</p> <ul style="list-style-type: none"> <li>• Very little missing outcome data (less than 10%, considering N of subjects included over N of subjects eligible (after exclusion of prevalent cases, participants with missing variables) for the analysis);</li> <li>• Reasons for missing subjects unlikely to be related to outcome (for survival data, censoring unlikely to be introducing bias);</li> <li>• Missing outcome data balanced in numbers across study groups, with similar reasons for missing data across groups (i.e. unlikely to be related to exposure),</li> </ul> <p><b>OR</b> missing data have been imputed using appropriate methods and characteristics of subjects lost to follow up or with unavailable records are described in identical way and are not significantly different from those of the study participants.</p> |
|   | +      | <p>There is indirect evidence that loss of subjects (i.e., incomplete outcome data) was adequately addressed and reasons were documented when subjects were removed from a study,</p>   |

| Question   | Rating | Explanation for expert judgement  |
|--|--------|---|
|  |        | <p><b>OR</b> it is deemed that the proportion lost to follow-up would not appreciably bias results (i.e. losses are not expected to be related to both exposure and outcome, considering N of subjects included over N of subjects eligible for the analysis). This would include reports of no statistical differences in characteristics of subjects lost to follow up or with unavailable records from those of the study participants.</p> <p>Generally, the higher the ratio of participants with missing data to participants with events, the greater potential there is for bias.</p> <p>For studies with a long duration of follow-up, some withdrawals for such reasons are inevitable.</p>   |
|  | NR     | There is insufficient information provided about numbers of subjects lost to follow-up  |
|  | –      | There is indirect evidence that loss of subjects (i.e., incomplete outcome data) was unacceptably large (greater than 20% in each group, Genaidy et al., 2007) and not adequately addressed   |
|  | – –    | <p>There is direct evidence that loss of subjects (i.e., incomplete outcome data) was unacceptably large and not adequately addressed.</p> <p>Unacceptable handling of subject attrition includes:</p> <ul style="list-style-type: none"> <li>• Reason for missing outcome data likely to be related to true outcome, with either imbalance in numbers or reasons for missing data across study groups (i.e. likely to be related to the exposure);</li> <li>• Or potentially inappropriate application of imputation.</li> </ul>   |
| <b>3. Did selection of study participants result in appropriate comparison groups?</b> | ++     | <p><b>Cohort studies:</b> There is direct evidence that subjects (both exposed and non-exposed) were similar (e.g., recruited from the same eligible population, recruited with the same method of ascertainment using the same inclusion and exclusion criteria, and were of similar age and health status), recruited within the same time frame</p> <p><b>Case-control studies:</b> There is direct evidence that cases and controls were similar (e.g., recruited from the same eligible population including being of similar age, gender, ethnicity, and eligibility criteria other than outcome of interest as appropriate), recruited within the same time frame, and controls are described as having no history of the outcome.</p> <p><i>Note: A study will be considered low risk of bias if baseline characteristics of groups differed but these differences were considered as potential confounding or stratification variables</i></p> |
|  | +      | <p><b>Cohort studies:</b> There is indirect evidence that subjects (both exposed and non-exposed) were similar (e.g., recruited from the same eligible population, recruited with the same method of ascertainment using the same inclusion and exclusion criteria, and were of similar age and health status), recruited within the same time frame</p> <p><b>OR</b> differences between groups would not appreciably bias results.</p> <p><b>Case-control studies:</b> There is indirect evidence that cases and controls were similar (e.g., recruited from the same eligible population, recruited with the same method of ascertainment using the same inclusion and exclusion criteria, and were of similar age), recruited within the same time frame, and controls are described as having no history of the outcome, <b>OR</b> differences between cases and controls would not appreciably bias results</p>                                   |
|  | NR     | <p><b>Cohort studies:</b> there is insufficient information provided about the comparison group</p> <p><b>Case-control studies:</b> there is insufficient information provided about the appropriateness of controls</p>  |
|  | –      | <b>Cohort studies:</b> There is indirect evidence that subjects (both exposed and non-exposed) were not similar, recruited within very different time frames  |

(a): Mean  $\pm$  SD (range), unless specified otherwise.

(b): Dietary intakes were adjusted for energy intake using the nutrient density method and expressed as per  $\mu\text{g}/4184$  kJ (1,000 kcal) per day (Willett al., 1997).

## List of annexes

These Annexes can be found in the online version of this output, under the section 'Supporting Information', at <https://doi.org/10.2903/j.efsa.2023.7704>

- Annex A. Protocol for the Scientific opinion on the tolerable upper intake level for selenium
- Annex B. Statistical analysis of evidence from studies identified in the published scientific literature as preparatory work for the setting of a Tolerable Upper Intake Level for selenium
- Annex C. EFSA's intake assessment of selenium
- Annex D. Intake data from Competent Authorities in European Member States
- Annex E. References excluded at the stages of full-text screening and data extraction
- Annex F. Public consultation outcome
