Abstract

The aim of this study is to evaluate development of side effects, thrombotic or obstetric complications in our antiphospholipid syndrome (APS) patient group, after vaccination against coronavirus disease 2019 (COVID-19). A cohort was formed from patients who have previously been followed up with a diagnosis of APS. The patients of the cohort were evaluated retrospectively to find out if they were vaccinated with CoronaVac and/or BNT162b2 vaccines which are being used in our country. To evaluate the side effects seen after the vaccination, the information was collected by the patients in their outpatient appointments or making a phone call. Thirty-five APS patients who had received at least 1 dose of any of the COVID-19 vaccines were included in the study. Median (min-max) number of vaccine doses per patient was 2 (1-3). Eleven patients had a booster dose after primary vaccination. Twenty patients were ever vaccinated with BNT162b2 and 18 with CoronaVac. Among BNT162b2 recipients, 9 (45.0%) and among CoronaVac recipients 15 (42.9%) reported an adverse event after a vaccine administration. The most common adverse events were myalgia and malaise after any dose of both vaccines. No vaccine-related new thrombotic events or APS flares were observed. Our results were comparable with those reported in the literature. Comprehensive large-scale studies are needed for more accurate results on the evaluation of side effects after COVID-19 vaccination in APS patients.

KEYWORDS antiphospholipid syndrome, COVID-19, vaccination

1 | INTRODUCTION

Antiphospholipid syndrome (APS) is an autoimmune disorder characterized by presence of antiphospholipid antibodies (aPL) comprising lupus anticoagulant (LAC), anti- β 2-glycoprotein I (anti- β 2GPI) and/or anti-cardiolipin (aCL) antibodies together with venous/arterial thrombosis and/or obstetric comorbidity.¹ COVID-19 is a highly contagious disease, caused by the RNA virus severe acute respiratory syndrome coronavirus 2 (SARS CoV 2).² The course of the disease ranges from asymptomatic illness to severe disease with life-threatening complications such as acute respiratory distress syndrome (ARDS).³ In addition to this, in considerable number of cases, the clinical scenario is complicated by coagulopathy.⁴ Tendency to hypercoagulation worsens

the prognosis and is thought to be related with development of cytokine storms.

Infections are acknowledged as one of the precipitating factors for multifactorial pathogenetic processes of APS via triggering proinflammatory cascades that promote the clinical manifestations in individuals with pre-existing aPLs.⁵ Likewise, development of aPL positivity has been reported in COVID-19.6

SARS CoV 2 is thought to trigger hypercoagulation and formation of aPLs via host immune response to viral antigens. Therefore, hypothetically, a similar reaction may occur after vaccination against SARS CoV 2. Concerns regarding COVID-19 vaccines started to occur several months after the mass COVID-19 vaccination campaign began, upon seeing unexpected thromboembolic events.⁷⁻⁹ In a patient group like APS, in which the individual is already prone to thrombotic events, the tolerability of COVID-19 vaccines is intriguing in this manner.

The aim of the study was the evaluation of APS flares as well as adverse events of COVID-19 vaccination in APS patients.

2 **METHODS**

2.1 Study design

The study was designed as a cross-sectional, retrospective cohort study with approval by our institutional ethics committee and was therefore performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and its later amendments. An official permission was obtained from the Ministry of Health to conduct this study, dated February 20, 2021.

The medical records of the patients who were followed up in our clinic with a diagnosis of APS, were investigated for the presence of vaccine-related adverse events and APS disease activation (thrombosis, embolism or pregnancy complications) after any dose of a COVID-19 vaccine. Data were confirmed from patients either via telephone calls or during follow-ups. A questionnaire form was prepared for the patients. In this guestionnaire, the date of APS diagnosis, the symptoms/findings at the time of diagnosis, history of medications for APS, COVID-19 infection, data regarding COVID-19 vaccines if they were vaccinated and adherence to APS treatment during the vaccination period and occurrence of any new thrombotic event and/or obstetric complication within 3 months after a COVID-19 vaccine were questioned. Patient-reported adverse events related to COVID-19 vaccines occurring during the 1-month period after vaccination were recorded. Verbal or written consent was obtained from the patients.

2.2 Patients

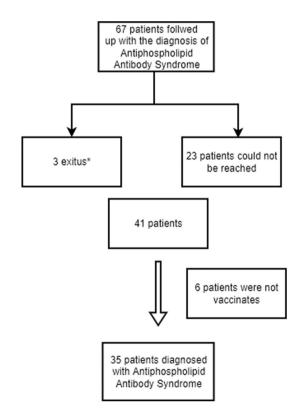

18 years and over, diagnosed with APS and vaccinated with any of the COVID-19 vaccines, were included into the study (Figure 1).

2.3 Main outcomes and other variables

Occurrence of an APS disease flare after COVID-19 vaccination (CoronaVac or BNT162b2) or an adverse event due to the vaccines were selected as main outcome variables and collected from medical records and patient questionnaires. Any event related by the patient with vaccine administration within 24 hours to 1 month after vaccination were recorded as an adverse event. APS activation was defined as new thromboembolic event and/or obstetric complication. Data regarding demographics, comorbidities and medical treatment administered for APS were collected from the hospital database.

2.4 Statistical analysis

Data were analyzed using Statistical Package for the Social Sciences (SPSS) 22.0 software. Normality of continuous variables was evaluated with Shapiro-Wilk test and visually with plots and histograms. Continuous variables were presented either with median (minimummaximum) or mean±standard deviation, according to normality. Categorical variables are presented with numbers and percentages.

The patients who meet the Sapporo classification criteria for APS (also named as Sydney Criteria), who are followed up in our clinic,

FIGURE 1 Selection of the patients participating in the study. *The reason of the exitus is not COVID-19 infection or any of the SARS-CoV-2 vaccines administrated.

3 | RESULTS

Thirty-five patients who had received at least 1 dose of any of the COVID-19 vaccines were included in the study. Demographics, comorbid diseases and APS characteristics, medications and adherence to treatment during vaccination are presented in Table 1.

3.1 | Outcomes

The median (min-max) age of the patients was 43 (28–63) years. The number of the female patients was 33 (94.7%). Four (11.4%) of the patients were active smokers. The most common comorbidity was hypertension (17.1%) (Table 1).

In 22 (62.9%) of the patients there was a history of a thrombotic event at the time of diagnosis or during the course of the disease. Eleven (52.4%) of these patients had a history of cerebrovascular disease, 10 (47.7%) of them had a history of deep vein thrombosis, 2 (9.6%) of them had a history of pulmonary thromboembolism. Twenty-one (63.6%) of the patients had experienced an obstetric complication (history of abortion, stillbirth). All of these thromboembolic events and obstetric complications occurred prior to

vaccination. Most common active APS medications were hydroxychloroquine (28 patients [82.4%]), acetylsalicylic acid (16 patients [59.3%]), warfarin (16 patients [48.5%]), and corticosteroids (15 patients [50%]) (Table 1). Thirty-two (97%) of the patients adhered to treatment during the vaccination period.

Vaccination characteristics and adverse events are presented in Table 2. Median (min-max) number of vaccine doses per patient was 2 (1-3). Eleven patients had a booster dose after primary vaccination. Twenty patients were ever vaccinated with BNT162b2 and 18 ever with CoronaVac. Among BNT162b2 recipients, 9 (45.0%) reported an adverse event after a vaccine administration and among CoronaVac recipients 15 (42.9%) reported an adverse event after a vaccine administration. In patients with adverse events, the most common adverse events after a CoronaVac dose were myalgia (33.3%), malaise (22.2%) and local pain/arm pain (16.6%). In BNT162b2 recipients most common adverse events were myalgia (30%), malaise (20%) and fever (15%). In 1 patient, nosebleed due to increased international normalized ratio (INR) and need for hospitalization was observed after a dose of BNT162b2 vaccine. APS flare was observed in none of the patients within the 3-month period after any vaccine dose. No patient became pregnant or gave birth during the follow-up.

When the frequency of adverse events after first, second and booster doses were evaluated, it was observed that adverse events were more common after the first dose in BNT162b2 recipients and after the booster dose in CoronaVac recipients (Table 2).

SARS CoV 2 polymerized chain reaction (PCR) test was positive in 8 (22.9%) of the patients. No serious disease courses or death were observed in any of these patients. None of them required hospitalization. There were 71.4% of the patients infected prior to vaccination. In those who were positive for COVID-19 after vaccination, it was determined that the disease was seen 2 months after the last dose.

4 | DISCUSSION

Our results demonstrated that out of 35 APS patients with COVID-19 vaccination, 45.0% of BNT162b2 and 42.9% of CoronaVac recipients reported an adverse event. Only a single patient had an event requiring hospitalization. No mortality was observed. None of the patients suffered from an APS flare. The majority of patients adhered to APS treatment during the vaccination period.

APS is characterized by thrombotic events, microangiopathy and obstetric complications. While deep venous thrombosis is the most frequently reported manifestation, cerebrovascular events are the most common arterial involvement. Early or late fetal loss, prematurity and preeclampsia are the most common fetal and obstetric signs.¹⁰ Clinical manifestations may not always occur despite presence of aPLs. Therefore, a "two-hit theory" has been proposed, which requires a second trigger in addition to the aPLs in circulation, in order to develop clinical manifestations.¹¹ In some studies, it has been thought that antibodies lose their normal function under -WILEY- Rheumatic Diseases

The presence of coagulopathy as part of the systemic inflammatory response syndrome is a common feature in severe cases of COVID-19. Changes in coagulation parameters (elevated D-dimer, prolonged prothrombin time, thrombocytopenia, and/or low fibrinogen levels) were detected in approximately 20%–50% of the hospitalized COVID-19 patients.¹³ COVID-19 is related to thrombotic events (especially venous thromboembolism [VTE]) rather than hemorrhagic events.

Infectious agents can cause aPL production by molecular mimicry.¹⁴ It has been reported that aPL antibodies can be synthesized by B cell clones as a result of a molecular mimicry between exogenous molecules and β2GPI.¹⁵ This molecular similarity between the β 2GPI epitope and the pathogens such as Haemophilus influenzae, Neisseria gonorrhoeae, cytomegalovirus and tetanus toxoid, has been demonstrated in previous studies.¹⁵ In addition; detection of these antibodies has also been reported in patients with COVID-19.¹⁶ A systematic review and meta-analysis of the literature examining the presence of acute ischemic stroke in individuals infected with SARS CoV 2 found a high prevalence of aPL in these patients, with LAC positivity in 41.7% of cases.¹⁷ In a cohort of 122 COVID-19 patients, 16 of whom had major thrombotic events, immunoglobulin G (IgG)/IgA/IgM of anti-β2GPI were detected in 15.6%/6.6%/9.0% of patients, respectively.¹⁸ However, interestingly, no significant correlation was observed between the risk of thrombotic events and aPL positivity. It was stated that attention should be paid to the anti-B2GPI antibodies identified in these patients exhibiting a different epitope specificity compared to the aPL antibodies elicited during APS.

Hypothetically, it is possible to observe similar presentations after vaccination. Several studies have shown that aPLs can be detected in the sera of the individuals who were vaccinated with tetanus toxoid, seasonal influenza, and human papillomavirus vaccines, with or without causing clinical manifestations of APS.^{19,20} A similar situation was detected following COVID-19 vaccines.²¹ Induction of experimental APS was accomplished by hyperimmunization with different adjuvants (glycerol or aluminum hydroxide) or different adjuvant pretreatments (glycerol or complete Freund adjuvant). There is varying evidence that these adjuvants induce autoantibody production.²²

Several concerns that COVID-19 vaccines may cause hypercoagulation were raised several months after the mass COVID-19 vaccination campaign began, upon reports of unexpected thromboembolic events. Currently available COVID-19 vaccination strategies include messenger RNA (mRNA)-based (BNT162b2 and mRNA-1273), adenoviral vector-based (ChAdOx1-S and Ad26.COV2) and inactive (CoronaVac) formulations. The safety profile of ChAdOx1-S was recently reviewed by the European Medicines Agency (EMA) Pharmacovigilance Risk Assessment Committee (PRAC) due to several reports of coagulopathy events developing days to weeks after the first or second injection of the vaccine.²³ Given the numerical imbalance in clinical trials, venous thromboembolism was also included among the safety concerns of the Risk Management Plan (RMP) of the adenoviral vector-based COVID-19 vaccine Ad26. COV2. Recently, several experimental studies have been conducted to investigate the mechanism of vaccine-induced thrombosis development, and as a result, a new possible mechanism has been proposed.⁷ Accordingly, it is hypothesized that the development of thrombosis is associated with a soluble adenoviral spike protein variant that binds to angiotensin converting enzyme 2 (ACE2) expressing endothelial cells. This gives an idea why thrombosis is more common with administration of adenovirus-based vaccines compared to mRNA-based vaccines. However, the relationship of COVID-19 vaccines with thrombotic events is still unclear, but it is thought that an immune-mediated mechanism similar to that in APS may occur.⁵

COVID-19 vaccines being administrated at the time of this study in our country are inactivated CoronaVac and mRNA-based BNT162b2 vaccines. In a study of 406 healthcare workers who received CoronaVac, it was stated there was no significant difference in the presence of aPL autoantibodies before and after vaccination, and no thrombosis was observed in this study during follow-up.²⁴ Also in our study, no post-vaccine thrombotic complication was observed in any patient who received the CoronaVac vaccine in accordance with these results. A recent study comprising 39 APS patients vaccinated with inactive COVID-19 vaccines reported no induction of thrombotic events, similar to our results.²⁵

The impact of COVID-19 mRNA-based vaccines on the thrombotic process is still being discussed. In a study in which safety and tolerability of mRNA-based vaccine were evaluated among patients with APS diagnosis and/or aPL positivity, no vaccine-related new thrombotic event was reported.²⁶ Although no safety issues emerged in clinical trials compared to the placebo group, a case report described the development of deep venous thrombosis 1 day after receiving a second dose of BNT162b2 in a 66-year-old woman with no prior coagulation defects.^{9,27} Similarly, only a single vaccine-related thrombotic event was reported among 161 APS patients: deep vein thrombosis which occurred 39 days after the second dose of an adenovirus-based COVID-19 vaccine, without requiring hospitalization.²⁸ A descriptive analysis examining the relationship between administration of BNT162b2, mRNA-1273 and ChAdOx1 nCov-19 vaccines with the development of thrombotic events, including cerebral vein thrombosis, reported finding 0.21 cases of thrombotic events per 1 million vaccinated people, between December 13, 2020 and March 16, 2021, to The Health Organization Global Database for Individual Case Safety Reports (VigiBase).²⁹ These thrombotic events were reported in association with both the mRNA vaccines (BNT162b2 and mRNA-1273) and the analyzed DNA vaccine (ChAdOx1 nCov-19). In the details of the analysis, it was stated that thrombotic events were reported in 4 female patients (4/1197, 0.4%) after BNT162b2. In our study, none of the BNT162b2 recipients suffered from a thrombosis or an APS flare.

Our study has several limitations. The study has the typical limitations of a single-center retrospective case study. The number of the evaluated patients was few. Different results may be obtained by examining more patients. The other important limitation is that Rheumatic Diseases

the data regarding vaccine experience of our subjects collected via telephone survey and mainly based on subject self-reports could not be confirmed by clinicians. Lastly, since this is a real-life study, vaccine types and doses administered to our patients were highly heterogeneous.

5 | CONCLUSION

Our results suggest that CoronaVac and BNT162b2 vaccination did not develop thrombotic events and the vaccination-related adverse events were comparable with those reported in the registry studies. However, due to the inadequate literature data, comprehensive large-scale studies are needed for more accurate results on the evaluation of side effects after COVID-19 vaccination in APS patients.
