Abstract

Background: The *MUC5B* promoter variant (rs35705950) and telomere length are linked to pulmonary fibrosis and computed tomography (CT)-based qualitative assessments of interstitial abnormalities, but their associations with longitudinal quantitative changes of the lung interstitium among community-dwelling adults is unknown.

Methods: We used data from participants in the Multi-Ethnic Study of Atherosclerosis with high attenuation areas (HAAs, Exams 1–6 (2000–2018)) and *MUC5B* genotype (n=4,552) and telomere length (n=4,488) assessments. HAA was defined as the percent of imaged lung with attenuation of –600 to –250 Hounsfield units. We used linear mixed effects models to examine associations of *MUC5B* risk allele (T) and telomere length with longitudinal changes in HAAs. Joint models were used to examine associations of longitudinal changes in HAAs with death and interstitial lung disease (ILD).

Results: The *MUC5B* risk allele (T) was associated with an absolute change in HAAs of 2.60% (95% CI 0.36–4.86) per 10 years overall. This association was stronger among those with a telomere length below an age-adjusted percentile of 5% (p-value for interaction=0.008). A 1% increase in HAAs per year was associated with 7% increase in mortality risk (rate ratio (RR)=1.07, 95% CI 1.02–1.12) for overall death and 34% increase in ILD (RR=1.34, 95% CI 1.20–1.50). Longer baseline telomere length was cross-sectionally associated with less HAAs from baseline scans, but not with longitudinal changes in HAAs.

Conclusions: Longitudinal increases in high attenuation areas were associated with the *MUC5B* risk allele and a higher risk of death and ILD.

Keywords

interstitial lung disease; imaging; Mucin-5B; telomere lengthening

INTRODUCTION

Interstitial lung disease (ILD) is a group of chronic respiratory disorders characterized by inflammation and fibrosis of the lung parenchyma.¹ Non-fibrosing ILDs can become fibrotic

which may lead to rapid deterioration, chronic respiratory failure, and death. By the time of diagnosis, patients often have significant physiologic impairments and decreased exercise capacity, with a poor median survival.^{2,3}

An increasing number of studies have focused on visual, qualitative assessment of computed tomography (CT) scans for changes suggestive of ILD, termed interstitial lung abnormalities (ILA) when identified in research studies or incidentally in the clinical context.⁴ These studies have yielded important insights into novel risk factors for progressive fibrosing ILD. A recent Fleischner Society position paper defining the radiological criteria for ILA also highlighted the need for quantitative CT methods for evaluation of disease extent and progression as a key research priority.⁴

One of the strongest known risk factors for pulmonary fibrosis is the *MUC5B* promoter polymorphism (rs35705950); it is associated with a 4-times fold higher odds of idiopathic pulmonary fibrosis (IPF). Recent studies have shown that this gain-of-function promoter variant is linked to other types of fibrosing ILDs like chronic hypersensitivity pneumonitis and rheumatoid-arthritis related ILD.⁵⁻⁷ The polymorphism is associated with ILA among the general population and in cohorts of smokers, suggesting that carriers of this allele may be at higher risk of developing fibrosing ILDs.⁸ Shorter telomere length, a marker of accelerated cellular senescence, is another intrinsic risk factor that is associated with a higher risk of pulmonary fibrosis, more severe disease, mortality, and a higher prevalence of ILA.^{6,9,10} The few prior studies that have examined the *MUC5B* polymorphism and telomere length in IPF and chronic hypersensitivity pneumonitis did not show evidence of interaction between these genetic factors, suggesting distinct mechanisms by which they influence pathogenesis. However, study of the *MUC5B* promoter polymorphism and telomere length in other ILDs and in earlier stages of ILD is lacking.^{6,11}

Whether these genetic risk factors (and their interactions) are linked to a quantitative measure of lung parenchymal changes and its progression over time among a racially/ethnic diverse sample of community-dwelling adults remains unclear. We hypothesized that the *MUC5B* promoter polymorphism (rs35705950) would be associated with longitudinal increases in high attenuation areas with effect modification by telomere length over time in the Multi-Ethnic Study of Atherosclerosis (MESA). We also examined whether longitudinal changes in HAAs are associated with death and ILD-related clinical events.

METHODS

Study Participants

MESA is an ongoing prospective cohort with the original intent of investigating subclinical cardiovascular disease.¹² There were 6,814 U.S. adults between the ages of 45 and 84 years without clinical cardiovascular disease recruited at Exam 1 (2000–2002) and followed longitudinally, with repeat exams that included additional data collection. Participants who provided consent for genetic analyses were included in this study. All MESA participants provided written informed consent and institutional review board approval was obtained at all participating study sites.

MUC5B Genotype and Telomere Length

MUC5B (rs35705950) genotypes were obtained from whole genome sequencing (WGS) that was performed on DNA samples from whole blood in MESA as part of the National Heart Lung and Blood Institute TOPMed Program. Procedures related to the TOPMed program have been previously described in detail.¹³ Briefly, Illumina HiSeq X Ten instruments were used for WGS that targeted a mean depth of at least 30 × (paired-end, 150-bp reads). PCR-free library preparation kits from KAPA Biosystems were used for all sequencing. Using blood samples from MESA Exam 1, telomere length was extracted from the TOPMed WGS using TelSeq and has been previously described. Briefly, counts of sequencing reads that contained fixed number of repeats of the telomeric nucleotide motif “TTAGGG” were used to estimate individual telomere lengths and accounted for batch corrections. TelSeq estimates of telomere length have a Pearson correlation of 0.68–0.72 with Southern blot data in TOPMed.¹⁴ There were no repeat telomere length measurements from WGS in MESA.

High Attenuation Area

MESA participants underwent cardiac CT scans at Exams 1 (2000–2002), 2 (2002–2004), 3 (2004–2005), 4 (2005–2007), and 5 (2010–2012), and full-lung scans at Exam 6 (2016–2018) using the MESA/SPIROMICS protocol.¹⁵ Sixty-six percent of the lung volume from the carina to lung bases were captured by cardiac scans. The intraclass correlation coefficient for lung density measures between cardiac and full-lung scans is 0.93.¹⁶ HAAs from Exam 6 full-lung scans were assessed in the lower two-thirds lung fields to be consistent with the previous cardiac scans; this approach has been used previously for other densitometry-based measures like percent emphysema.¹⁷ HAAs was defined as the percentage of voxels with attenuation values in the range of –600 and –250 Hounsfield units (HU), as previously described.¹⁸ The Pulmonary Analysis Software Suite (PASS) at the University of Iowa’s Advanced Pulmonary Physiomic Imaging Laboratory (APPIL) was used by trained technicians for segmentation and correction of the lung.¹⁹ Percent emphysema was defined as the percentage of lung voxels below –950 HU.²⁰

Mortality and ILD

Vital status of participants was determined by the contact of each MESA participant or family member by interviewers every 9–12 months. The National Death Index was used to supplement this review and ensure complete follow-up. Mortality was adjudicated up until December 31, 2018. Hospitalization data were complete as of December 31, 2013. Inpatient medical records were reviewed by an adjudication panel and International Classification of Diseases, Ninth Revision (ICD-9, 495.XX, 515.X, or 516.XX) and 10th Revision (J60.X–J64.X, J67.X, or J84.X) were used to determine whether participants who were hospitalized or died had ILD as previously described.²¹ Further details are in the supplement.

Statistical Analysis

We used linear mixed effects models with random intercept and slope to examine associations of the *MUC5B* risk allele (T) with the longitudinal change in HAAs over time (Exams 1 through 6, 2000–2018). We used a genetic additive model to present our results.⁵

We used mixed effects model to account for within-subject correlations among repeated measurements of HAAs over time for each participant. Such modeling approach has been used in other studies.^{17–22} Measurements of HAAs from all six exams were used in our linear mixed effects model. Additional information is provided in the supplement.

The longitudinal analysis was adjusted for scanner parameters, principal components of genetic ancestry, baseline age, sex, race/ethnicity, smoking status, and cigarette pack-years, and time-varying covariates of height, weight, cigarettes smoked per day, and percent emphysema. We included interaction terms of covariates with the time since initial HAAs assessment to evaluate the impact of covariates on HAAs trajectories over time. We performed an analysis of the overall cohort and race/ethnic-specific analyses due to the heterogeneity of *MUC5B* (rs35705950) genotype frequencies.^{23–24} Positive and negative beta estimates from the term, “*MUC5B* risk allele × time since initial HAAs assessment”, were interpreted as more rapid progression and slower progression in HAAs over time, respectively. We used natural log-transformed HAAs as the outcome in all of our regression models. To improve interpretability, we exponentiated the regression coefficients of our log-transformed HAAs analysis to report our outcomes as percent change in HAAs.

We examined whether telomere length modified the association between *MUC5B* and HAAs based on a previous study that examined interactions between *MUC5B* and telomere length in pulmonary fibrosis.⁶ Studies have used different percentile cutoffs for telomere length as there is uncertainty of what is a relevant cutoff in general population-based cohorts.^{25–28} Therefore, stratified analyses were performed using age-adjusted percentile cutoffs for telomere length at 5%, 10%, and 25%. We accounted for baseline age in generating each of these cutoffs by using the percentile cutoff for each of the age groups: <50 years, 50–60, 60–70, and >80 years.

We examined associations of baseline (Exam 1) telomere length with Exam 1 HAAs using linear regression models with adjustment for baseline scanner parameters, age, sex, race/ethnicity, smoking history, cigarette pack-years, height, weight, percent emphysema, and principal components of genetic ancestry. For the longitudinal HAAs analysis, we used the same approach as our *MUC5B* analysis. We report results per 1-standard deviation increment in natural log-transformed telomere length.

We performed pre-specified stratified analyses by smoking status (never versus ever) based on past studies that suggest overproduction of mucin 5B may impair clearance of cigarette particles that leads to lung injury.²⁹ Sex was also examined as a potential effect modifier due to the differential associations of sex and pulmonary fibrosis risk.¹ For associations between telomere length and HAAs, we performed a stratified analysis by race/ethnicity. The log-likelihood ratio was used to test for effect modification in cross-sectional analyses. We used the F-test of the three-way interaction term, “effect modifier × primary exposure variable of interest × time since initial HAAs assessment”, to determine effect modification in longitudinal analyses.¹⁷

Joint modelling was used to examine the association of longitudinal changes of HAAs with time-to-event data (i.e., overall death and ILD-related events). This approach uses

linear mixed effects models to model longitudinal changes of a time-varying covariate of interest (i.e., HAAs) and examine its association with a time-to-event outcome using a Cox regression model.³⁰ For the ILD analysis, we used a composite binary outcome of ILD-related death or hospitalization. Due to the time when events were adjudicated, we used HAAs from Exams 1 through 5 (2010–2012) for the joint model. Results are reported as rate ratios (RR) per 1% increment in HAAs per year. A description of this method and the covariates we adjusted for in the models are in the supplement.

MUC5B and telomere length analyses were performed using SAS version 9.4 (SAS Institute, Cary, NC, USA). The “nlme”, “survival”, and “JMbayes2” packages were used for the joint model analysis in R version 3.6.1 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

There were 4,552 MESA participants with *MUC5B* genotype and Exam 1 HAAs assessments (Figure S1). Table 1 shows the baseline characteristics of the study sample. Over 50 percent of the cohort were women, Asian, African-American, or Hispanic, and had a history of smoking. There was a higher proportion of self-identified non-Hispanic White participants with the GT or TT genotype compared with other races/ethnicities (Table S1). Participant characteristics among those with longer versus shorter telomere length are shown in Table S2.

MUC5B and HAA

Table S3 summarizes the number of CT scans performed at each exam between 2000 and 2018 for our longitudinal analysis. There were 4,552 MESA participants with the *MUC5B* genotype and at least two repeat HAAs measurements between 2000 and 2018. Representative CT images of increasing HAAs between Exams 1 and 6 are shown in Figure 1.

Each *MUC5B* risk allele (T) was associated with an increase in HAAs of 2.60% (95% CI 0.36 to 4.86) per 10 years (Table 2) (Figure 2). In comparison, smoking 10 cigarettes per day on average was associated with an increase in HAAs of 4.69% (95% CI 2.24 to 7.15) per 10 years (Table S4). The association between *MUC5B* and HAAs was stronger among those with a telomere length below an age-adjusted cutoff of 5% (p-value for interaction=0.008). There was no significant effect modification with a telomere length cutoff of 10% and 25%. There was not a significant interaction with sex or smoking (Table S5). The *MUC5B* and HAAs association was strongest among non-Hispanic White participants with an increase in HAAs of 3.05% (95% CI 0.64 to 5.46) per 10 years, and was significant after applying a Bonferroni corrected p-value of 0.0125 (Table S6). Associations between *MUC5B* and HAAs were in the same direction but weaker and not significant in the other race/ethnic subgroups (Table S6).

Telomere Length and HAA

There were 4,488 MESA participants with telomere length and Exam 1 HAAs assessments (Figure S1). Shorter baseline telomere length was associated with more HAAs on Exam

1 cardiac CT. A 1-SD decrease in log-transformed telomere length was associated with a HAAs of 6.51% (95% CI 2.62 to 10.24) (Table 3). Participants with a telomere length below the 25th percentile had more baseline HAAs compared with those with longer telomeres (1.56%, 95% CI 0.04 to 3.11). Associations were not statistically significant using 5th and 10th percentile cutoffs. Baseline telomere length was not associated with a longitudinal change in HAAs overall and in stratified analyses (Table 3 and Table S7).

HAAs, Mortality, and ILD

Among the 4,552 participants, there were 4,517 (99%) who had adjudicated death status and complete covariate data. There was a total of 827 deaths with an event rate of 111.1 (95% CI 103.8 to 118.9) per 10,000 person-years. A 1% increment in HAAs per year was associated with a 7% higher risk of overall death (RR 1.07, 95% CI 1.02 to 1.12) after adjustment for covariates (Table 4). The association between longitudinal changes in HAAs and mortality were not significantly different by *MUC5B* risk allele carrier status, shorter telomere length, sex, or smoking history (p-values for interaction > 0.40) (Table S8). There were 4,443 participants with adjudicated ILD-related outcomes with a total of 29 events and an event rate of 5.5 (95% CI 3.7 to 7.7) per 10,000 person-years. A 1% increment in HAAs per year was associated with a 34% higher risk of ILD (i.e., ILD-related hospitalization or death) (RR 1.34, 95% CI 1.20 to 1.50).

DISCUSSION

The *MUC5B* (rs35705950) promoter variant was associated with more high attenuation areas over time among community-dwelling adults. This association was stronger among those with shorter telomere length using an age-adjusted 5th percentile cutoff and non-Hispanic White individuals. Shorter baseline telomere length was associated with more HAAs at baseline, but not with changes in HAAs over time. Longitudinal increases in HAAs were associated with worse survival and a higher risk of ILD-related events.

Prior studies have identified a strong association between the *MUC5B* (rs35705950) gain-of-function promoter variant and a higher risk of pulmonary fibrosis.^{5 31} *MUC5B* encodes the protein mucin 5B and is highly expressed in the lungs of adults with pulmonary fibrosis, particularly in the distal airways.³² Overexpression of *MUC5B* impairs mucosal host defenses, clearance of inhaled materials, and alveolar repair upon injury, and has been linked to a higher prevalence of ILA and its progression, further suggesting its pathogenic role in pulmonary fibrosis.^{8 33} Ours is the first study to report on the association of the *MUC5B* polymorphism with longitudinal quantitative changes in CT density (that could represent earlier stages of ILD) in a more general population cohort.

Our longitudinal analysis shows that the *MUC5B* (rs35705950) risk allele (T) was associated with increasing HAAs over time. This is consistent with prior studies that have identified associations between the *MUC5B* risk allele and other quantitative CT-based interstitial lung measures. Those previous studies have largely been cross-sectional and used cohorts comprised of individuals with a significant smoking history or first-degree relatives of adults with pulmonary fibrosis.^{34 35} This study extends the prior work to community-dwelling adults sampled without regard for respiratory symptoms or smoking

history. Notably, the association between *MUC5B* and HAAs was not affected by smoking history. Previous studies did not find an association between *MUC5B* and HAAs assessed from a single timepoint; the focus of our study was to examine longitudinal changes in HAAs.^{36 37} Another difference from prior work was that we accounted for changes over time in scanner models, height, and weight. Our longitudinal analysis over an 18-year span with repeated CT measurements supports the potential unidirectional relationship between the *MUC5B* variant and interstitial lung changes that may represent the early stages of ILD.⁸

Race-ethnic specific analyses revealed that the association between *MUC5B* (rs35705950) and HAAs was stronger in non-Hispanic White participants compared with other groups. Consistent with prior literature, the genotypes GT and TT were rare in the Asian and African-American subgroups and less common in the Hispanic group in MESA compared with the non-Hispanic White group.²³ Thus, we may have been under-powered to detect differences in the smaller racial/ethnic groups. There has been one prior study demonstrating an association between *MUC5B* (rs35705950) and ILA in a cohort of adults from Mexico.³⁸ Few other studies of genetic risk factors for early ILD/ILA have focused on underrepresented racial and ethnic groups, highlighting a pressing need for research in this area. African-American patients with ILD have been shown to have a younger age at diagnosis and longer survival time, underscoring the importance of research into the determinants of racial/ethnic differences in disease risk and progression.³⁹ The recent identification of variants related to obstructive lung disease and ILD in Hispanic/Latinx cohorts of admixed populations and African ancestry demonstrates that such studies are feasible.^{40–42}

In addition to the *MUC5B* polymorphism, telomere length has been strongly implicated in pulmonary fibrosis. Adults with IPF and other fibrosing ILDs who have shorter telomere lengths have an accelerated decline in their lung function and reduced survival.^{9 43} In our study, shorter absolute telomere length was associated with more HAAs from Exam 1 scans, which is consistent with prior ILA studies.^{10 44} However, when using different telomere length thresholds, only telomere lengths below the 25th percentile showed a significant association with HAAs. Our findings highlight an important knowledge gap. More research is needed to determine what is a relevant percentile cutoff for telomere length and its relationship to chronic diseases in the general population.

In contrast to the cross-sectional analyses, baseline telomere length was not associated with longitudinal changes in HAAs. A potential reason may be the dynamic nature of telomeres, with lengths that can change over time. In addition to telomerase-related genetic variants (e.g., *TERC*, *PARN*), environmental factors influence telomere length, including socioeconomic status (i.e., neighborhood status, home ownership), nutrition, cigarette smoking, dietary supplementation, and physical activity.^{45–50} We did not have repeat measures of telomere length at each exam in MESA and thus were not able to examine whether longitudinal changes in telomere length and its rate of attrition may be more informative in how cellular senescence relates to longitudinal changes in lung density.

We also found that individuals with the *MUC5B* risk allele and a baseline telomere length below an age-adjusted 5th percentile cutoff had more HAAs over time. It has been

speculated that individuals with a genetic predisposition (i.e., *MUC5B* risk allele carrier, telomerase mutations, etc.), in combination with other environmental risk factors, may increase one's risk of developing pulmonary fibrosis.⁵¹ Previous studies investigating this have largely been case-control in design, with samples comprised of clinically-diagnosed patients or adults of relatives with disease.^{6 44} It is intriguing to consider the possibility that our finding of an interaction between *MUC5B* and telomere length on progression of HAA, in a prospective, population-based cohort of community-dwelling individuals, may support this hypothesis. However, the subgroup nature of this analysis is exploratory as replication in independent cohorts and investigation of the potential intersection of biological pathways of *MUC5B* and telomere biology are needed.

More consequential may be our finding that increased HAAs over time were associated with worse overall mortality and a higher risk of ILD-related clinical events. This finding suggests that an increase in HAAs may indicate ongoing pathological processes in the lung, which have clinical implications. Notably, the effect estimate of the association between *MUC5B* and HAAs was comparable to that of cigarette smoking, which is a universally accepted risk factor for ILD.⁵² Increases in HAAs among carriers of the *MUC5B* risk allele had a higher risk for overall death compared with non-carriers. However, this interaction was not statistically significant. In contrast, among patients with IPF, the *MUC5B* risk allele was shown to be associated with improved survival.⁵³ However, this association has been suggested to be due to index event bias.⁵⁴ Further research is needed to understand the complex relationship between *MUC5B*, disease progression and survival in patients with fibrosing ILD.

This study had several limitations. First, histopathological correlations of HAAs are unknown. However, HAAs are associated with ILA, biomarkers of extracellular matrix remodeling, and ILD-related outcomes, suggesting that they have construct validity as a measure of parenchymal lung injury and fibrosis.^{18 21} Second, one of the concerns with HAAs, and other CT densitometric-based quantitative measures, is potential confounding by body habitus, atelectasis, and artifacts generated from foreign bodies, calcifications, and lung densities unrelated to ILD.³⁶ Although we cannot completely rule out residual confounding, we demonstrate that one of the strongest genetic risk factors for pulmonary fibrosis (i.e., *MUC5B* promoter variant), which does not appear to be influenced by adiposity or has a role in adipogenesis, is strongly associated with more HAAs. Notably, the effect estimate of the association between *MUC5B* and HAAs was comparable to that of cigarette smoking, which is a universally accepted risk factor for ILD.⁵² This provides further validity for HAAs as a risk factor for ILD.

Third, we did not have repeated measurements of WGS-extracted telomere length. Although telomere length from WGS correlates with laboratory-based measurements, further research is needed to improve and refine the techniques to extract telomere length from WGS, and obtain consensus on the platforms and relevant cutoffs more broad clinical use. Fourth, we may have been under-powered to detect a significant association in the underrepresented racial/ethnic subgroups.^{23 55} Fifth, we acknowledge the possibility of survival bias (an issue common to longitudinal population cohort studies), which may have influenced our findings. Finally, there was a very low number of ILD-related events, which is not unexpected

for a population cohort without known cardiovascular disease at baseline, and adjudicated ILD diagnoses from outpatient records were not available in this study population. The increasing incidence of ILD that is likely due to growing awareness of this condition and the adjudication of ILD-related outcomes by more cohort studies will be important to determine whether radiological tools can help identify at-risk individuals.⁵⁶

In conclusion, longitudinal increases in HAAs were associated with the *MUC5B* (rs35705950) promoter variant and a higher risk of death and ILD-related events in a population-based cohort of community-dwelling adults. This study demonstrates the feasibility and potential utility of using a quantitative assessment of lung parenchymal changes to investigate intrinsic risk factors for pulmonary fibrosis in a diverse cohort of community-dwelling adults. Quantitative CT assessments, especially more sophisticated texture-based methods that can more definitively distinguish ILD-specific characteristics from artifact, hold promise for the detection of ILD at its earlier stages and track its progression. Future studies that develop and refine quantitative methods to detect early interstitial lung changes and expand to more diverse study populations will be important in identifying novel factors that contribute to the development and progression of ILD.

The MESA project is conducted and supported by the NHLBI in collaboration with MESA investigators. Support for MESA is provided by contracts 75N92020D00001, HHSN268201500003I, N01-HC-95159, 75N92020D00005, N01-HC-95160, 75N92020D00002, N01-HC-95161, 75N92020D00003, N01-HC-95162, 75N92020D00006, N01-HC-95163, 75N92020D00004, N01-HC-95164, 75N92020D00007, N01-HC-95165, N01-HC-95166, N01-HC-95167, N01-HC-95168, N01-HC-95169, UL1-TR-000040, UL1-TR-001079, and UL1-TR-001420. Also supported in part by the National Center for Advancing Translational Sciences, CTSI grant UL1TR001881, and the National Institute of Diabetes and Digestive and Kidney Disease Diabetes Research Center (DRC) grant DK063491 to the Southern California Diabetes Endocrinology Research Center.

Whole genome sequencing (WGS) for the Trans-Omics in Precision Medicine (TOPMed) program was supported by the National Heart, Lung and Blood Institute (NHLBI). WGS for “NHLBI TOPMed: Multi-Ethnic Study of Atherosclerosis (MESA)” (phs001416.v1.p1) was performed at the Broad Institute of MIT and Harvard (3U54HG003067-13S1). Core support including centralized genomic read mapping and genotype calling, along with variant quality metrics and filtering were provided by the TOPMed Informatics Research Center (3R01HL-117626-02S1; contract HHSN268201800002I). Core support including phenotype harmonization, data management, sample-identity QC, and general program coordination were provided by the TOPMed Data Coordinating Center (R01HL-120393; U01HL-120393; contract HHSN268201800001I). Infrastructure for the CHARGE Consortium is supported in part by the NHLBI grant R01-HL105756. We gratefully acknowledge the studies and participants who provided biological samples and data for MESA and TOPMed.

What is already known on this topic

The *MUC5B* (rs35705950) risk allele (T) and telomere length are associated with pulmonary fibrosis and qualitative assessments of interstitial lung changes on computed tomography (CT). There are fewer studies that have examined their relationship with longitudinal interstitial lung changes among community-dwelling adults.

What this study adds

More high attenuation areas over time on computed tomography were associated with the *MUC5B* risk allele, particularly those with shorter baseline telomere length, and a higher risk of overall death and interstitial lung disease.

How this study might affect research, practice or policy

Our study suggests that quantitative computed tomography assessments and their longitudinal measures may be a potential tool to identify earlier stages of interstitial lung disease.

Figure 1. Computed tomography (CT) axial images that show an increase in high attenuation areas over time between Exams 1 (2000–2002) and 6 (2016–2018). Panels A and B are CT images of one participant with high attenuation areas percent of 4.34 at Exam 1 and 12.21 at Exam 6. Panels C and D are CT images of another participant with high attenuation areas percent of 7.38 at Exam 1 and 17.42 at Exam 6.

Figure 2. Predicted high attenuation areas (HAAs) over time by number of *MUC5B* (rs35705950) risk alleles (T). Linear mixed effects model with random intercept and slope adjusted for scanner parameters and principal components of genetic ancestry. Baseline sex, self-reported race/ethnicity, age, smoking status, cigarette pack-years, and their interaction term with “time since initial HAAs assessment.” Also adjusted for time-varying covariates height, weight, percent emphysema, and cigarettes smoked per day. Y-axis is log-scale.

Table 1

Study Sample Characteristics

Characteristic	Overall	<i>MUC5B</i> Genotype		
		GG	GT	TT
No. Participants	4,552	3,959	569	24
Age	61 (10)	61 (10)	61 (10)	60 (9)
Female sex	51%	51%	53%	50%
Race/ethnicity				
Non-Hispanic White	41%	37%	68%	75%
Asian	13%	15%	2%	0
African-American	24%	25%	10%	4%
Hispanic	22%	23%	20%	21%
Smoking Status				
Never smoker	46%	47%	40%	21%
Former smoker	40%	39%	46%	75%
Current smoker	14%	14%	14%	4%
Cigarette pack-years	12 (22)	11.5 (21.2)	13.9 (23.4)	19.4 (30.0)
Height (cm)	167 (10)	167 (10)	168 (10)	169 (7)
Weight (kg)	79 (17)	78 (17)	80 (18)	86 (21)
Telomere length (kb)	4.4 (0.9)	4.4 (0.9)	4.4 (0.9)	4.1 (0.9)

Abbreviations: HAA=high attenuation area

Continuous variables presented as mean (standard deviation)

Categorical variables presented as percentage

Associations of *MUC5B* (rs35705950) risk allele with longitudinal changes in high attenuation areas

Table 2

Model	No. Participants	% Longitudinal change in HAAs per 10 years (95% CI) per <i>MUC5B</i> (rs35705950) risk allele (T)	P-value*
Overall	4,552	2.60 (0.36 to 4.86)	0.02
Stratified by telomere length percentile cutoff			
Below 5 th percentile	221	15.13 (5.60 to 24.75)	0.008
Above 5 th percentile	4,267	1.93 (-0.40 to 4.27)	
Below 10 th percentile	446	5.26 (-1.35 to 11.91)	0.41
Above 10 th percentile	4,042	2.30 (-0.11 to 4.71)	
Below 25 th percentile	1,119	5.03 (0.83 to 9.25)	0.19
Above 25 th percentile	3,369	1.72 (-0.94 to 4.38)	

Abbreviations: CI=confidence intervals; HAAs=high attenuation areas

Overall model is adjusted for scanner parameters and principal components of genetic ancestry. Baseline age, sex, self-reported race/ethnicity, smoking status, cigarette pack-years were also adjusted for including their interaction terms with “time since initial HAAs assessment.” Time-varying covariates height, weight, percent emphysema, and cigarettes smoked per day were also adjusted for in the model.

Stratified models include their respective three-way interaction term (e.g., “telomere length percentile below 5% × *MUC5B* risk allele × time since initial HAAs assessment”).

* P-values for stratified analysis represent p-values for interaction.

All results are reported per risk allele (T) of the *MUC5B* (rs35705950) promoter variant

Table 3

Associations of baseline telomere length with high attenuation areas

Model	No. Participants	Mean percent change in Exam 1 HAAs (95% CI)	P-value	% Longitudinal change in HAAs per 10 years (95% CI)	P-value
Absolute telomere length*	4,488	-6.51 (-10.24 to -2.62)	0.001	0.32 (-4.68 to 5.55)	0.90
Age-adjusted telomere length percentile cutoffs					
Above 5 th percentile	4,267	0.0 (REF)		0.0 (REF)	
Below 5 th percentile	221	0.44 (-2.55 to 3.52)	0.78	0.87 (-2.82 to 4.56)	0.65
Above 10 th percentile	4,042	0.0 (REF)		0.0 (REF)	
Below 10 th percentile	446	0.16 (-2.00 to 2.36)	0.88	1.41 (-1.28 to 4.10)	0.30
Above 25 th percentile	3,369	0.0 (REF)		0.0 (REF)	
Below 25 th percentile	1,119	1.56 (0.04 to 3.11)	0.04	0.11 (-1.74 to 1.96)	0.91

Abbreviations: CI=confidence intervals; HAAs=high attenuation areas

* Reported per standard deviation increment of log-transformed telomere length

Exam 1 HAAs model: Adjusted for scanner parameters, principal components of genetic ancestry, and baseline age, sex, self-reported race/ethnicity, smoking status, cigarette pack-years height, weight, and percent emphysema.

Longitudinal HAAs model: Adjusted for scanner parameters and principal components of genetic ancestry. Baseline age, sex, self-reported race/ethnicity, smoking status, cigarette pack-years were also adjusted for including their interaction terms with "time since initial HAAs assessment." Time-varying covariates height, weight, percent emphysema, and cigarettes smoked per day were also adjusted for in the model.

Table 4

Associations of longitudinal changes in high attenuation areas with mortality and interstitial lung disease

Model	No. Participants	Total Person-years	Events	Event Rate per 10,000 Person-Years (95% CI)	Rate Ratio per 1% Increment in HAAs per year (95% CI)	P-value
Overall mortality	4,517	74,415	827	111.1 (103.8 to 118.9)	1.07 (1.02 to 1.12)	<0.001
Interstitial lung disease	4,443	53,173	29	5.5 (3.7 to 7.7)	1.34 (1.20 to 1.50)	<0.001

Abbreviations: CI=confidence intervals; HAAs=high attenuation areas

Models adjusted for sex, self-reported race/ethnicity, baseline age, smoking status, cigarette pack-years, height, weight, systolic and diastolic blood pressures, total cholesterol, high-density lipoprotein cholesterol, diabetes history, cancer history, coronary artery calcium score, percent emphysema, and total intentional exercise (met-min/week).

Interstitial lung disease events defined as a hospitalization or death related to interstitial lung disease using ICD-9 codes (ICD-9 codes 495.XX, 515.XX, or 516.XX and ICD-10 codes J60.X-J64.X, J67.X, or J84.X)
