Abstract

Diabetic nephropathy (DN), which is a common microvascular complication with a high incidence in diabetic patients, greatly increases the mortality of patients. With further study on DN, it is found that epigenetics plays a crucial role in the pathophysiological process of DN. Epigenetics has an important impact on the development of DN through a variety of mechanisms, and promotes the generation and maintenance of metabolic memory, thus ultimately leading to a poor prognosis. In this review we discuss the methylation of DNA, modification of histone, and regulation of non-coding RNA involved in the progress of cell dysfunction, inflammation and fibrosis in the kidney, which ultimately lead to the deterioration of DN.

Key words diabetes, diabetic nephropathy, epigenetics, metabolic memory

Introduction

Diabetes, as a major medical problem in this century, threatens human health. About 92.4 million adults in China suffer from diabetes (accounting for 9.7% of the total adult population), and 60.7% of them have not been diagnosed or received relevant treatments [\[1\]](#page-5-0). More seriously, the incidence rate of diabetes has markedly increased in the last few decades around the world. According to statistics from the International Diabetes Federation, there were 463 million diabetic patients in 2019. It is estimated that the number of people with diabetes will increase to 700 million by 2045 [\[2\]](#page-5-1).

Previously, in the Diabetes Complications and Control Trial (DCCT), patients with type I diabetes regulated their blood glucose level through receiving standard or intensive treatment. It has been demonstrated that the progression of microvascular complications is significantly reduced in patients with intensive treatment [\[3\]](#page-5-2). As a consecutive experiment of DCCT, the Diabetes Intervention and Complications Epidemiology (EDIC) trial showed that compared with patients who had received intensive treatment throughout the trial, the incidence of diabetes complications of the patients who had received standard treatment and switched to intensive treatment a few years later is still higher $[4,5]$ $[4,5]$. Therefore, for some diabetic patients, especially those who start to strengthen blood sugar control after 8-11 years of illness, only applying measures to control blood sugar within the normal range cannot effectively prevent the occurrence of related cardiovascular complications [\[6](#page-5-5)–[9](#page-5-6)].This kind of hyperglycemic stress state that the body continues to maintain even if blood sugar returns to normal is defined as 'hyperglycemia memory' [\[10](#page-5-7),[11](#page-5-8)].

Current studies showed that some signal transduction mechanisms in the diabetic state, including oxidative stress, advanced glycation end products (AGEs) receptor (RAGE) activation, tyrosine kinases, mitogen-activated protein kinases (MAPKs), protein kinase C (PKC), and nuclear factor kappa beta (NF-κB), participate in the development of high-glycemic memory [[12](#page-5-9)–[17\]](#page-6-0). In addition, the AGEs and transforming growth factor-beta (TGF-β) produced in high-glycemic memory can have serious adverse effects on the target cells of renal damage [[18–](#page-6-1)[21\]](#page-6-2). Whole-genome analysis denoted that genetic testing technology alone cannot make an accurate assessment of the risk of diabetes and its complications [\[22\].](#page-6-3) The discovery of 'metabolic memory' has become sound evidence of the mechanism of epigenetics with prolonged effects [\[23\],](#page-6-4) which has attracted massive attention during the study of the pathogenesis of DN. Moreover, previous studies did not reveal a causal link between epigenetics and changes in gene sequences but did prove that epigenetics affects phenotypes [\[24\],](#page-6-5) causing changes in external characteristics, revealing the interaction between genetic material and the environment, including DNA methylation, post-translational histone modifications, and non-coding RNA regulation ([Figure](#page-1-0) 1) [[25–](#page-6-6)[29\]](#page-6-7). Epigenetic modification regulates relative gene expressions on one side, which enable the human body to respond quickly to the change in the surrounding circumstances, and guarantees to remember these reactions to establish a internal metabolic memory on the other side [\[30\].](#page-6-8) DN is a ubiquitous microvascular complication among diabetic patients, and the main pathogenesis of the end-stage renal disease. Its pathological characteristics include the thickened glomerular basement membrane (GBM), increased mesangial matrix, tubulointerstitial fibrosis, and podocyte loss [\[31\]](#page-6-9). The formation mechanism of DN is quite complicated, including genetic and non-genetic factors. High-throughput sequencing technology revealed that epigenetics regulates gene expression through a single or synergistic effect, which ultimately influences the occurrence and progression of DN [\[32\]](#page-6-10). Hence , epigenetics has been extensively studied in the microvascular endothelial damage caused by high glucose. So, studies on the mechanism by which epigenetic modifications mediate the morbidity and mortality of patients with diabetes and on its microvascular complications are of great practical significance [\[27\]](#page-6-11).

Therefore, this article reviews the latest progresses in the research about epigenetics in the pathogenesis of DN.

DNA Methylation

DNA methylation is catalyzed by the DNA methyltransferases (DNMTs), with the methyl group being transferred to the 5' end of the cytosine residue in the dinucleotide cytosine guanine (CpG) [\[33\]](#page-6-12). Among these DNMTs, DNMT1 plays a role during the replication of DNA, while DNMT3a and DNMT3b mainly have the function of re-methylation during cell development [\[34\]](#page-6-13). DNA methylation directly interferes with the binding of the transcription complex in the promoter region or indirectly recognizes 5-methylcytosine, through the methyl-binding protein, to recruit the co-repressor to bind to the promoter region [\[35\]](#page-6-14). Hence, transcription disorders may cause abnormal methylation of key genes and consequently lead to some diseases [\[36\]](#page-6-15). During the development of DN from hyperglycemia, there are 694 hypomethylated CpG sites and 174 hypermethylated sites in the genome, including the inflammation of glucose metabolism, oxidative stress, mitochondrial stress and fat metabolism, which are involved in DN pathogenic gene locus [\[37\]](#page-6-16). Comparison of the type 1 diabetes patients with or without complications showed that DNA methylation of key genes changes over time $[38]$, which provides direct evidence for a relationship between DNA methylation and hyperglycemia-induced metabolic memory.

Chronic oxidative stress is another crucial cause of DN [\[39\].](#page-6-18) Various studies have revealed that oxidative stress regulates DNA methylation and results in disease accordingly [\[40](#page-6-19)–[42](#page-6-20)]. Furthermore, the existence of metabolic memory exacerbates the production of reactive oxygen species (ROS) [\[43\]](#page-6-21). ROS, via modulating the activity of DNMT and damaging DNA, regulates methylation of key genes sequentially. Namely, ROS, as extremely reactive compounds, can produce many damaged sites in DNA. Superoxide dismutase 2 (SOD2), which is a key factor in anti-oxidative stress, can be inhibited by DNA methylation, thus mediating smooth muscle cell proliferation [\[44\].](#page-6-22) On the other hand, the abnormal methylation of SOD2 activates hypoxia inducible factor-1α (HIF-1α) [\[45\]](#page-6-23), which inhibits HO-1-mediated control of mitochondrial dynamics, and prevents the overproduction of ROS $[46,47]$ $[46,47]$ $[46,47]$ $[46,47]$. So, HIF-1 α can exert a protective effect in DN.

The expression of DNMT1 is increased in mouse podocytes stimulated by high glucose [\[48\]](#page-6-26), while this tendency can be attenuated

[Figure](#page-1-0) 1. The potential mechanisms of epigenetic regulation of diabetic nephropathy

after treatment with 5-azacytidine, an inhibitor of DNMT1, accompanied by a reduction of proteinuria and glomerular hypertrophy and an improvement of podocyte motility. Hence, DNMT1 may be a therapeutic target for protecting against DN podocyte injury [\[48\]](#page-6-26). In the kidneys of diabetic mice, the proximal tubular cells showed DNA hypomethylation of myo-inositol oxygenase (MIOX), which could be firmly bound by the transcription factor Sp1 on the gene promoter, thus mediating kidney damage progress [\[49\]](#page-6-27). Similar effects of abnormal DNA methylation models come under observation in podocytes cultured in a hyperglycemic environment [\[50\]](#page-6-28). The promoter region of matrix metalloproteinase (MMP)-9 also contains demethylated CpG sites, which can be induced by hyperglycemia, leading to the epithelial-mesenchymal transition (EMT) of podocytes [\[51\]](#page-6-29). The analysis of clinical samples of DN patients revealed that the demethylated promoter region of MMP-9 is not only correlated with the diagnostic indicators of DN positively, but also correlated with the glomerular filtration rate (GFR) negatively. This phenomenon denotes that the demethylation level of the promoter region of MMP-9 has a strong causal relationship with the pathophysiology of DN [\[52\].](#page-6-30) In addition, further research revealed that the connection between DNA methylation and histone modification could be mediated partially through methylcytosinebinding proteins, such as MECP2 and MBD2, which can recruit histone deacetylases to the methylated region [\[53](#page-6-31),[54](#page-7-0)]. As a mark of repressive chromatin, DNA methylation could also dimethylate H3K9 through the interaction of G9a and DNMT1 with the replication complex [\[54](#page-7-0),[55](#page-7-1)].

In vivo experiments have confirmed that change of the methylation level of differentially methylated regions of necrosis factoralpha (TNF- α) with the use of dCas9-Tet1 system could alter TNF- α expression at the transcriptional level $[56]$. Moreover, TNF- α , produced by macrophages/monocytes [\[57\]](#page-7-3), was proved to be related to the development of DN consequentially. In addition, it was reported that DNMT1 is up-regulated in peripheral immune cells of diabetic patients, which mediates the hypermethylation of the negative regulators of mTOR, causing the activation of the mTOR signaling pathway and resulting in the renal inflammation [\[58\].](#page-7-4) What's more, in the leukocyte DNA methylation patterns of T2DM patients, the methylation of 77 CpG sites was found to be associated with a decrease in GFR [\[59\]](#page-7-5). Among these targets, Cdc42 GTPase activating protein (CdGAP), FK506-binding protein like (FKBPL), and activating transcription factor 6 beta (ATF6B) show consistent associations with the directionality of matching kidney tissue fibrosis. Moreover, CdGAP, FKBPL, and ATF6B have been reported to participate in mediating immune cell migration, inflammation and glomerulosclerosis [[60](#page-7-6)–[62\]](#page-7-7), indicating that the argument of DNA methylation in peripheral immune cells is a potential biomarker of DN progression.

Histone Modification

Histones are highly conserved proteins in eukaryotic cells, which can associate with DNA to make up the nucleosomes, thereby constituting the basic unit of chromatin structure. Histones are modified by a series of specific enzymes, and the types of modifications include methylation, acetylation, phosphorylation, and ubiquitination [\[63\].](#page-7-8) Moreover, histone modification functions as a crucial part of the regulation of transcription, DNA replication, DNA repairment and chromatin aggregation. Current studies on histone modification mainly focus on the specific amino acid residues of histone H3 and H4. At present, many studies are carried out on histone methylation-demethylation, acetylation-deacetylation and lactylation. The following parts will introduce the roles of these aspects in DN.

Methylation and demethylation

Histone methylation can induce activation or repression of the transcription process, depending on the changes in the number and position of methyl groups caused by the combined action of histone methyltransferase and histone demethylase. In the glomerular mesangial cells of the diabetic model, H3 histone modification plays an important role. H3 histone lysine methylation (H3Kme) can augment the expressions of TGF-β1 and the extracellular matrix (ECM) proteins-related genes, such as CTGF, collagen-α¹ and PAI-1 [[64](#page-7-9),[65\]](#page-7-10). Moreover, H3K4me1/2/3, H3K36me2/3, and H3K79me2 can accumulate the pro-inflammatory cytokines and exacerbate the ECM during glomerular fibrosis, ultimately leading to the deterioration of DN [\[66\].](#page-7-11) Conversely, H3K9me2/3 and H3K27me3 can inhibit the expressions of fibrotic factors, superoxide dismutase and pro-inflammatory genes, thus decreasing inflammation and fibrosis in the kidney, and eventually delaying the progression of DN [\[67\].](#page-7-12) Further experiments demonstrated that the specific histone methyltransferase for H3K27me is the enhancer of zeste homolog 2 (Ezh2), which can accelerate the process of renal fibrosis [\[68\].](#page-7-13) H3K27me3 and Ezh2 repress and maintain the expressions of fibrosis and inflammatory genes in the renal mesangial cells under normal conditions [\[67\]](#page-7-12). However, this combination in podocytes is suppressed under a diabetic environment [\[69](#page-7-14)[,70](#page-7-15)], and TGF-β inhibits the H3K27me3 and Ezh2 levels to mediate mesangial dysfunction, thus eventually leading to kidney damage [\[67\]](#page-7-12). In addition, Ezh2-methylated H3K27 can serve as an anchor point for CpG methylation, leading to the formation of silent chromatin, and ultimately, to transcriptional gene silencing [\[71\]](#page-7-16). Therefore, further investigation is necessary to clarify the role of Ezh2 in the pathological process of DN development.

In contrast, H3K27me-specific histone demethylases are lysinespecific demethylase 6A (KDM6A, also known as UTX) and 6B [\[72\].](#page-7-17) Previous studies have pointed out that the expression of KDM6A increases in the kidney tissue of diabetic mice and DN patients [\[73\].](#page-7-18) Moreover, the use of KDM6A inhibitor or si-RNA in diabetic model mice improves renal dysfunction [\[73\]](#page-7-18). In addition, pathophysiological indicators, such as proteinuria level, kidney weight, apoptosis, thickening of GBM, and fibrosis are improved in KDM6A-knockout diabetic mice [\[74\]](#page-7-19). Meanwhile, kruppel-like factor, as a transcription factor, can enhance the dedifferentiation effect of KDM6A on podocytes, leading to the disappearance of foot processes [\[74\],](#page-7-19) which deserve further investigation to find the potential therapy targets of DN.

Histone methyltransferase plays an important role in hyperglycemia-mediated injury as well. Previous studies showed that SET7/9 is related to the regulation of the TGF-β1/p21 pathway in chronic kidney disease [\[65\].](#page-7-10) In our previous experiment, SET8 was found to be a member of the SET domain-containing methyltransferase family, which is involved in the production of hyperglycemic memory [\[75\]](#page-7-20). SET8, as the only known lysine methyltransferase involved in the monomethylation of lysine 20 of histone H4 (H4K20) [\[76\],](#page-7-21) modulates the expressions of proinflammatory enzymes and NLRP3 inflammasome activation in the hyperglycemic HUVECs [[77](#page-7-22)–[79\]](#page-7-23). Furthermore, overexpression of SET8 leads to histone methylation, thereby regulating downstream signaling pathways and protecting DN $[80]$.

Acetylation and deacetylation

Over the decades, the research about acetylation and deacetylation of histone in T2DM and microvascular complications has increased gradually. This key process is catalyzed by histone acetyltransferase (HAT) and histone deacetylase (HDAC). Among them, acetylation loosens chromosomal DNA and activates gene expression, while histone deacetylase inhibits gene transcription [\[81\]](#page-7-25).

HAT catalyzes the acetylation of histones, relaxes the chromatin structure, and promotes transcription positively. In DN, the hyperglycemic environment increases the activities and expression levels of HATs, including p300, CREB-binding protein (CBP), and CBP-associated factor (CAF) [\[82\].](#page-7-26) In addition to histones, HAT also acetylates a variety of other proteins such as S-mads, p53/Sp1, and NF-κB, which would further mediate the upregulation of pro-inflammatory cytokines and ECM, and deteriorate the process of DN fibrosis [\[83\]](#page-7-27). As an activator, CAF possesses the activity of an intrinsic HAT [\[84\].](#page-7-28) Some studies further proved that CAF is closely correlated with the H3K18Ac levels, and enriched on the promoters of inflammatory molecules ICAM-1 and MCP-1. Intervention at this site has the potential to improve inflammation-related renal diseases [\[85\].](#page-7-29) Additionally, CBP and p300, as transcriptional co-activators of many vital transcription factors, can play a vital regulatory role in epigenetics by catalyzing the acetylation of histones and transcription factors [\[86\]](#page-7-30). Because of their similar structure and redundant function, CBP and p300 often refer to combine jointly. In renal mesangial cells, TGF-induced PAI-1 and p21 are highly related to the interaction between p300/CBP and Smads or Sp1, while H3K9/14Ac increases the p300/CBP-induced promoter activation, which in turn exacerbates the glomerular dysfunction associated with DN [\[87\]](#page-7-31). The subsequent experiments demonstrated that curcumin analogue, C66, as an inhibitor of CBP/p300, can protect renal injury in diabetic mice via restraining the expression of JNK and inhibiting the diabetes-related increase in the expression of p300/CBP and acetylation of H3K9/14Ac [\[88\]](#page-7-32). In addition, C66 can protect diabetic aortic pathological changes by inhibiting JNK function, accompanied by a boost in the Nrf2 expression [\[89\].](#page-7-33) In summary, these data implied that HAT plays a critical role in acetylating histones and may be a potential target for the treatment of DN.

As mentioned above, histone deacetylase inhibits gene transcription in the process of histone acetylation and deacetylation. Till now, 18 HDACs have been found and classified into 4 distinct classes according to their homology to yeast HDAC, including Class I (HDACs1, 2, 3, and 8); Class II being composed of II-a (HDACs4, 5, 7, and 9) and II-b (HDACs6 and 10); Class III, sirtuins (SIRTs1–7) and Class IV (HDAC11) [\[90\].](#page-7-34) Different HDACs participate in the pathogenesis of DN through distinct pathways. Among the 4 different classes, HDAC1, as a pro-apoptotic factor, participates in TGF-β1-induced apoptosis [\[91\]](#page-7-35). HDAC2 can promote fibrosis [\[92\]](#page-8-0). In TGF-β1-treated cells, the knockdown of HDAC2 can reduce the ECM components, implicating the impact of HDAC2 on fibrosis in the kidney [\[93\]](#page-8-1). Hydrogen peroxide (H_2O_2) , known as a potent oxidative stressor, also increases the level of HDAC2 [\[93\]](#page-8-1), and this could be the latent mechanism of DN which deserves further study. HDAC4 was confirmed as a contributor to podocyte damage in diabetic patients, and it can inhibit autophagy through deacetylation of STAT1 [\[94\].](#page-8-2) In addition, sirtuins are also involved in the development of diabetes. SIRT1 inhibits high glucose-induced senescence of vascular cells by reducing ROS accumulation [\[95\].](#page-8-3) p66Shc is mainly expressed in renal tubular cells, and a previous study showed that high glucose-induced down-regulation of sirtuin-1 promotes p66Shc expression by increasing the levels of histone H3 and p66Shc acetylation [\[96\]](#page-8-4). Normally in glomerular mesangial cells, SIRT1 not only intercepts the activity of the pro-hypertrophic Akt signaling pathway, but also enhances the anti-hypertrophic AMP-activated protein kinase (AMPK) activation [\[97\].](#page-8-5) However, the high glucose-induced decrease of SIRT1 leads to the activation of HIF-1α, which induces the expressions of endothelin-1, TGF-β1 and VEGF, thus leading to the pathological angiogenesis and fibrosis of the kidney. It has also been reported that the progress of inflammation and fibrosis can be reversed by mir-217 gene silencing through regulating the SIRT1/HIF-1 α signaling pathway [\[98\]](#page-8-6). The progress of peritubular capillary rarefaction and fibrosis can be observed in the mice with knockout of SIRT1, and SIRT1 can ameliorate albuminuria actively in diabetic mice [\[99\].](#page-8-7)

As an inhibitor of HDAC, valproate facilitates autophagy and depresses the NF-κB/iNOS signaling, thereby improving the podocyte damage and renal injuries [\[100\]](#page-8-8). Treatment with sodium butyrate (NaB) can significantly decrease the levels of blood sugar and creatinine, improve histological alterations including collagen accumulation and fibrosis, and inhibit the expressions of HDACs, NFκB activation, and DNA damage in the diabetic kidney tissue [\[101\].](#page-8-9) NaB can also upregulate the expression of Nrf2. Compared with the wild-type mice treated with NaB, C57BL/6 Nrf2-knockout mice developed more severe oxidative stress and inflammation in the aortic endothelium [\[102\]](#page-8-10). Moreover, NaB increases the synergistic effect between the transcription factor and the p300 on the promoter of the Nrf2, which could be abolished by the p300 inhibitor C646 [\[102\]](#page-8-10).

Lactylation

With the in-depth research on histone, a new type of histone modification, named histone lactylation, was identified [\[103\]](#page-8-11). Lactylation of histone lysine residues serves as an epigenetic modification that directly stimulates gene transcription [\[104\].](#page-8-12) In a previous study, histone lactylation was found to accelerate the pulmonary fibrosis of mice and humans [\[105\]](#page-8-13). This modification pattern also promotes tumorigenesis through activating m⁶A reader protein directly [\[106\].](#page-8-14) In addition, a histone modification and transcription assay revealed that histone lactylation can directly activate gene transcription in a p53-dependent p300-mediated pathway [\[104\]](#page-8-12), it means that p300 is not only an acetyltransferase, but also a promising candidate lactyltransferase. Currently, histone lactylation has not been reported in DN. Therefore, this new mode of histone modification is worthy of further study.

Non-coding RNAs

Recent studies have demonstrated that non-coding RNAs (ncRNAs) play a vital role in the progression of renal disease, and may be adopted as novel biomarkers and treatment sites of the DN. ncRNA refers to RNA that does not encode any protein, and the most famous ones are miRNAs and long non-coding RNAs [\[32](#page-6-10)[,107,](#page-8-15)[108](#page-8-16)]. They regulate the expressions of genes through modulating protein synthesis at the post-transcription and translation levels [\[109\].](#page-8-17)

miRNAs, as a kind of endogenous ncRNAs composed of 22 nucleotides, can bear the function of degrading or inhibiting translation through participating in the regulation of post-transcriptional gene expressions via binding to target mRNA [\[110\]](#page-8-18). Most of them are the primitive transcripts produced by RNA polymerase acting on the intron regions of protein-coding genes [\[111\]](#page-8-19). Researchers have illustrated that the process of miRNA regulation is complex, which means that a single miRNA can simultaneously regulate multiple target genes and vice versa [\[112](#page-8-20),[113](#page-8-21)]. What's more, numerous pieces of evidence have shown that the expression, regulation, and localization of miRNA can be modulated by changes in the cellular environment accordingly [\[114\]](#page-8-22).

The hyperglycemia environment can increase the expressions of part of the miRNAs. Among them, miR-21 expression is elevated in DN by inhibiting the expression of TIMP3. As a result, high glucoseinduced inflammatory responses and podocyte apoptosis are aggravated in the DN patients [\[115\].](#page-8-23) The other mechanism by which miR-21 regulates renal injury is via the regulation of Smad7 level. Knockdown of miR-21 would restrain the TGF-β and NF-κB signaling pathways and restore Smad7 level in diabetic mice [\[116\]](#page-8-24). Moreover, it has been shown that miR-21 can enhance the leakage of the slit membrane through inhibiting PTEN-mediated movement of podocytes, thus leading to albuminuria [\[117\]](#page-8-25). At the same time, the changing trend of miR-21 in serum is consistent with that in kidney tissue, which enables the level of miR-21 in serum to reflect the kidney function indirectly and to be regarded as a biomarker for the diagnosis of DN [\[118\]](#page-8-26). Another oxidative stress-related miRNA is miR-217, and it was characterized in podocytes cultured in a hyperglycemic environment. PTEN is the target of miR-217, which would affect cell apoptosis and ROS production through the pathway of PI3K/AKT/mTOR [\[119\].](#page-8-27) From the aspect of inflammation, miR-27 as a pro-inflammatory miRNA, can negatively regulate Nrf2 [\[120\]](#page-8-28) and PPAR γ /β-catenin [\[121\],](#page-8-29) thus inducing the pro-inflammatory cytokines in the podocytes of the diabetic model. EMT, carried out by the EMT-activated transcription factor (EMT-TF), is one of the important mechanisms of tissue fibrosis. It has been demonstrated that the ubiquitin E3 ligase complex Skp1-Pam-Fbxo45 (SPFFbxo45) can dynamically repress EMT-TF, while miR-27a can reduce the expression of Fbxo45 directly, thereby hindering the degradation of EMT-TF and guaranteeing the occurrence of EMT [\[122\].](#page-8-30) Different from the aforementioned findings, another study indicated a nephroprotective role of miRNA-29 [\[123\].](#page-8-31) Wang et al. [\[123\]](#page-8-31) discovered low levels of miRNA-29 exist in high glucose-induced early-stage renal fibrosis, advanced diabetic renal fibrosis, and advanced nondiabetic kidney disease. However, another study reported that the expression of miR-29c was higher in kidney tissue, urine sediment, and blood samples of DN patients than that in normal controls. Finally, in-depth research demonstrated that miR-29c is closely related to the increased secretion of inflammatory cytokines [\[124\]](#page-8-32). In HK-2 cells cultured in high glucose medium, miR-34a-5p accelerates the transcriptions of SIRT1-related fibrotic genes through the signaling of SIRT1/TGF-β [\[125\].](#page-8-33) Furthermore, miR-133b and miR-199b can also induce EMT and renal fibrosis through SIRT1/TGF-β pathway [\[126\]](#page-8-34).

Among the down-regulated miRNAs, miR-192 is dysregulated and mediates the activation of TGF-β/Smad3 signaling in the early development of renal fibrosis [\[127,](#page-8-35)[128](#page-8-36)]. In the kidneys of diabetic rats, TGF-β targets ZEB1/2 in the proximal tubular epithelial cells through silencing miR-192 expression. It should be noted that ZEB1 and ZEB2 are E-box-binding proteins which have an important impact on the early phase of EMT [\[129\].](#page-8-37) In addition, the miR-192 level in serum and urine is relatively stable and hard to degrade, which may denote that miR-192 could be used to diagnose the level of kidney damage better than the commonly used clinical test index, i.e., the albumin-to-creatinine ratio [\[130\]](#page-9-0). Another downregulated miRNA in DN is miR-30e, and the overexpression of miR-30e can promote the proliferation of renal tubular endothelial cells and inhibit EMT through inhibiting GLIPR-2 expression, thus ultimately avoiding renal fibrosis [\[131\]](#page-9-1). Moreover, miR-25 decreases in a timedependent manner in HK-2 cells cultured in high glucose medium. Overexpression of miR-25 can inhibit the production of ROS and activate the PTEN/AKT pathway to produce anti-apoptotic effects [\[132\].](#page-9-2) Liu et al. [\[133\]](#page-9-3) also found that miR-25 overexpression in the podocytes of DN mice can reduce proteinuria, attenuate glomerular fibrosis, and inhibit the RAS system to decrease renal hypertension. Furthermore, monocyte chemoattractant protein (MCP)-1 recruits macrophages to inflammatory sites, thus aggravating the development and progression of DN. It was reported that miR-374a has an anti-inflammatory effect through the negative regulation of MCP-1 expression [\[134\].](#page-9-4) In DN patients, restoration of miR-374a expression can effectively prevent inflammation in renal tubular epithelial cells [\[134\].](#page-9-4)

Long Non-coding RNAs

As mentioned above, long non-coding RNAs (lncRNAs), which have a nucleotide length greater than 200 nt with no protein-coding function, is another type of ncRNAs that can regulate gene expression. Similar to protein-coding mRNAs, lncRNA is also transcribed by RNA polymerase II or polymerase III, and most of them have 5-caps and 3-terminal polytails. However, the conserved sequences between species are less than 10%, and the expression abundance is not high. Therefore, they have strong tissue and cell specificity [\[135](#page-9-5)–[137\]](#page-9-6). In terms of its function, lncRNA can regulate gene expression at the levels of transcription, post-transcription, and translation [\[138\].](#page-9-7) The biological evidence for extracellular lncRNA is limited, but numerous studies have successfully illustrated that, similar to miRNA, lncRNAs exist in vesicles or circulate freely in biological fluids [\[139\]](#page-9-8). More importantly, under normal circumstances, lncRNAs are usually expressed at low levels, but the levels will increase specifically at a specific stage of disease progression [[140](#page-9-9)[,141\]](#page-9-10).

As the first lncRNA that has been demonstrated to be related to kidney diseases, plasmacytoma variant translocation (PVT1) was confirmed to have a close relationship with the occurrence and development of DN [\[142\].](#page-9-11) As a type of lncRNA located in the 8q24 region of the human chromosome, the increase of PVT1 expression would promote cell proliferation and inhibit cell apoptosis [\[143\].](#page-9-12) In addition, the expression of PVT1 was found to be upregulated in glomerular mesangial cells under high glucose conditions. Meanwhile, PVT1 regulates the expression of the main components of ECM and its main regulator PAI-1 in a manner independent of the TGF-β1 pathway. Compared with the effect of inhibiting TGF-β1, knockout of PVT1 was proved to be a more effective approach in reducing the levels of FN1, COL4A1, and PAI-1 [\[144\]](#page-9-13). Moreover, it has been shown that under high glucose environment both PVT1 and its derivative miR-1207-5p can enhance the expressions of FN1, TGF-β1, and PAI-1 in glomerular mesangial cells independently of each other, thereby increasing ECM accumulation and accelerating the process of renal fibrosis of DN [\[145\]](#page-9-14). In addition, PVT1 also activates the pathway of PI3K/Akt/mTOR via up-regulating miR-935p [\[146\]](#page-9-15), which promotes the progress of cell proliferation, migration and invasion. Apart from PVT1, H19 is also expressed in the nucleus and is significantly increased in some diseased conditions [\[147,](#page-9-16)[148](#page-9-17)], which has been reported to participate in renal diseases [\[149\].](#page-9-18) It has been reported that H19 is increased in TGF-β2-induced fibrosis in proximal tubular cells [\[150\]](#page-9-19), implying that inhibition of H19 alleviates fibrosis and reconstructs normal tissue of the kidney. Meanwhile, it is interesting to note that inhibition of H19 also changes miR-29a level and inhibits endothelial-to-mesenchymal transition (EndMT) through attenuating the TGF-β/Smad signaling pathway, leading to the block of fibrosis in DN [\[151\].](#page-9-20)

Hyperglycemia can promote inflammation, oxidative stress, and fibrosis of the kidneys and it is an important cause of the occurrence and development of DN. Among these three adverse consequences, chronic inflammation plays a particularly important role in the early stage of DN. It was reported that knockout of lncRNA Gm4419 can improve NF-κB/NLRP3 inflammatory complex-mediated cell inflammation, fibrosis, and proliferation [\[152\].](#page-9-21) Similarly, increased expression of lncRNA GM6135 promotes inflammatory reaction by augmenting TLR4 expression in diabetic mice. As a member of TLRmediated signaling, TLR4 secrets pro-inflammatory cytokines by sponging related miRNAs [\[153\].](#page-9-22) In addition, lncRNA Tug1 not only participates in regulating ECM accumulation, but also regulates the process of DN via modulating mitochondrial damage. Meanwhile, it has been proven that $PGC-1\alpha$ plays an important role in cell energy and mitochondrial homeostasis, while the expression levels of PGC-1α and lncRNA Tug1 were decreased in diabetic environment [\[154\]](#page-9-23). Similarly, Long et al. [\[155\]](#page-9-24) denoted that overexpression of lncRNA Tug1 can augment the expression of $PGC-1\alpha$ and repair mitochondrial damage. Moreover, Tug1 can promote PGC-1α expression and improve mitochondrial energy balance, thus delaying the progression of DN [\[155\].](#page-9-24) In addition, Tug1 antagonizs the effect of miR-377 on downregulating PPARγ, and inhibits high glucose-mediated ECM accumulation. Meanwhile, lncRNA TUG1, as a response of miR-377, can reduce miR-377 expression, thereby inhibiting its target gene PPAR^γ and alleviating the accumulation of ECM in renal mesangial cells [\[156\].](#page-9-25) Apart from that, the level of lncRNA MIAT is increased in retinal endothelial cells under a high glucose environment, while knockout of MIAT can significantly improve diabetic retinal microangiopathy and inhibit the proliferation, migration, and blood vessel formation of retinal endothelial cells. As a competitive endogenous RNA, MIAT can regulate endothelial cell function by forming a regulatory pathway together with VEGF and miRNA-150-5p, thus participating in diabetic microangiopathy [\[157\].](#page-9-26) Simultaneously, the level of lncRNA MIAT in the kidney tissue of diabetic mice is also decreased, and it is negatively correlated with the creatinine and urea nitrogen levels. In the meantime, overexpression of MIAT can reverse the inhibitory effect of high glucose on Nrf2 expression, confirming that MIAT can regulate the viability of HK-2 cells by stabilizing Nrf2 expression and improving the prognosis of DN obviously [\[158\]](#page-9-27).

Conclusions

Epigenetics is very important for the pathogenesis and the development of DN. In the past decades, with the development of medical technologies, great progresses have been made in the diagnosis and treatment of DN. Among these new technologies and concepts, the epigenetic mechanisms have pioneered novel horizons for the cause of diseases and made great contributions to the development of more meaningful and effective treatments. However, the current knowledge of epigenetics is still quite limited, which means that there are still many unknowns in this field worth further research, especially the novel functions of histone lactylation in DN. In short, actively exploring the unknown aspects of epigenetics is particularly important for reducing the severity and related risks of DN and improving the prognosis of diabetic patients.

Funding

This work was supported by the grants from the National Science Foundation of China (No. 81871590) and Shanghai Sailing Program (No. 20YF1407800).

Conflict of Interest

The authors declare that they have no conflict of interest.
