# **Methods**

Here we present a summary of our data sources and methods. We provide details on <sup>2</sup> pre-processing for data from Johns Hopkins' daily death counts, the American Community Survey, the Center for Medicare and Medicaid Services, the VERA <sup>4</sup> Institute, the Center for Disease Control's PLACES dataset, the US Department of <sup>5</sup> Transportation, the Oxford COVID-19 Government Response Tracker, the New York <sup>6</sup> Times, Delphi Epidata, Google, and The COVID Tracking Project. We then provide details on our clustering and modeling methodology.

## Data Sources <sup>9</sup>

The section presents the data sources and caveats for the variables studied in this 10 analysis. The contract of the

### Response Variable <sup>12</sup>

County-level COVID-19 death is provided by the Center for Systems Science and <sup>13</sup> Engineering at Johns Hopkins University's publicly available data repository [\[1\]](#page-9-0). We  $_{14}$ limit our data to the 50 states and Washington D.C. We also apply a 7-day average to 15 smooth the daily death counts to account for noise in the data.

### American Community Survey 17 and 17 and

We obtain race/ethnic composition, education, age, income, population density, and 18 household crowding from 2019 5-year estimates of the US Census Bureau American Community Survey (ACS) [\[2\]](#page-9-1). We break down race/ethnicity by percent white (not  $\frac{20}{20}$  Hispanic), Black, Asian, Hispanic, and other. Each white non-Hispanic, Black <sup>21</sup> non-Hispanic, Asian non-Hispanic, and Hispanic percentage indicate estimates for the 22 number of individuals who are precisely one race/ethnicity.

We calculate education as the percent of the population with at least a high school  $_{24}$ diploma. A high "education" value indicates a highly educated county. We also break 25 down age by percent of the population under the age of 19 and the percent of the  $\frac{26}{26}$ population over the age of 65. Income represents the median household income of a  $_{27}$ county, and population density is calculated by dividing a county's population by its  $\frac{28}{28}$ available land area, as provided by the Census Bureau. Finally, household crowding is  $_{29}$ also provided by the ACS and is the estimation of the number of households with more  $\frac{30}{20}$ people than rooms.  $\frac{31}{2}$ 

We note that the values of all variables from the ACS are considered constant across  $\frac{32}{2}$ the pandemic and were gathered before COVID-19 hit the US. This means, for example,  $\frac{33}{2}$ that our income variable does not account for income shocks that occurred as a result of  $\frac{34}{4}$ the pandemic.  $\frac{35}{25}$ 

#### Center for Medicare and Medicaid Services 36 and 36

We obtain nursing home data from the Centers for Medicare & Medicaid Services, which  $\frac{37}{27}$ provide data for the average number of nursing home residents per day, organized by  $\frac{38}{10}$ provider  $[3]$ . We divide this number by a county's population to determine the  $\frac{39}{2}$ percentage of the population that is in a nursing home. These data were most recently <sup>40</sup> updated in February 2021. As a result, the data might reflect the impact that  $41$ COVID-19 has had on the elderly population. <sup>42</sup>

#### $VERA$  Institute  $\frac{43}{43}$

We obtain incarceration data from the VERA Institute of Justice that determine jail  $\frac{44}{40}$ and prison populations at the county-level [\[4\]](#page-9-3). We elect to use only the jailed  $\frac{45}{45}$ population to proxy the incarcerated population because prison data was only available <sup>46</sup> in all states in 2014. In contrast, jail data has been available since 2018. Using  $\frac{47}{47}$ incarceration data that is more than five years old might not reflect the currently incarcerated population. Delaware, Rhode Island, Vermont, and Connecticut do not <sup>49</sup> have local jails, and therefore, do not participate in the Bureau of Justice Statistics jails  $\sim$ data collection [\[4\]](#page-9-3). We assume that these states do not have any jailed population.  $\frac{51}{100}$ 

### $PLACES$  dataset  $52$

We obtain obesity data from the CDC's PLACES dataset which is derived from the 53 Behavioral Risk Factor Surveillance Survey [\[5\]](#page-9-4). Obesity is calculated as the percentage  $_{54}$ of the adult (18 years or older) obese population. <sup>55</sup>

#### US Department of Transportation  $\frac{56}{66}$

Air Travel data is obtained from the US Department of Transportation and contains the  $\frac{5}{57}$ scheduled international passenger traffic every year  $[6]$ . We average the provided  $\frac{58}{58}$ quarterly numbers from 2019, yielding data on 250 airports. We then classify an airport <sup>59</sup> as a major international airport if it falls within the top third of airports with the most  $\epsilon_0$ international passenger traffic. We choose this threshold because the histogram of <sup>61</sup> international flights from the 250 airports is tri-modal (S7 Fig). We calculate the  $\frac{62}{2}$ distance to a major airport as the straight-line distance from the center of a county, as  $\frac{63}{100}$ provided by Johns Hopkins, to the closest major airport. If a county contains a major <sup>64</sup> airport, this distance is zero.  $\frac{65}{65}$ 

### Oxford COVID-19 Government Response Tracker 66

We determine governor stringency using the Oxford COVID-19 Government Response  $\frac{67}{67}$ Tracker (OxCGRT) [\[7\]](#page-9-6). OxCGRT tracks all government COVID-19 responses and ranks  $\frac{68}{68}$ each regulation on a scale from 0 to 100 based on the stringency of the response, where  $\epsilon_{0}$ 100 is the most stringent. We calculate the average stringency for all state-wide  $\frac{70}{20}$ responses in each period, excluding the last four weeks of the period to account for the  $\frac{71}{10}$ lag between governor interventions and deaths  $[8]$ .

### **Election Results** 73

Political leaning is obtained from The New York Times' 2020 election data. We calculate political leaning as the number of individuals who voted for Joe Biden  $_{75}$ subtracted from the number of individuals who voted for Donald Trump divided by the  $\tau$ total number of voters. This calculation results in a value between  $-1$  and  $1$ , where a  $77$ value of  $-1$  represents a county where all voters voted for Joe Biden, and a value of  $1 \qquad \pi$ represents a county where all voters voted for Donald Trump.

## Delphi Epidata <sup>80</sup>

Public mask usage data is obtained from Facebook's COVID-19 symptom survey and is  $\frac{1}{81}$ an estimate of the percentage of people who wore a mask for most or all of the time  $\frac{82}{2}$ while in public in the five days before filling out the survey  $[9]$ . This survey contains  $\frac{1}{3}$ only data beginning on September 8, 2020. Because mask usage is known to be a  $\frac{84}{100}$ dynamic variable that has changed over the past year, we choose to include only mask  $\frac{1}{100}$ usage data for period  $3 \mid 10$ .

Unfortunately, these data are sparse at the county level compared to our other data  $\frac{1}{87}$ sources. S10 Fig suggests that counties with these data might not be representative of  $\bullet$ all counties. Of the counties without mask data, approximately 2000 are Republican, and about 200 are Democratic. The excluded counties, however, tend to have higher  $\frac{90}{20}$  $\text{death rates.}$  91

Because of the limitation of these data, however, we present results both including  $\frac{92}{2}$ and excluding counties with mask usage data (Fig  $5$  and S6 Fig).

### Google Mobility 34

We use Google's mobility data as a proxy for social distancing and interactions between  $\frac{1}{95}$ individuals who do not live together [\[11\]](#page-9-10). Google provides these data as percent changes  $\frac{96}{96}$ in mobility from a baseline value. The data is separated into retail and recreation, grocery and pharmacy, parks, transit stations, workplace, residential mobility. We average the percent change in workplace mobility from the baseline in each period for <sup>99</sup> counties with available data. We choose to use workplace mobility because this is the  $_{100}$ least sparse category that we believe still proxies for interactions between individuals  $_{101}$ not living together. For a robustness check, we also averaged workplace and retail and 102 recreation mobility if counties had both data points available with similar results. If a  $_{103}$ county did not have both data points available, we used only workplace mobility. <sup>104</sup>

## The COVID Tracking Project 105 and 105

We use The COVID Tracking Project's Racial Data Tracker to obtain state-level 106 estimates of COVID-related deaths broken down by race and ethnicity. Because there  $_{107}$ are no reliable county-level datasets on COVID-related deaths by race/ethnicity, we 108 multiply the state level estimates by the proportion of a state's Black, Hispanic, or total 109

November 5, 2022 4[/11](#page-10-0)

### population in a given county (using the Census Bureau's state and county population <sup>110</sup> numbers). 111

## $\text{Plotting}$  and  $\frac{112}{2}$

All maps are created using the U.S. Census Bureau's 2019 county shapefiles [\[12\]](#page-9-11). S12 113 Fig plots counties using the urbnmapr package in R  $[13,14]$  $[13,14]$ , which uses census shapefiles  $\frac{114}{2}$ under the hood. All other maps use Matplotlib to directly plot the county shapefiles. 115 S11, S13, and S14 Fig are constructed with R. All other plots are created with a <sup>116</sup> combination of Matplotlib [\[15\]](#page-9-14), GeoPandas [\[16\]](#page-9-15), and seaborn [\[17\]](#page-10-1).  $\frac{17}{117}$ 

## $\sum_{118}$

We first convert smoothed daily death data (using a 7-day smoothing) to  $z$ -scores (mean  $119$ subtracted from data, divided by the standard deviation) to allow cross-county comparisons. These z-scores are stored in a matrix  $\mathcal A$  where each row of the matrix  $\frac{121}{221}$ contains the standardized time series of death counts in a particular county, and each 122 column represents one day of data. The matrix  $\mathcal A$  is  $3067 \times 382$  since we have  $3067$  123  $\text{counties}$  and 382 days of data.  $\frac{124}{24}$ 

We then perform a  $k$ -means clustering on our data using Python tslearn's  $125$ TimeSeriesKMeans package (with euclidean distance metric and 10 random 126 initializations) [\[18](#page-10-2)[–20\]](#page-10-3). By clustering the data, we can think of the time series for each  $127$ county as a point in a 382-dimensional space. The k-means clustering algorithm can be  $_{128}$ described as follows: (1) A total of k counties are randomly chosen as the initial cluster  $_{129}$ centers. (2) All other counties are assigned to one of the  $k$  clusters based on their  $\frac{130}{130}$ minimum distance to the cluster means. (3) The new mean is then calculated as the  $_{131}$ centroid of each k cluster. Steps (2) and (3) are repeated until convergence is reached. <sup>132</sup> We use simple Euclidean distance for this analysis, although we also tried other distance 133 metrics such as dynamic time warping, and we obtained similar results. 134

We select the number of clusters  $(k)$  using an elbow plot. An elbow plot for k-means 135 clustering shows the total distance from each county to its assigned cluster center. <sup>136</sup> Because increasing the number of clusters decreases the total distance, a "kink" in the <sup>137</sup> elbow plot represents a new cluster that does not significantly reduce the total distance. <sup>138</sup> Then, a kink in the elbow plot does not significantly reduce the total distance, thus 139 yielding a reasonable choice for k. S9 Fig shows the elbow plot that results from  $\frac{140}{2}$ performing k-means clustering on A. We observe a kink in the plot around  $k = 3$  and  $141$ therefore choose to perform 3-means clustering. To select the optimal clusters, we run  $_{142}$ 3-means clustering with ten different combinations of counties as the initial three  $\frac{143}{143}$ clusters and select the configuration with the smallest total distance from each county <sup>144</sup> to the cluster center.

## Model Details <sup>146</sup>

In this section, we present the model details for our virus introduction and virus spread  $_{147}$ models. The matrix of the state of the s

## Virus Introduction Models and the set of the s

To predict virus introduction, we run a logistic regression without any regularization. 150 We consider the virus to be introduced to a county in a given period if at least five  $\frac{151}{151}$ deaths occurred in the county throughout the period. To account for spatial 152 autocorrelation, we include latitude and longitude on all models. We choose to exclude <sup>153</sup> latitude and longitude in our visualization of feature importance and model coefficients <sup>154</sup> because latitude and longitude are not inherent measures of risk or disease spread. We <sup>155</sup> additionally run a logistic regression with L1 regularization to predict virus introduction  $_{156}$ as a robustness check. 157

#### Virus Spread Models **158**

Regressions. To predict virus spread, we first run two different regressions: a LASSO <sup>159</sup> regression and a random forest regression. The LASSO regression can help select only 160 the most important variables, and the random forest regression captures nonlinearities  $_{161}$ in the data. To calculate feature importance in the random forest regression, we  $_{162}$ calculate permuted feature importance. This metric perform a random permutation on  $_{163}$ a given explanatory variable and calculates the resulting loss in accuracy of the model. <sup>164</sup> To address spatial autocorrelation in these regressions, we include latitude and <sup>165</sup> longitude as predictors in all models.

We run the LASSO regression using Python sklearn  $[21]$ . This regression seeks to  $_{167}$ minimize the following objective function:

$$
\frac{1}{2 \cdot N} \cdot ||y - Xw||_2^2 + \alpha \cdot ||w||_1 \tag{1}
$$

where N is the number of data points, y is the observed death rate, X is a matrix of  $_{169}$ the independent variables, w is a vector of coefficients, and  $\alpha$  determines how much to  $\alpha$ penalize coefficients. A large  $\alpha$  will force more coefficients towards zero. We run the  $_{171}$ LassoCV model with values of  $\alpha$  ranging from 0 to 1 with a step size of 0.001 and 5-fold  $\frac{172}{172}$ cross-validation. We then weight the regression by the log of a county's population.  $173$ 

The second regression we consider is a random forest regression. To ensure that we  $_{174}$ find the optimal model that does not over-fit when trained on all of our data, we first fit  $_{175}$ the model using all variables but  $70\%$  of counties as training data. We perform a grid  $_{176}$ search using 5-fold cross-validation on our training data and select the hyper-parameters  $\frac{177}{200}$ that yield the lowest Mean Absolute Error (MAE). The hyper-parameters on which we <sup>178</sup> perform the grid search are the following: (i) number of estimators (either 50, 70, or 90), <sup>179</sup> (ii) maximum number of features (either the number of features or the square root of the <sup>180</sup> number of features), (iii) maximum tree depth (between 5 and 100), (iv) the minimum  $_{181}$ number of samples required to split a node  $(2, 5 \text{ or } 10)$ , (v) and the minimum number of  $\frac{182}{182}$ samples required for a leaf node  $(1, 2 \text{ or } 4)$ . We toggle bootstrapping on and off as well.  $_{183}$ We repeat this process three times, which yields an optimal random forest configuration  $_{184}$ for each period (see S16 Fig for out-of-sample predictions). Once we have these optimal  $_{185}$ configurations, we fit the models on all counties and predict purely in-sample. <sup>186</sup>

We test four monotonic transformations of our input variables to account for 187 nonlinear relationships between explanatory and response variables: squared, square 188 root, log, and exponential. If any of these transformations yields a higher Pearson's 189 correlation with either death rate or log-transformed death rate than the correlation 190 between the untransformed variable and death rate, we apply the transformation to the <sup>191</sup> given variable. We find the optimal transformation for each variable in each period. In <sup>192</sup> all three time periods, most explanatory variables yield higher correlations to the log of <sup>193</sup> our response variables, so we take the logarithm of our response variable in the <sup>194</sup> remainder of our analysis.

Finally, it is important to distinguish between counties that are included in virus 196 introduction vs. virus severity. In our virus spread models, we consider a county that  $_{197}$ was either introduced to COVID-19 in the period of interest or a previous period. In 198 our virus introduction models, however, we consider all counties and aim to predict <sup>199</sup> counties first exposed to the virus in the period of interest. For example, for virus <sup>200</sup> spread models in period 2, we only include counties that were introduced to the virus in  $_{201}$ 

period 1 or 2. In running period 2 virus introduction models, we only attempt to  $_{202}$ predict counties first exposed to the virus in period 2 out of all counties.

Excluding Variables. Throughout our regression models, we choose to exclude  $_{204}$ variables that are measures of a similar idea. Excluding these variables improves the <sup>205</sup> condition number of the matrix of explanatory variables, making our results more <sup>206</sup> trustworthy. The condition number is a measure of how much output can change given  $_{207}$ a small perturbation in the input [\[22\]](#page-10-5). We remove density (as crowding serves as a <sup>208</sup> proxy), percent under 19 (as percent over 65 serves as a proxy), and certain <sup>209</sup> race/ethnicity variables (percent white not Hispanic, Asian, and other, as percent Black <sup>210</sup> and Hispanic serve as a proxy). We keep all obesity, education, and income despite their  $_{211}$ correlations because these variables address different concepts and vulnerabilities. <sup>212</sup> Removing these variables reduces the condition number of the matrix of explanatory 213 variables from 133.99 to 107.41 for our virus introduction analyses. In period 2 spread <sup>214</sup> analysis, which only includes counties exposed in period 1 or 2, removing these variables  $_{215}$ reduces the condition number from 150.98 to 119.35. Finally, in our period 3 spread  $_{216}$ analysis, removing these variables reduces the condition number from  $93.61$  to  $58.20$   $_{217}$ 

CAR Poisson Model. We also implemented a conditional autoregressive (CAR) <sup>218</sup> Poisson model of COVID-19 county death rates in the United States. The inclusion of a <sup>219</sup> conditional autoregressive spatial component in this model is intended to address how 220 robust the relationships are between observed covariates and COVID-19 death rates,  $_{221}$ given the expected correlations in rates between counties which neighbor one another. <sup>222</sup>

The implementation of our model is based on the Stan Case Study, *Exact Sparse* 223  $CAR\ Models\ in\ Stan\ [23].$  $CAR\ Models\ in\ Stan\ [23].$  $CAR\ Models\ in\ Stan\ [23].$  Spatial models, including CAR models and improvements on  $_{224}$ the Besag-York-Mollié model, have often been used in current epidemiology and disease <sub>225</sub> risk mapping applications to distinguish spatially structured effects from the effects of  $_{226}$  $\alpha$  observed covariates [\[24,](#page-10-7)[25\]](#page-10-8).  $\alpha$ 

To describe our model, we write the deaths observed as  $y_1, y_2, ..., y_{2683}$  for each of  $\qquad$  228 the 2,683 counties which have neighboring counties and for which all covariates were  $_{229}$ available and hence were considered in our main manuscript. Letting  $X_i$  for i in 230 1... 2,683 represent the vector of observed covariates for the *i*th county and similarly  $P_i$ represent the population of the *i*th county, we write that 232

$$
y_i \sim \text{Poisson}(\exp(X_i \beta + \phi_i + \log(P_i))),
$$

where  $\beta$  is a vector of the estimated coefficients for the covariates and  $\phi_i$  is the 233 spatial component of the model. See [\[23\]](#page-10-6) for the details of the prior distributions on  $\beta$  234 and  $\phi$ . This model is fit twice with data from periods 2 and 3 separately.

Given the computational complexity in fitting these models with over 2600 county 236 observations and a large number of covariates, we opted only to select the variables that <sup>237</sup> had the highest features importance measures in the LASSO and spatial linear models  $\frac{238}{2}$ from our main manuscript. To include parameters parsimoniously, we chose to include <sup>239</sup> parameters that appeared in the top three most important features from the LASSO <sup>240</sup> and spatial linear models for periods 2 and 3. Since we only modeled the probability of  $_{241}$ counties being seeded during period 1 and did not model death rates, we have only <sup>242</sup> calibrated the spatial model presented here to the deaths data from periods 2 and 3. <sup>243</sup>

All analyses for the CAR Poisson models were conducted using R version 4.0.2 [\[14\]](#page-9-13) <sub>244</sub> and the model analyses were conducted in the Bayesian statistical computing and <sup>245</sup> modeling framework Stan using the No-U-Turns Hamiltonian Monte Carlo <sup>246</sup> Sampler  $[26,27]$  $[26,27]$ .

Spatial Lag Model. We also predict virus spread with a spatial lag model that <sup>248</sup> better accounts for spatial auto correlations. We run the spatial lag regression using <sup>249</sup> pysal's ml lag model [\[28\]](#page-10-11). This model attempts to find the maximum likelihood <sup>250</sup> estimate of the following: 251

231

$$
y = \rho Wy + \beta X + \epsilon \tag{2}
$$

where y is the median death rate, X is a matrix of independent variables,  $\rho$  and  $\beta$  252 are the spatial autoregressive coefficient and independent variable coefficients, <sup>253</sup>

respectively, and  $Wy$  represent the spatial lag. W is a weight matrix that determines  $_{254}$ how heavily nearby counties impact a given county. For our analysis, we construct  $W_{255}$ using n nearest-neighbors, where all n nearest-neighbors are weighted equally. We first  $_{256}$ run the spatial lag model using all variables with values of n ranging from 1 to 20 and  $_{257}$ find that  $n = 5$  yielded the lowest mean absolute error (MAE).

For all of the models described, we also vary the cutoff at which we consider the 259 virus introduced in a county. We ran the same set of analyses using 1 and 3 as the death  $_{260}$ cutoff (instead of 5). Finally, we remove the weights on the LASSO regression. All of  $_{261}$ these robustness checks yield a similar narrative as the one described in our Results. <sup>262</sup>

### Model Results for Periods 1 and 2 263

In this section, we present the results for virus introduction and virus severity for  $_{264}$ periods 1 and 2.

#### Period 1 (January 26, 2020 - June 2, 2020): Democratic Counties are First <sub>266</sub>  $\mathbf{Exposed\ to\ COVID-19} \hspace{2.5cm} \footnotesize$

In period 1, we focus on virus introduction since the disease spread is almost entirely  $_{268}$ driven by how early a county was exposed to the virus. The coefficients of a LASSO 269 regression model support this and can be seen in S3 Fig.  $270$ 

From any of the models presented in S4 Fig, we see that distance to a major airport  $\frac{271}{271}$ is one of the strongest predictors of being exposed in period 1. The coefficient on this  $272$ variable is negative, suggesting that counties farther from a major airport are less likely  $_{273}$ to be exposed. We also note that Democratic counties are more likely to be exposed to <sup>274</sup> the virus in this period. S4 Fig shows the tests we run to address whether we observe 275 more virus introduction in Democratic counties due to proximity to international  $_{276}$ airports. We begin by removing distance to an airport and crowding from the analysis  $277$  $(S4(A)$  Fig; accuracy: 0.79; sensitivity: 0.81; specificity: 0.69). This results in a  $_{278}$ coefficient on political leaning of  $-7.20$ . Adding distance to an airport back into the  $279$ model (accuracy: 0.80; sensitivity: 0.82; specificity: 0.73), the coefficient on political  $_{280}$ leaning reduces in magnitude to  $-6.26$ , a 13% change. Finally, we add crowding back  $_{281}$ into the model  $(S4(B)$  Fig; accuracy: 0.84; sensitivity: 0.86; specificity: 0.79), further  $\frac{282}{282}$ reducing the coefficient on political leaning to  $-2.30$ , an additional 63% decrease. Between distance to an airport and crowding, the coefficient on political leaning has 284 reduced by  $68\%$ .

### Period 2 (June 3, 2020 - October 7, 2020): COVID-19 Spreads to 286 Republican Counties 287

County-level mask-wearing data were not available for periods 1 or 2, and thus we cannot conduct any tests with behavioral variables. As a result, we focus on 289 vulnerabilities, demographics, and political variables.

Counties far from airports are more likely to be exposed to the virus for the first 291 time as the disease spreads to more rural, Republican areas, as shown by  $S5$  Fig  $_{292}$ (accuracy: 0.69; sensitivity: 0.71; specificity: 0.56). This Fig hows the results of running  $_{293}$ the same logistic regression as  $S_4(B)$  Fig, just using virus introduction for period 2 as  $_{294}$ the response variable. Both the coefficients on political leaning and airport are positive; <sup>295</sup>

however, other variables such as nursing home population and income are more important in determining virus introduction in period 2.  $_{297}$ 

Based on the feature importance and coefficients obtained from the regression <sup>298</sup> analyses, we conclude that among counties that have been exposed to the virus, more 299 severe COVID-19 spread is correlated with indicators of higher social vulnerability (as  $\frac{300}{200}$ indicated in the socio-economics and vulnerabilities boxes of S1 Fig). Fig 5A shows a  $\frac{301}{200}$ distribution of the death dates across all US counties in period 2 and Fig 5B and Fig  $5C_{302}$ indicates which variables have the most predictive power. The top variables in both  $\frac{303}{20}$ models are vulnerability-related: education and race/ethnicity. <sup>304</sup>

We also conclude that Republican areas have higher death rates. There may be a 305 significant impact of behavioral variables such as mask usage and social distancing, but  $\frac{306}{200}$ we are unable to test these impacts in period 2. Instead, we see that the importance and coefficient on political leaning are small relative to the coefficients on  $\frac{308}{200}$ vulnerability-related variables. Therefore, vulnerable populations were significantly <sup>309</sup> impacted by COVID-19, and Republican counties and counties with less strict <sup>310</sup> regulations were hit hardest.

## Results for CAR Poisson Model <sup>312</sup>

We found that the results of fitting a spatial sparse CAR Poisson model were consistent  $\frac{313}{2}$ with our findings from the main analyses for periods 2 and 3 (S11 Fig).  $_{314}$ 

These model estimates reflect the associations between county-level covariates and <sup>315</sup> COVID-19 death rates after accounting for the estimated spatial correlation structure 316 included in the model.  $317$ 

We found that higher percentages of residents in nursing homes, Black non-Hispanic  $\frac{318}{216}$ population percentages, and Hispanic population percentages at the county level were 319 associated with higher COVID-19 death rates during period 2. Counties with higher <sup>320</sup> high school graduation rates were associated with having lower COVID-19 death rates  $\frac{321}{221}$ in period 2 after accounting for spatial correlations. During period 3, counties where the  $\frac{322}{20}$ population voted more Republican (positive political lean), and counties with higher  $\frac{323}{2}$ percentages of the population living in nursing homes were associated with higher  $324$  $\text{COVID-19}$  death rates. Counties with higher median income, greater high school  $\frac{325}{25}$ graduation rates, and policy strictness during period 3 were found to have lower  $\text{COVID-19 death rates.}$  327

We present the spatial model component visualized as  $\exp(\phi_i + \log(P_i))$ , the  $\qquad$  328 expected COVID-19 deaths per capita in each period conditioning out the effects from <sup>329</sup>  $covariates, in S12 Fig.  $330$$ 

 $S12$  Fig allows us to visualize the estimated spatial correlation structure and how  $\frac{331}{331}$ neighboring counties tend to be correlated with one another. In essence, we expect to  $\frac{332}{20}$ see that counties with high rates are surrounded by counties with high rates and  $\frac{333}{333}$ vice-versa for low rate counties.  $\frac{334}{2}$ 

Contemporary advice recommends that Bayesian models should be considered to  $\frac{335}{335}$ have converged only if the Markov chains have convergence diagnostics of  $_{336}$  $R<1.05$  [\[26](#page-10-9)[,29\]](#page-10-12). In S14 Fig, we present the R convergence diagnostics for our  $337$ non-spatial and spatial effects for both periods 2 and 3, which are all below 1.05.  $\frac{338}{2}$ 

## ${\rm Results~for~Spatial~Lag~Model} \hspace{2cm} \nonumber$

We found that the results of fitting a spatial lag model were mostly consistent with our  $\frac{340}{2}$ findings from the main analyses for all periods  $(S15 \text{ Fig})$ . In period 1, the day county is  $_{341}$ seeded is the strongest predictor of the number of deaths in a county. In period 2, the  $\frac{342}{2}$ nursing home population, education, and race/ethnicity are the top three predictors. In  $\frac{343}{2}$ period 3, the spatial lag model less readily picks out political leaning, although the <sup>344</sup>
