Supplementary Note 1: Characterizations

The uniaxial tension tests are performed with a universal test machine (Insight 10, MTS Systems Corp., Eden Prairie, MN, USA) with a cross-head speed of 5 mm/min. Dynamic thermomechanical properties are conducted on a DMA machine (Q800, TA Instruments, New Castle, DE, USA) with a temperature ramped at a rate of 10°C/min. The shape memory behavior of B1 and B2 are conducted by following method. For hot programming, the sample was stretched to 100% with the rate of 10%/min at 100°C and the temperature was then decreased to 25°C with the rate of 10°C/min and held isothermally for 5 mins before remove the load. The recovery was conducted by increase the temperature to 100°C at 10°C/min and isothermal for 5 mins. For cold programming, the sample was stretched to 100% with the rate of 10%/min at 25°C and held for 5 mins before remove the load. The recovery was then conducted by increase the temperature to 100°C at 10°C/min. More material properties of the ink and g-DLP printed materials were reported in our previous paper.[1]

Supplementary Note 2: Finite element modeling

2.1 Constitutive model

The rubbery material B3 is modeled as an incompressible neo-Hookean solid as it is elastic in the studied temperature range (25-100 °C). The cold-draw and shape memory behaviors of the glassy material (B1 and B2) are captured using an incompressible, stress- and temperature-dependent, multi-branch viscoelastic model, which consists of one equilibrium branch (neo-Hookean model assumed) and multiple nonequilibrium branches (modeled by visco-hyperelastic Maxwell elements) in parallel. In this model, the Cauchy stress $\boldsymbol{\sigma}$ is

$$\boldsymbol{\sigma}(t) = -p\mathbf{I} + \boldsymbol{\sigma}_{ins}^{D}(\mathbf{b}_t) + \text{dev}\left[\mathbf{F}_t\left(\int_0^t \dot{\zeta}\left(\int_s^t \frac{d\xi}{\alpha(\xi)}\right)\mathbf{F}_s^{-1}\boldsymbol{\sigma}_{ins}^{D}(\mathbf{b}_s)\mathbf{F}_s^{-T}\frac{ds}{\alpha(s)}\right)\mathbf{F}_t^{T}\right] \quad (1)$$

where $\mathbf{F}$ is the deformation gradient, $\mathbf{b} = \mathbf{F}\mathbf{F}^T$ is the left Cauchy-Green tensor, the subscript "t" or "s" denotes the deformation from time 0 to t or s. $\boldsymbol{\sigma}_{ins}^{D}$ is the instantaneous Cauchy stress due to mechanical deformations and follows the neo-Hookean strain-energy potential. $\text{dev}(\bullet) \equiv (\bullet) - (1/3)(\mathbf{I}:(\bullet))\mathbf{I}$ is the deviatoric operator. p is an undetermined pressure depending on the boundary conditions. $\zeta(t)$ is the relaxation modulus ratio following the Prony series

$$\zeta(t) = g_{eq} + \sum_{i=1}^{n} g_i \exp\left(-\frac{t}{\tau_i^R}\right), \dot{\zeta}(t) = -\sum_{i=1}^{n}\frac{g_i}{\tau_i^R}\exp\left(-\frac{t}{\tau_i^R}\right)$$

$$\text{with } g_{eq} = \frac{E_{eq}}{E_{ins}}, g_i = \frac{E_i}{E_{ins}}, E_{ins} = E_{eq} + \sum_{i=1}^{n} E_i \quad (2)$$

where E_{eq} is the modulus of the equilibrium branch, E_i the instantaneous modulus of branch i, E_{ins} the total instantaneous modulus; they are taken to be small-stress moduli and assumed to be temperature-independent. τ_i^R denotes a reference relaxation time of the branch i.

The shift factor, $\alpha(t)$, written as a function of time t in Eq.(1) for brevity, is taken to not only depend on temperature but also stress at time t. Therefore, α can be written as[2]

$$\alpha = \alpha_T \alpha_S \tag{3}$$

where α_T denotes the temperature-dependent shift factor, α_S the stress-dependent shift factor.

The temperature-dependent shift factor α_T is taken to follow the Williams-Landel-Ferry (WLF) approximation for $T>T_{ref}$, i.e.,

$$\lg(\alpha_T) = -\frac{C_1(T - T_{ref})}{C_2 + (T - T_{ref})}, \tag{4}$$

and the Arrhenius form for $T<T_{ref}$, i.e.,

$$\ln(\alpha_T) = -\frac{AF_c}{k_b}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right). \tag{5}$$

In Eqs.(4)-(5), C_1, C_2, and AF_c/k_b are material constants, T is the current temperature, T_{ref} represents a structural transition temperature. T and T_{ref} are in Kelvin scale. Note that $\alpha_T = 1$ at $T = T_{ref}$.

The stress-dependent shift factor α_S is taken to follow[2]

$$\ln(\alpha_S) = -\frac{E_S}{k_b T}\frac{M}{s} \tag{6}$$

$$\text{with } M = \sqrt{\frac{1}{2}\mathbf{M}':\mathbf{M}'} \tag{7}$$

where M is the equivalent shear stress, $\mathbf{M}$ is the Mandel stress, $\mathbf{M}'=\text{dev}(\mathbf{M})$, E_S is the activation energy, and s is the athermal shear strength. To capture the softening effects, s evolves through

$$\dot{s} = h_0\left(1 - \frac{s}{s_{sat}}\right)\dot{\gamma}^v, \; s = s_0 \text{ when } \gamma^v = 0, \tag{8}$$

where s_0 is the initial value of s, s_{sat} is the saturation value of s, h_0 is a prefactor, γ^v is the

8

viscous strain, and $\dot{\gamma}^v$ is the viscous flow rate. For a specific branch, $\dot{\gamma}_i^v = M/(\mu_i \tau_i)$, with μ_i denoting the instantaneous shear modulus and $\tau_i = \alpha \tau_i^R$ the relaxation time. Thus, τ_i^R can be interpreted as the relaxation time under small stress and at the reference temperature T_{ref}. Here, to capture essential physics while facilitating the numerical implementation, we use

$$\dot{\gamma}^v = \frac{M}{\mu_{ins} \alpha \tau_0} \tag{9}$$

to define an effective viscous flow rate, instead of that of a specific branch. $\mu_{ins} = E_{ins}/3$ due to the incompressibility. τ_0 is treated as a fitting parameter.

2.2 Numerical implementation

We implement the material model into Abaqus through the built-in viscoelastic model in which the Prony-series and user-defined shift factor can be specified. The Prony-series parameters are specified as those under small stress and at the reference temperature T_{ref} (at which $\alpha = 1$). The shift factor Eq.(3) is implemented through user subroutines USDFLD and UTRS. USDFLD is invoked to access stress values of an integration point and update α_S following Eqs.(6)-(9), which will be passed into UTRS to update α_T and finally α. The updates are in an explicit (or forward Euler) manner.

We also implement the material model into a MATLAB script for the uniaxial tension to assist the parameter identification. We derive the following integration algorithm for the stress updates. The stress at an arbitrary time t, i.e., Eq.(1), can be rewritten as

$$\boldsymbol{\sigma}(t) = -p\mathbf{I} + \boldsymbol{\sigma}_{ins}^D(\mathbf{b}_t) - \text{dev}\left[\sum_{i=1}^{n} \frac{g_i}{\tau_i^R} \mathbf{T}_{2i}(t)\right]$$

$$\text{with } \mathbf{T}_{2i}(t) = \mathbf{F}_t \left(\int_0^t \exp\left(-\int_s^t \frac{d\xi}{\alpha(\xi)\tau_i^R} \right) \mathbf{F}_s^{-1} \boldsymbol{\sigma}_{ins}^D(\mathbf{b}_s) \mathbf{F}_s^{-T} \frac{ds}{\alpha(s)} \right) \mathbf{F}_t^T \tag{10}$$

9

Then, the stress at $t+\delta t$ can be updated as

$$\boldsymbol{\sigma}(t+\delta t) = -p\mathbf{I} + \boldsymbol{\sigma}_{ins}^{D}(\mathbf{b}_{t+\delta t}) - \mathrm{dev}\left[\sum_{i=1}^{n}\frac{g_{i}}{\tau_{i}^{R}}\mathbf{T}_{2i}(t+\delta t)\right] \tag{11}$$

where

$$\mathbf{T}_{2i}(t+\delta t) = \exp\left(-\frac{\delta t'}{\tau_{i}^{R}}\right)\delta\mathbf{F}\mathbf{T}_{2i}(t)\delta\mathbf{F}^{T} + \frac{\delta t}{2\alpha(t)}\left[\begin{array}{c} \exp\left(-\dfrac{\delta t'}{\tau_{i}^{R}}\right)\delta\mathbf{F}\boldsymbol{\sigma}_{ins}^{D}(\mathbf{b}_{t})\delta\mathbf{F}^{T} \\ +\dfrac{\alpha(t)}{\alpha(t+\delta t)}\boldsymbol{\sigma}_{ins}^{D}(\mathbf{b}_{t+\delta t}) \end{array}\right] \tag{12}$$

$$\delta t' = \int_{t}^{t+\delta t}\frac{dx}{\alpha(x)} \approx \frac{\delta t}{2}\left(\frac{1}{\alpha(t)} + \frac{1}{\alpha(t+\delta t)}\right), \ \delta\mathbf{F} = \mathbf{F}_{t+\delta t}\mathbf{F}_{t}^{-1}$$

The trapezoidal integration rule has been used to derive Eq.(12).

2.3 Parameter identification

The SMP parameters including E_{eq}, E_{i}, τ_{i}^{R}, C_{1}, C_{2}, and AF_{c}/k_{b} are identified using DMA results from multi-temperature and multi-frequency tests.[3] Temperature ramps from 10°C to 130°C in 5°C increment. At each temperature, the material is kept isothermal and stress-free for 5 min and then subjected to a cyclic loading at multiple frequencies (0.1Hz~20Hz). The SMP parameters are identified in two steps. First, the storage modulus E' versus test frequency ω data at different temperatures can be shifted to a master curve at T_{ref}, obtaining discrete data points of $\alpha(T)$. Performing nonlinear numerical fitting to these data points using Eqs.(4)-(5) yields the material constants C_{1}, C_{2}, and AF_{c}/k_{b} (see **Supplementary Figure 8a** for B1 and **9a** for B2). Second, with the multi-branch model, the storage modulus E' and loss modulus E'' can be written as

$$E' = E_{eq} + \sum_{i=1}^{n}\frac{E_{i}\left[\omega\tau_{i}^{R}\alpha(T)\right]^{2}}{1+\left[\omega\tau_{i}^{R}\alpha(T)\right]^{2}} \tag{13}$$

10

$$E'' = \sum_{i=1}^{n} \frac{E_i \omega \tau_i^R \alpha(T)}{1 + \left[\omega \tau_i^R \alpha(T) \right]^2} \tag{14}$$

Using Eqs.(13) and (14), performing nonlinear numerical fitting to the shifted E' and E'' versus ω data yields the material constants E_{eq}, E_i, τ_i^R (see **Supplementary Figure 8b** for B1 and **9b** for B2). The obtained parameters are listed in **Supplementary Table 1** and **2**.

The cold-draw parameters s_0, s_{sat}, h_0, τ_0, and E_S/k_b are identified using uniaxial tensile data for different strain rates at room temperature. The parameters are roughly estimated following the procedure of [2] and further optimized by numerical fitting. The obtained parameters lead to simulated stress-strain curves in good agreements with the experiments at multiple strain rates for the two glassy materials (**Supplementary Figure 10**). The obtained parameters are listed in **Supplementary Table 1** and **2**.

All parameters identified above are further used to simulate a complete process of the cold-drawing (i.e., stretching, holding, releasing) and heat-recovering. The simulated stress and strain curves, along with the temperature history, achieve good agreements with the experiments for the two glassy materials (**Supplementary Figure 11**).

Supplementary Note 3: Derivation of hinge folding angle

The folding angle (θ) of the hinge depends on the mechanical properties and geometric designs of two constituent materials (i.e., hinge dimension, fiber position and dimension, etc.). To obtain the folding angle, we first derive the bending curvature using the Euler-Bernoulli beam theory. Consider a composite hinge consisting of glassy fibers and a rubbery matrix (**Supplementary Figure 12**). After stretch and release, let ε_T

denote the temporarily fixed strain of the glassy fiber due to stretch, which is the mismatch strain between two material phases. Then the longitudinal strain (perpendicular to cross-section) for an arbitrary point of position y can be written as

$$\begin{aligned}
\varepsilon_f &= -\varepsilon_T + \varepsilon_{NP} - \kappa y' \\
\varepsilon_m &= \varepsilon_{NP} - \kappa y'
\end{aligned} \tag{15}$$

where ε_{NP} is the longitudinal strain of a neutral plane (NP), representing the in-plane stretching due to balance of forces; $\kappa y'$ represents the bending strain due to balance of moments, with κ denoting the curvature of NP (positive value means curling up) and $y'=y-y_{NP}$ the relative position to NP (position y_{NP}). It is seen that NP has zero longitudinal strain due to bending. The balance laws for forces and moments are

$$\begin{aligned}
\int_{A_f} E_f \varepsilon_f dA + \int_{A_m} E_m \varepsilon_m dA &= 0 \\
\int_{A_f} E_f \varepsilon_f y' dA + \int_{A_m} E_m \varepsilon_m y' dA &= 0
\end{aligned} \tag{16}$$

where E_f and E_m are the Young's modulus of the fiber and matrix, respectively.

Inserting (15) into (16) gives the curvature κ

$$\kappa = \frac{E_m A_m \left(\overline{y}_m - \overline{y}_f \right) \varepsilon_{NP}}{E_f I_{NP-f} + E_m I_{NP-m}}. \tag{17}$$

with relevant variables given by

$$\varepsilon_{NP} = \frac{E_f A_f}{E_f A_f + E_m A_m} \varepsilon_T \tag{18}$$

$$\overline{y}_f = \frac{\int_{A_f} y dA}{A_f}, \overline{y}_m = \frac{\int_{A_m} y dA}{A_m} \tag{19}$$

$$I_{NP-f} = \int_{A_f} \left(y - y_{NP} \right)^2 dA, I_{NP-m} = \int_{A_m} \left(y - y_{NP} \right)^2 dA \tag{20}$$

$$y_{NP} = \frac{E_f A_f \overline{y}_f + E_m A_m \overline{y}_m}{E_f A_f + E_m A_m} \tag{21}$$

$$A_f = w_f t_f, A_m = w_0 t_0 - w_f t_f \tag{22}$$

where ε_{NP} is the axial strain (perpendicular to cross-section) of a neutral plane due to force balance. A_f and A_m are the total area of the fiber and matrix in the cross-section, $\bar{y}_f$ and $\bar{y}_m$ the corresponding area-mean y position, and $I_{NP\text{-}f}$ and $I_{NP\text{-}m}$ the second area moment of the fiber and matrix with respect to the neutral plane, respectively. w_f, w_0, t_f, and t_0 are geometric parameters as shown in **Supplementary Figure 12**. With the help of (18)-(22), κ can be analytically evaluated using (17).
Supplementary Figure 12. Schematic of a bent hinge (top) and a general cross-section design (bottom).

Neglecting the boundary effects between the hinge and panels, the folding angle can be given by

$$\theta = \kappa l_H \left(1 + \varepsilon_{NP}\right) \tag{23}$$

where l_H is the initial length of hinge.

The analytical prediction of folding angle relies on ε_T as an explicit function of applied strain ε_p and visco-plasticity of the material, which is hard to obtain due to the complex constitutive behavior of the glassy material. However, for the glassy material used here, an empirical form is easily obtained by fitting the experimental data, i.e.,

$\varepsilon_T = \varepsilon_P \cdot r_T$, with $r_T = -0.27\varepsilon_P^2 + 0.51\varepsilon_P + 0.71$ being the fixity as shown in Figure 2C of main text. Using this empirical formula and Eqs.(23), the theoretical prediction of the strain-angle relation achieves good agreement with FEA and experiment (**Figure 2C** of main text).
