Genetic linkage analysis of 14 candidate gene loci in a family with autosomal dominant osteoarthritis without dysplasia

I Meulenbelt, C Bijkerk, F C Breedveld, P E Slagboom

Abstract

The role of various gene loci was investigated in a family in which familial osteoarthritis (FOA), with onset at an early age, is transmitted as an autosomal dominant mendelian trait. The absence of clinical and radiographic signs of dysplasia and calcium pyrophosphate deposition disease (CPDD) indicates that the basic disease process in this family is osteoarthritis (OA). Genetic linkage analysis of 14 candidate genes resulted in the exclusion of 10 important genes (COL2A1, COL9A1, COL9A2, COL11A1, COL11A2, COMP, the CPDD region, CRTL-1, CRTM, and MMP3). Other relevant genes were not informative in this family. The candidate loci previously identified in FOA and heritable skeletal disorders associated with OA are clearly not involved in the development of the primary FOA phenotype in the family investigated, indicating genetic heterogeneity.

Osteoarthritis (OA) is a degenerative disease of the joints, characterised by degradation of the hyaline articular cartilage and remodelling of the subchondral bone with sclerosis. Genetic factors play a role in the aetiology of familial OA (FOA) with an early age of onset (20-40 year) in multiple joints.

Research into the genetic loci involved in FOA has so far mainly been focused on the type II procollagen gene (COL2A1). The COL2A1 gene encodes the major stress resisting element and the most abundant structural collagenous protein in cartilage.[1] Genetic studies of families and unrelated patients with an FOA phenotype accompanied by mild spondyloepiphyseal dysplasia (SED) have shown linkage to COL2A1 and mutations in the gene in approximately 25% of the cases.[2] However, only a few studies have focused on families where OA is the only and primary disease process without any dysplasia. Genetic studies showed positive linkage to COL2A1 in two such FOA families.[3 4] Mutation analysis of the COL2A1 gene in 45 unrelated FOA patients showed only one COL2A1 mutation.[5] Studies on other candidate genes have not been reported for FOA. Genes, however, identified in heritable skeletal disorders associated with generalised OA may also play a possible role in FOA (table 1).

We have investigated the role of 14 candidate genes for FOA in a four generation Dutch family of Jewish descent in which the pedigree included 21 persons (fig 1). Informed consent and complete medical history was obtained for all family members. The study was approved by the Medical Ethics Committee of the Academic Hospital Leiden. Physical examinations were performed on all members of the third generation and on seven out of 14 direct descendants in the fourth generation. All clinical evaluations and diagnostic decisions were made before the genetic linkage analyses.

The family included many members affected with OA with an age of onset between 20 and 40 years. Symptoms began with intermittent acute pain and swelling in one or both knee joints with subsequent development of OA in other joints. The hip was only rarely affected (table 2). Radiographic signs of chondrodysplasia, spinal dysplasia, or abnormal development of the epiphyses of the peripheral joints were absent (fig 2). Some subjects had marked Heberden nodes (table 2, fig 3). The mean ratio of upper to lower segment of affected members was 0.95 (range 0.89 to 1.02), indicating the absence of a short trunk form of dysplasia. All family members had normal stature (table 2). The diagnosis was "pure" familial OA transmitted as an autosomal dominant mendelian trait (fig 1, table 2).

Genetic linkage analysis was performed using either intragenic or closely linked

markers to the candidate genes (table 3). Genomic DNA samples of family members were collected by mouth swabs.[37] All markers, except D20S19, were analysed by genomic PCR containing α[32P]-dCTP.[38] Alleles were separated by standard electrophoresis through a denaturing polyacrylamide gel (3.5-6%) and visualised by autoradiography.[38] Alleles of marker D20S19 were analysed by Southern blotting and hybridisation with the clone pCMM20 radioactively labelled with α[32P]-dCTP.[38]

Two point lod scores between the disease phenotype of family members and the markers were calculated using MLINK from the LINKAGE package version 5.1.[39] Multipoint lod score analysis was performed using the LINKMAP program.[40] The disease locus was modelled as an autosomal dominant trait. People with clinical and radiographic evidence of OA in two or more joints were considered affected. Penetrance was modelled to rise linearly from 0% at age 15 to 100% at 40 years,

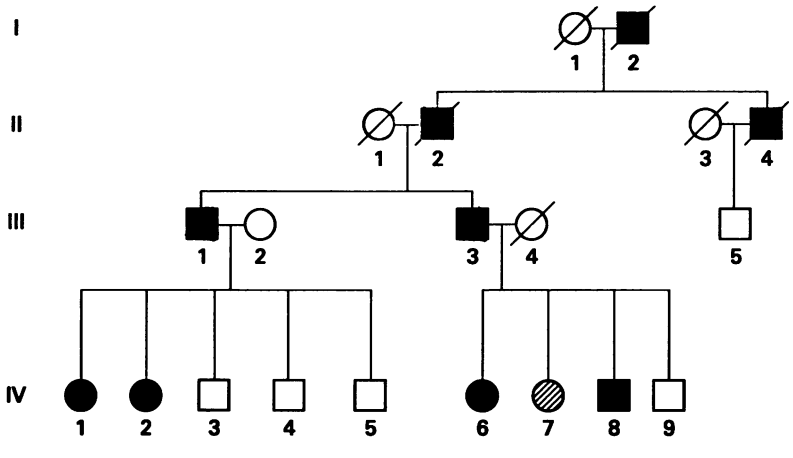

Figure 1 Pedigree of the FOA family used for linkage analysis. The hatched symbol represents diagnostic uncertainty, the filled symbols represent affected subjects.

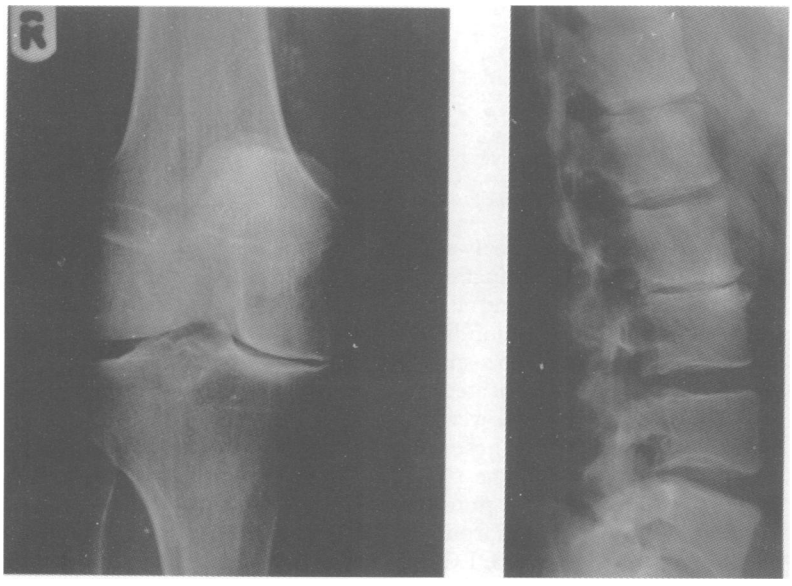

Figure 2 X rays of III.1 aged 53 years. (A) Right knee joint showing marked OA medially and chondrocalcinosis laterally, without evidence of epiphyseal dysplasia. (B) Lumbosacral spine joints (lateral view) showing osteophytosis and discus degeneration at level L2-L3. No dysplastic features.

Figure 3 X ray of III.3 aged 65 years showing hand joints with marked OA in DIP, PIP, CMC1, MCP-I, and II. Heberden and Bouchard nodes are visible.

*The excluded distance is calculated with odds of 100:1 against linkage in Kosambi centiMorgans (KcM).

based on the onset age of OA as described previously.[3] Subjects with ages of onset above 40 years were considered as phenocopies.

Lod scores and the recombination fractions yielding a lod score of −2 are shown in table 4. Since the lod scores over the genetic region covered by the COL2A1, COL9A1, COL9A2, COL11A1, CRTL-1, COMP, CPDD, and MMP3 genes are ≤ −2 (odds 100:1 against linkage), these genes were excluded from being involved in causing FOA in this family. The COL9A3, COL11A2, DCN, CRTM, LOX, and PLOD genes could not be excluded by two point linkage analysis (table 4). The COL11A2 and CRTM genes were excluded (lod scores ≤ −2, table 5) by using multipoint lod score analysis with fixed markers and known recombination fractions (table 3). For the COL9A3 and PLOD genes, the excluded region surrounding the highly polymorphic markers was too small to exclude the genes. The markers located within the DCN and LOX genes (table 3) were not informative in important meioses. These genes could, therefore, not be excluded. The COL9A3 and DCN loci are mapped in regions containing too few alternative polymorphic markers and the genetic location of the LOX and PLOD genes is not well defined.

*Computed by division of the location scores with 2 ln (10).

In summary, 10 genes were excluded from involvement in FOA in this family. Among these loci were important candidate genes involved in several heritable skeletal disorders, mild chondrodysplasia and epiphyseal dysplasia associated with early onset OA in multiple joints (COL2A1, COL9A1, COL9A2, COL11A1, COL11A2, COMP, and the CPDD region). Other possible candidate genes encoding non-collagenous structural components, or genes involved in post-translational modification and remodelling of cartilage, were also excluded (CRTL-1, CRTM, and MMP3). The COL9A3, DCN, LOX, and PLOD genes could not be excluded as the cause of FOA in our family.

We have shown once more that FOA is genetically heterogeneous and that 10 important OA candidate genes are not involved in the pathogenesis of an FOA phenotype without dysplasia. Unidentified genes may be detected in future studies of this and other families in which FOA is the primary disease process.

We would like to thank Dr J K van der Korst, Dr P J J M Rompa, and Professor Dr J J Rasker for providing us with the *x* rays and medical histories of their patients, Saskia de Wildt for technical support, and Dr M Warman and Dr C J Williams for helpful discussions. This work was supported by the TNO-Health Organisation, the "Dutch League against Rheumatism" of the Netherlands, and Looscofoundation.
