\* Farah et al. (2013) and Silva et al. (2015) analyzed data from the same participants and the same intervention, however, both studies analyzed different outcomes.

### eMethods 2. Data Analysis

#### *Effectiveness of exercise types (traditional meta-analysis)*

To determine the effect of physical exercise on insulin sensitivity outcomes comparing to a control group, random-effects inverse-variance models with the Hartung-Knapp-Sidik-Jonkman adjustment were used to assess the effects. To determine changes in outcomes (i.e., fasting glucose, fasting insulin, HOMA-IR and 24-h oral glucose tolerance test), the change differences between the exercise and control groups were calculated by using the pooled standard deviation (SD) of change in both groups. In cases where change scores SD were not available, they were estimated from 95% confidence intervals (CI) for either change outcome or intervention effect differences as well as pre-SD and post-SD values. It is important to clarify the following aspects regarding our statistical analyses: (1) meta-analyses were only performed for insulin sensitivity outcomes that were included in five or more studies <sup>56</sup>; (2) to avoid double-counting and following the Cochrane Handbook recommendations, when a study included more than two arms in comparison with a control group, we halved the number of participants in the control group for each of the comparisons <sup>57</sup>.

The presence of small-study effects was assessed using the Luis Furuya-Kanamori index (LFK) <sup>58</sup>. A value of -1 indicates no asymmetry, while values between -1 and -2 indicate minor asymmetry, and values greater than -2 indicate major asymmetry <sup>58</sup>.

A sensitivity analysis was conducted to assess the robustness of the summarized estimates and to identify whether a specific study contributed to any discrepancies. For this analysis, we systematically excluded one study at a time from the pool of included studies, conducting the meta-analysis multiple times, with each iteration excluding a different study.

#### Dose-response meta-analysis

The energy expenditure dose of exercise in terms of METs-min per week was calculated using the Compendium of Physical Activities <sup>59</sup> according to frequency, intensity, type, and duration for each arm. Energy expenditure was classified into seven different groups by approximating the estimated METs-min per week to the closest convenient pre-specified grouping categories of 0 (control group), 500, 750, 1000, 1500, 2000 or 2500 METs-min per week (Supplementary Material 2). Non-linear dose-response meta-analyses were conducted to explore the dose-response association of exercise dose (i.e., METs-min per week) on insulin resistance markers using *drmeta* command following the recommendations by Crippa et al. <sup>60</sup>. We also carried out a sensitivity analysis using only those studies that included children and adolescents with a higher HOMA-IR levels than 3.16 <sup>61</sup>.

#### Network meta-analysis

First, we qualitatively summarize the included randomized clinical trials and RCT in an *ad hoc* table describing direct and indirect comparisons. Second, before conducted the network meta-analysis (NMA), three assumptions were checked <sup>62</sup>: a) to prevent bias in the comparisons, which could lead to heterogeneity and inconsistency, the similarity and comparability of the trials included in the NMA were examined and confirmed. Similarity was assessed by checking whether samples in each exercise type were similar in the baseline distribution of variables understood as effect modifiers (i.e., sex, age); b) to ensure that the study-related conditions were homogenous, the absence of

heterogeneity in the results of pairwise comparisons was confirmed. The size and clinical relevance of heterogeneity was determined by the  $\tau^2$  statistic rated as low degree of clinical relevance (<0.04), moderate (0.04 to 0.14), or substantial (0.14 to 0.40)<sup>63</sup>; c) consistency and transitivity were checked to ensure that no relevant discrepancies exist between direct and indirect evidence. The similarity assumption was determined using the node-splitting method <sup>64</sup>.

To perform the NMA, the next steps were followed: we assessed the strength of the available evidence using a network geometry graph to display the evidence in the network for insulin resistance outcomes. In these figures, the size of the nodes was proportional to the number of participants in trials who received the intervention specified in the node, the thickness of continuous line connecting nodes proportional to number of trials directly comparing the two intervention <sup>65</sup>.

Comparative evaluation of the interventions effect on fasting glucose, insulin, and HOMA-IR were conducted through a random effects pairwise meta-analysis <sup>66</sup> and a frequentist NMA <sup>67</sup> for comparisons between interventions and control. We assessed heterogeneity using the  $I^2$  statistic, ranging from 0% to 100% <sup>68</sup>. Based on the values of  $I^2$ , we categorized heterogeneity as not important (0% to 30%), moderate (30% to 60%), substantial (60% to 75%), or considerable (75% to 100%) <sup>68</sup>. Similarly, the corresponding *p* values were considered.

Rankograms were established to indicate the probability that each treatment is the best available intervention. Furthermore, we estimated the surface under cumulative ranking (SUCRA)<sup>65</sup> for each intervention. The SUCRA assigns a value ranging from 0 to 1 to each intervention in the rankogram, which allows them to be ranked. A SUCRA value of approximately 0 denotes the worst available intervention, while a value of approximately 1 indicates the best available intervention. SUCRA condenses the information about the effectiveness of each intervention into a single value, simplifying the complex results of network meta-analysis into just a few numbers. The significance of the SUCRA is highest when there is a consistent difference in preference between consecutive ranks across the entire rating scale. However, SUCRA scores were reported as percentages, for clarity. eMethods 3. Excluded Studies and Reasons for Exclusion

#### **Reason for exclusion: Duplicated data**

Overweight and Obese Children: The" 4 Your Family" Randomized Controlled Trial.
Nutrients, 13(2), 341-341.

## Reason for exclusion: Not enough information on the type of exercise

van der Baan-Slootweg, O., Benninga, M. A., Beelen, A., van der Palen, J., Tamminga-Smeulders, C., Tijssen, J. G., & van Aalderen, W. M. (2014). Inpatient treatment of children and adolescents with severe obesity in the Netherlands: a randomized clinical trial. JAMA pediatrics, 168(9), 807-814.

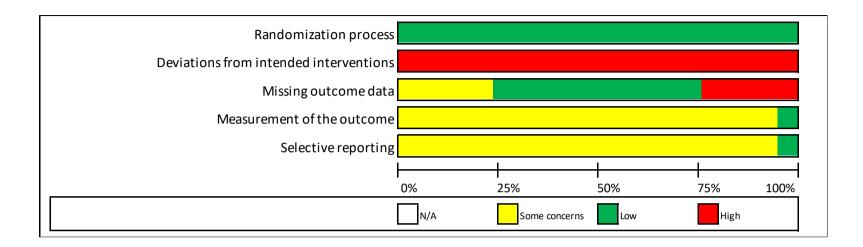

## eTable 2. Results of the Cochrane Risk-of-Bias Tool for Randomized Controlled Trials (RoB-2)

All studies were deemed to be at low risk of bias for the "randomization process" domain since we only included randomized studies. Inversely, the domain "Deviations from intended interventions" was rated to be at high risk of bias in all studies due to the impossibility of blinding participants and people delivering the intervention to group assignment in the exercise interventions. For the rest of the items, most studies were considered to have some concerns regarding risk of bias.
