**Supplementary Fig. 2 Spatiotemporal distribution of bacterial adhesion to geometrically constrained cell monolayers.** Top: spatially heterogeneous adhesion results between *S. aureus* expressing GFP and circular monolayers of IEC-6 cells at 1, 1.5, 2 and 2.5 h of infection. The intensity maps presented spatial distributions of normalized GFP intensities of adherent *S. aureus*. Scale bars, 100 μm. Bottom: average normalized GFP intensities along the radial directions of the micropatterns and statistical comparison of the normalized GFP intensities at the center and the edge of these circular cell monolayers at 1, 1.5, 2 and 2.5 h of infection. All measured values were shown as the mean ± SD ($n = 3$; two-tailed unpaired *t*-test). All representative data were repeated at least three times with similar results. Source data are provided as a Source Data file.

**Supplementary Fig. 3 Bacteria-cell heterogeneous adhesion phenomenon independence of cell types and adhesive substance coated on PAAm substrates. a** Representative images of circular monolayers of monoclonal IEC-6 cells and HaCat cells infected by *S. aureus* and the corresponding spatial distribution of normalized GFP intensities of adherent *S. aureus*. Note that, in order to exclude the influence of cell phenotype, we allowed a single IEC-6 cell to proliferate within a specific micropatterned region so that it finally formed a micropatterned cell monolayer, which was referred to as monoclonal IEC-6 cell monolayer in our experiments. For better visualization, cell nuclei and F-actin cytoskeletons in the host cell monolayers were labelled with DAPI and Actin-Tracker Red-555 (Thermo Fisher), respectively. Scale bars, 100 μm. **b** Average normalized fluorescence intensities of adherent *S. aureus* along the radial directions of the micropatterns of monoclonal IEC-6 cells and HaCat cells. **c** Statistical comparison of the normalized GFP intensities at the center and the edge of the circular cell monolayers of monoclonal IEC-6 cells and HaCat cells (*n* = 4; two-tailed unpaired *t*-test). **d-e** Statistical comparisons of the normalized GFP intensities of adherent *S. aureus* at the center and the edge of the circular cell monolayers of IEC-6 cells on collagen I-coating (**d**) and polylysine-coating PAAm substrates (**e**) (*n* = 3; one-way ANOVA). All representative data were repeated at least three times with similar results. Source data are provided as a Source Data file.
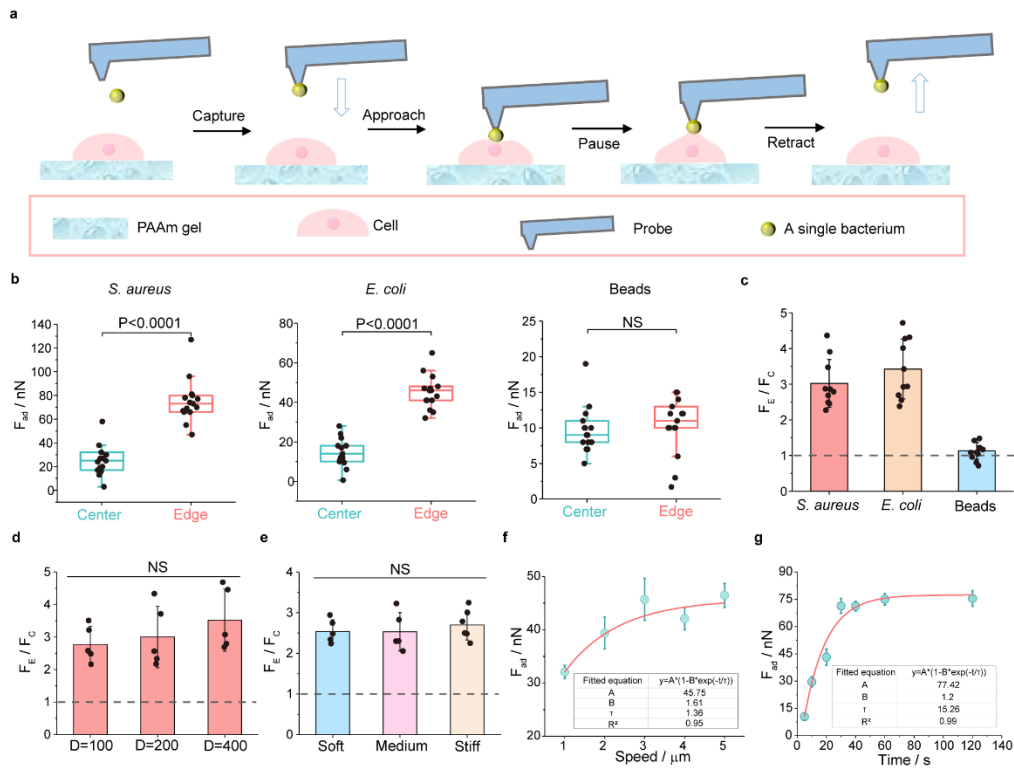

**Supplementary Fig. 4 Dependence of adhesion forces between single bacterium and micropatterned host cell monolayers on geometric constrains. a** Simplified schematic diagram of measuring adhesion forces between single bacterium and cell monolayers based on FluidFM-based SCFS. First, single bacterium was tightly immobilized to the probe opening by applying negative pressure (-200 mbar). Then, the cantilever with the single bacterium approached a selected adherent cell at a piezo speed of 1 μm/s and paused 30 s to interact with the cell when the force setpoint (100 nN) was reached. Finally, the cantilever was retracted from the cell at a piezo speed of 1 μm/s to complete the force spectrum experiment. **b** Comparison of the measured adhesion forces of *S. aureus*, *E. coli* and latex beads to host cells located at the center and edge of these micropatterned cell monolayers. The underlying PAAm substrate had a stiffness of 93.46 kPa (stiff substrate). Box plots indicate median (middle line), 25th, 75th percentile (box) (two-tailed unpaired *t*-test). **c** Ratio of the adhesion forces of *S. aureus*, *E. coli* and latex beads to host cells located at the edges of the micropatterned cell monolayers to the corresponding ones at the centers ($F_E/F_C$). **d** Ratio of the adhesion forces of *S. aureus* adhering to the edges of micropatterned cell monolayers with different micropattern diameters (100, 200 and 400 μm) to the corresponding centers (one-way ANOVA). **e** Ratio of the adhesion forces of *S. aureus* adhering to the edges of micropatterned cell monolayers cultured on substrates with different rigidities (soft, medium and stiff) to the corresponding centers. **f** Adhesion forces between *S. aureus* and IEC-6 cell monolayers at different probe speed. **g** Adhesion forces between *S. aureus* and IEC-6 cell monolayers at different probe contact time. All the measured data were shown as mean ± SD ($n \geq 3$), unless otherwise stated. Source data are provided as a Source Data file.

### Characterization of PAAm hydrogel stiffness

The elastic modulus of PAAm substrates was quantified by a Piuma nanoindenter equipped with a Chiaro indenter head (Optics11 Life, Netherlands). The adopted nanoindentation probe had a tip radius of 23 μm and its cantilever stiffness was 0.24 N/m in the experiments. At least four nanoindentation tests were performed at different locations on the soft, medium and stiff substrates. According to the obtained load-displacement curves, we employed the following Oliver-Pharr model[8] to estimate the elastic moduli of the PAAm hydrogel samples, *i.e.*,

$$E_{\text{eff}} = \frac{S/2}{\sqrt{R_{\text{i}}} \cdot \sqrt{h_{\text{max}} + h_{\text{r}}}} \tag{1}$$

where $E_{\text{eff}}$ was the measured elastic modulus, $R_{\text{i}}$ denoted the spherical tip radius, $S$ was the slope at the maximum indentation, $h_{\text{max}}$ represented the maximum indentation depth and $h_{\text{r}}$ stood for the final contact depth.

### Quantification of cellular traction forces in micropatterned cell monolayers

In general, both singe cells and micropatterned cell monolayers could exert cellular traction forces on extracellular matrices or elastic substrates to which they adhered. The well-developed cellular traction force microscopy (CTFM) provided a powerful tool to recover cellular traction forces[9,10]. In brief, PAAm hydrogel substrates with specific Young's modulus were first fabricated, as described in the Section of Methods. The only difference was that a certain amount of polystyrene fluorescent beads (200 nm in diameter, F-8807, ThermoFisher) needed to be added to the PAAm pre-polymerization solution in advance. Subsequently, a drop of the solution (~30 μl) was added onto a clean coverslip with collagen micropatterns and then covered with another activated coverslip, following a polymerization for 20 min at room temperature. During the time, the fluorescence beads could move to the interface between the PAAm substrate and the clean coverslip under gravity and finally form random fluorescence patterns near the surface of the PAAm substrate. In the experiments, cellular traction forces generated by a specific micropatterned cell monolayer induced the PAAm hydrogel substrate deformation and thus displace the random fluorescent beads near the substrate surface, which could be recorded with a confocal laser scanning microscope (CLSM, Nikon). In this manner, one could obtain the deformed fluorescent image. On the other hand, the originally undeformed fluorescent image could be acquired after the cell monolayer was completely digested with 1 M NaOH. Next, the well-developed digital image correlation (DIC) technique was employed to quantitatively calculate the substrate displacement field by comparing the deformed fluorescent image and the undeformed one[11,12]. Finally, the cellular traction force field was reconstructed from the substrate displacement data by means of the well-established CTFM[13-15].

**Quantification of Young's moduli of micropatterned cell monolayers with atomic force microscopy**

The Young's moduli of cells in micropatterned cell monolayers were quantified with an atomic force microscope (AFM, BioScope Resolve, Bruker). In the current experiments, the AFM probe had a semi-circular tip whose radius was 970 nm. Prior to the first measurement, the probe was calibrated to determine its actual spring constant (~0.028 N/m). Then, we obtained a series of force-indentation curves at different locations of a specific IEC-6 cell monolayer and estimated their Young's moduli based on the traditional Hertzian model[16], as exhibited in Supplementary Fig. 8f-h.

**Bacterial Kinetic Model**

To simulate the spatiotemporal dynamics of bacterial interactions with the underlying host cell monolayers, we first introduced a bacterial kinetic model to describe random movement of a single bacterium in a liquid environment. For the sake of simplification, we didn't consider bacterial reproduction and bacteria-bacteria interactions in the model. To facilitate subsequent Monte Carlo (MC) numerical simulations, we divided the two-dimensional square planar area where a host cell monolayer was located into small square grids with side lengths of 1 μm, which was equivalent to the size of a single bacterium such as *S. aureus*, approximately. We assumed that a certain number of bacteria underwent random movements above these delimited square grids under gravity, buoyancy, Stokes drag force, Brownian random force, and eventually came into contact with the underlying host cell monolayer in the liquid environment (Fig. 4c and Supplementary Fig. 9). It was very likely that some of the bacteria approached the underly host cell monolayer and created bacteria-cell adhesion regulated by the receptor-ligand binding. To ensure the efficiency of the MC numerical simulations, we only considered the spatiotemporal dynamics of bacteria within 50 μm above the square region containing a specific host cell monolayer. Simultaneously, we imposed periodic boundary conditions to the cubic simulation regions above the two-dimensional square planar areas, which consisted of 300, 400 and 600 square grids for the simulated micropatterned cell monolayers of 100, 200 and 400 μm in diameter, respectively. If an arbitrary bacterium left the simulation region at one boundary, another new bacterium would immediately enter from the opposite boundary to ensure that the total number of bacteria remained constant during the simulation. For some non-flagellated bacteria that could not move autonomously in a liquid environment[17], such as *S. aureus*, we simplified them to inert colloidal particles[18] in this model. Besides, we further hypothesized that the initial positions and velocities of the simulated bacteria were randomly and uniformly distributed. Based on the Brownian motion theory of suspended particles in a fluid environment[5,19], we might characterize the random motion of a single bacterium under gravity in a liquid environment via a Langevin equation, as presented in Equation (2) in the main text. Namely,

$$m\frac{d^2\mathbf{r}}{dt^2} = \mathbf{F}_D + \mathbf{F}_B + \mathbf{F}_G + \mathbf{F}_{buo} \tag{2}$$

in which, $m$ denoted the mass of a single bacterium, $\mathbf{r}$ was its position vector, $t$ was the time, $\mathbf{F}_D$, $\mathbf{F}_B$, $\mathbf{F}_G$ and $\mathbf{F}_{buo}$ represented the Stokes drag force, Brownian random force, gravity and buoyancy in the liquid environment, respectively. When the particle speed $\mathbf{v}$ was not large, we had

$$\mathbf{F}_D = -a\mathbf{v} = -a\frac{d\mathbf{r}}{dt} \tag{3}$$

with

$$a = 6\pi R\eta \tag{4}$$

where $a$ was the Stokes drag coefficient, $R$ denoted the equivalent radius of a single bacterium and $\eta$ stood for the liquid viscosity coefficient.

In general, the Brownian random force $\mathbf{F_B}$ was taken as a Gaussian distribution and satisfied the following conditions[5]

$$< \mathbf{F_B}(t) >= \mathbf{0} \tag{5}$$

$$< \mathbf{F_B}(t) \cdot \mathbf{F_B}(t') >= 2ak_BT\delta（t-t'）\mathbf{I}dt \tag{6}$$

where $k_B$ was the Boltzmann constant, $T$ was the absolute temperature, $\delta(x)$ was the Dirac function and $\mathbf{I}$ was the identity matrix.

The gravity $\mathbf{F_G}$ acting on a single bacterium could be expressed as

$$\mathbf{F_G} = mg = \frac{4}{3}\pi R^3 \rho g \tag{7}$$

where $R$ was the radius of the single bacterium, $\rho$ was the density, and $g$ was the acceleration of gravity.

According to the Archimedes' law, the buoyant force $\mathbf{F_{buo}}$ exerted on the single bacterium could be quantitatively written as

$$\mathbf{F_{buo}} = -\frac{4}{3}\pi R^3 \rho_f g \tag{8}$$

where $\rho_f$ was the density of the liquid around the bacteria.

Based on the classical Verlet algorithm[20], the position and velocity of a specific bacterium could be calculated in a recursive manner as

$$\mathbf{r}_{(t+\Delta t)} = 2\mathbf{r}_{(t)} - \mathbf{r}_{(t-\Delta t)} + a_t(\Delta t)^2 + \mathbf{O}((\Delta t)^4) \tag{9}$$

$$\mathbf{v}_{(t)} = \frac{1}{2\Delta t}(\mathbf{r}_{(t+\Delta t)} - \mathbf{r}_{(t-\Delta t)}) + \mathbf{O}((\Delta t)^2) \tag{10}$$

**Mechanochemical coupling model characterizing bacteria-cell adhesion**

To quantitatively describe the kinetics of bacteria-cell adhesion, we put forwards a mechanochemical coupling model to mimic the interaction between collagen IV molecules and collagen-binding proteins (Cna) such as adhesin expressed on *S. aureus* based on the high-affinity "dock, lock and latch (DLL)" mechanism[21-23]. In general, there were three subdomains N1, N2 and N3 in the "A region" in the Cna structure, which was the collagen binding region[24]. Specifically, the N1-N2 subdomain of Cna was a variant of the IgG fold with an open conformation. To form the binding of collagen IV receptors to Cna ligands, the binding groove on the N2 subdomain needed to be docked with the collagen triple helix ligand, then the conformational change locked N1-N2 around the collagen, and finally the C-terminal latch of N2 was inserted into the groove of N1 to latch the ligand[25] (Fig. 4a).

We utilized the classical MC simulations to dissect the spatiotemporal dynamics of random movement of bacteria and possible receptor-ligand binding and dissociation. To this end, we adopted a grid of uniformly sized squares to represent the bacteria-cell adhesion interfaces (Supplementary Fig. 9a). In the simulations, the density of collagen IV proteins on the micropatterned host cell monolayers was assumed to be directly related to the bacteria-cell adhesion energies that were beforehand measured via the FluidFM-based SCFS. The spatiotemporal dynamics of random movement of bacteria and subsequent bacteria-cell interactions was modeled stepwise in the MC simulations until a steady-state equilibrium was achieved. At each time step, spatial positions and velocities of all these bacteria and their states of adhesion to the underlying host cell monolayers were updated accordingly based on Equation (2) and (3) in the main text to determine whether the

ligand-receptor association or dissociation would occur. The spatiotemporal dynamics of interactions between fluorescent beads and the underlying micropatterned cell monolayers was also simulated in a similar manner except that the aforementioned mechanochemical interaction needed to be replaced by potential non-specific interactions, which might be beforehand quantified with the FluidFM-based SCFS.

**Quantification of infected cells using flow cytometry**

The IEC-6 cell monolayers cultured on the soft, medium and stiff PAAm substrates were infected by *S. aureus* expressing GFP for 2 h. Subsequently, they were washed with PBS to remove unadhered bacteria and then washed twice with 10 mg/ml gentamicin to eliminate uninternalized bacteria without interfering with internalized bacteria[26]. The infected cells were digested with 0.25% trypsin for 3 min, collected with 10% DMEM after centrifugation and resuspended with 3% BSA for the flow cytometry (BD FACSVerse). The cellular infection rate of internalized bacteria was quantified through detecting the GFP fluorescence signals of intracellular bacteria using the flow cytometry.

**Quantification of internalized bacteria with colony-count technique**

To quantify the internalized bacteria based on the colony-count technique, we also allowed *S. aureus* expressing GFP to infect the IEC-6 cell monolayers cultured on the soft, medium and stiff PAAm substrates for 2 h. Then, the uninternalized bacteria were eliminated with 10 mg/mL gentamicin while the internalized bacteria were released with 0.1% Triton X-100 in experiment. Finally, the internalized bacteria at a certain dilution concentration were smeared on LB agar with glass beads and incubated at 37 ℃ for 18 h to quantify the number of internalized bacteria.
