ABSTRACT

Tractable forms of predicting rates of inbreeding (ΔF) in selected populations with general indices, nonrandom mating, and overlapping generations were developed, with the principal results assuming a period of equilibrium in the selection process. An existing theorem concerning the relationship between squared long-term genetic contributions and rates of inbreeding was extended to nonrandom mating and to overlapping generations. ΔF was shown to be $\sim^{1}/_{4}(1-\omega)$ times the expected sum of squared lifetime ⁄ contributions, where ω is the deviation from Hardy-Weinberg proportions. This relationship cannot be used for prediction since it is based upon observed quantities. Therefore, the relationship was further developed to express ΔF in terms of expected long-term contributions that are conditional on a set of selective advantages that relate the selection processes in two consecutive generations and are predictable quantities. With random mating, if selected family sizes are assumed to be independent Poisson variables then the expected long-term contribution could be substituted for the observed, providing $\frac{1}{4}$ (since ω = ⁄ 0) was increased to $\frac{1}{2}$. Established theory was used to provide a correction term to account for deviations ⁄ from the Poisson assumptions. The equations were successfully applied, using simple linear models, to the problem of predicting ΔF with sib indices in discrete generations since previously published solutions had proved complex.

 \mathbf{W}^{RAY} and Thompson (1990) proved a fundamen-
tal relationship between the sum of squared long-
tal relationship between the sum of squared long-
tale ancestor. Furthermore, it was clear that under equilib-
tale term genetic contributions of ancestors and rates of rium conditions, the model would lend itself to geometinbreeding for random mating populations in discrete ric summation of terms across generations. This led to generations. One consequence of this relationship was simple forms for the expected long-term contribution that rates of inbreeding were tied to the numerator of an ancestor. Wray *et al.* (1994) extended the methods relationship matrix for the first time. This narrowed to index selection, although the form of the model is the conceptual gap between the central parameter for a hybrid of the approach of Woolliams *et al.* (1993) genetic evaluation of individuals using best linear unbi-
and Hill (1972), since the conditional arguments of
pathway extension that had been carried out for mass ased prediction and one of the key properties of a breed-
ing scheme. Another important consequence was to selection were found to be too complex for index selecing scheme. Another important consequence was to selection were found to be too complex for index selec-

RELATIONSHIP BETWEEN ΔF AND LONG-TERM where $r_{i,u}(q, t-1)$ is the average contribution to parents GENETIC CONTRIBUTIONS of sex *q* at time *t* - 1. (Note the breeding values and This section discusses the relationship between ΔF Mendelian sampling terms will depend on the allele but terms are zero. 2D*FCu*(*t* $-\Delta F C_u(t-1)$). After repeating this process for the $C_2(t)$

term $\sum_i f_{i,u}(m, t-1) r_{i,u}(f, t-1) a_{i,u}^2$ should be the sum of \qquad 1)], products of contributions of the ancestor to each male *E* and female mating pair:

$$
\sum_{i \text{ mates}} \sum_{(j(m),j^{*}(t))} r_{i,u}(j(m), t-1) r_{i,u}(j^{*}(f), t-1) a_{i,u}^{2} \qquad (3) \qquad \qquad -\frac{1}{4} \omega C_{1}(t-1) \\ = \Delta F \left[\frac{1}{2} \omega C_{1}(t-1) + \frac{1}{2} \omega C_{1}(t-1) \right]
$$

This will account for any nonrandom mating of parents. For a neutral locus, the covariance between r_i and a_i will be 0 (Woolliams and Thompson 1994; Woolliams *et al.* 1999), and the expectation of Equation 3 is *E*[$\sum_i \sum_{\text{mates } (i(m), i^*(f))} r_{i,u}(j(m), t-1) r_{i,u}(j^*(f), t-1)$]*E*[$a_{i,u}^2$]. $E[\Sigma_i \Sigma_{\text{mates } (f(m), f(l))} I_{iu}(j(m), t-1)I_{iu}(j^*(f), t-1)]E[a_{iu}^2]$.
Let the first of these, the expectation of the cross-prod-
ucts of contributions to mates be $C(t-1)$. Note that a given u. Therefore, $\frac{1}{2}C_0(t) \approx \frac{1}{2}C_0(t-1)$ Let the first of these, the expectation of the cross-products of contributions to mates, be $C_u(t-1)$. Note that (i) $C_{t-1}(t-1) = 0$ since an individual without offspring $C_4 \omega C_1(t-1) \approx \frac{1}{4}(1-\omega) C_1(t-\omega)$
subtracting the term $\frac{1}{2}\Delta F C_0(t)$, cannot contribute to both sexes and (ii) the first term in Equation 2 is ${}^{1}\!2C_0(t-1)$ since $A_{i,0}^2$ has a value ${}^{1}\!4$ for $E[F_{t+1} - F_t] = {}^{1}\!5C_0(t-1)$ **∕ ∕** each of its two alleles and 0 otherwise.

Assume equilibrium values for (i) the deviation from Hardy-Weinberg frequencies arising from the nonran-
dom mating (ω , equivalent to α_I of Caballero and α_I Hill 1992) and (ii) ΔF , attained by generation 2 (this assumption is removed later); then Equation 2 can be further simplified using results given in appendix a, Finally, note $E[F_{t+1} - F_t] = \Delta F E[1 - F_t]$ and that the namely, $\Sigma_{\text{alleles}} \, E[\,a_{i,u}^2] \, = \, \frac{1}{4}$ for $\,u = 1\,$ and $\,$ **∕ ∕** ΔF ^{*u*-1} for *u* \geq 2. Therefore,

$$
E[F_{t+1}] = \frac{1}{2}C_0(\hat{p}) + \frac{1}{4}C_1(\hat{p}) + \sum_{u=2}^{t-1} \frac{1}{4}(1-\omega)(1-\Delta P)^{u-1}C_u(\hat{p}) \qquad (4)
$$

$$
E[F_t] = \frac{1}{2}C_0(t-1) + \frac{1}{4}C_1(t-1)
$$
inbreeding c
+ $\sum_{u=2}^{t-2} \frac{1}{4}(1-\omega)(1-\Delta F)^{u-1}C_u(t-1)$. (5) $\Delta F = \frac{1}{2}$

C_u (t-1)].
$$
 (8)

term in square brackets in Equation 8 is $E[F_t]$, giving

$$
\Delta F = \frac{1}{4}(1-\omega) C_1(t-1)[1-\frac{1}{2}C_0(t)]^{-1}.
$$
 (9)

This result holds for *t* large enough for contributions from early generations to have converged. If it is assumed that the base generation used for defining the inbreeding coefficients was chosen to be part of a period of equilibrium, then $C_1(t-1) = C_0(t) = C$,

$$
\Delta F = \frac{1}{4}(1-\omega) C[1-\frac{1}{2}C]^{-1} \approx \frac{1}{4}(1-\omega) C, (10)
$$

Subtracting (5) from (4) and rearranging terms, where *C* is the sum of squared converged contributions for a generation, chosen arbitrarily within the period of equilibrium. Including the term neglected between + $\frac{1}{4}C_1(t) - \frac{1}{4}C_1(t-1)$ Equations 6 and 7 would replace $[1 - \frac{1}{2}C]^{-1}$ by $[1 - \frac{1}{2}C]$ ⁄ $(\frac{1}{2} + \frac{1}{4}\omega)C]^{-1}$. For random mating, omitting the term
+ $\frac{1}{4}(1 - \omega)(1 - \Delta F)C_2(t)$
1 - $\frac{1}{4}C^{-1}$ leads to an underestimate with a fractional ⁄ ⁄ ⁄ $[1 - \frac{1}{2}C]$ ⁻¹ leads to an underestimate with a fractional error of $\sim V_2C$, which in turn is \sim 2 ΔF . ⁄

Since $C = E[\sum_{m} \sum_{m} (f(m), f^{*}(f))T_{i,u}(f(m), t) T_{i,u}(f^{*}(f), t)]$ for large $u \ll t$, for any *i* the terms $r_{iu}(i/m)$, *t*) and $r_{iu}(i(f))$, *t*) converge to the same value for all *j* in generation *t* Assuming equilibrium, then a steady state of pedigree providing the population mixes. This value will be the development will occur and the expectation of the cross-
long-term contribution of ancestor *i* to the population mating. Thus $C = E[\Sigma_i r_i^2]$ for a generation of ancestors,

$$
\Delta F \approx \frac{1}{4}(1 - \omega) E \left[\sum_{i} r_i^2 \right] \tag{11}
$$

$$
E[\Delta F] \approx V_4(1-\omega) \left(X_{\rm m} E[r_{i(m)}^2] + X_{\rm f} E[r_{i(0)}^2] \right). \quad (12)
$$

in $C_{u-1}(t-1)$, and each term of the sum within the individual *i* being a selected ancestor; however, since

be given as tion will contain the equivalent of *L* cohorts, where *L*

$$
E[\Delta F] \approx \frac{1}{4}(1-\omega) \left(T_{\rm m} E[r_{i(m)}^2] + T_{\rm f} E[r_{i(1)}^2] \right), \quad (13)
$$

Thompson (1990) but the derivation differs in several aspects. First, in the derivation of Wray and Thompson unit time), where *L* is the generation interval. Thus the base was unselected and therefore not in equilibrium at the start of the selection process, and this led to consequently ignoring this term results in an underestian impression that the contributions used for estimating mate with a fractional error of $2 \times (\Delta F)$ per generation). rates of inbreeding must be the generation after an Equation 11 is obtained by summing over all individuals unselected base. It is now evident that the choice of born in a single cohort. With overlapping generations, generation on which the estimate is obtained is arbitrary individual ancestors within cohorts will have different except that it is at the start of some period of local life histories, since they will be used at different breeding equilibrium during which some "equilibrium ΔF " may ages or for different purposes. If X_q is the number of exist. Second, the derivation using the probability of individuals with a lifetime breeding profile categorized homozygosity for an assumed allele is of value since the by *q*, then the approximation will be proof of Wray and Thompson (1990) is heavily based *ⁱ*(*q*)], (14) upon the properties of the numerator relationship matrix. Third, it extends the result to incorporate nonrandom mating, although the result was given without proof where the expectations are over the squared contribuby Woolliams and Thompson (1994). Caballero and tions from a single cohort and are conditional on selec-Hill (1992) noted that the result of Wray and Thomp- tion in category *q.* Although the approach is different, son (1990) was a poor predictor of ΔF with nonrandom Equation 14 is equivalent to the result of Hill (1972, mating and it is now clear why this was so. 1979) when random selection and random mating is

be in equilibrium (which will imply the genetic variance rate of inbreeding is related to the sum of squared being selected upon is in equilibrium) this does not lifetime contributions irrespective of selection and nonimply that equilibrium values of ω and ΔF for the alleles random mating. defined in the arbitrary base are immediately attained. Equation 4, using appendix a, assumes that these pa-

rameters were in equilibrium for the Mendelian sam-

pling in generation 2. However, the following argument

CONTRIBUTIONS shows that this does not affect the result. Assume the of generations following (*i.e.*, up to attainment of equi- *squared contributions were available. However,* $E[r_i^2]$ *=* librium) there will be terms of the form $\delta C_u(t)$ in Equa-

then the structure of the preceding proof holds. The relationship between the variance of the long-term conreduction in the variance of the Mendelian sampling tributions and their expectations, which will then permit term over initial cohorts, before an equilibrium $\Delta F/$ development of general methods for the prediction of unit time is established, is not straightforward since it will depend upon the age structure of the population; eneed to assume random mating and is developed by but the previous argument used to overcome deviations conditioning on the selective advantage(s), *si*, for an from equilibrium can be applied. However, one distinc- ancestor. The selective advantage(s) of the ancestor, if

 $r_i = 0$ for an unselected ancestor, Equation 12 can also tion in overlapping generations is that the base genera- $E[\Delta F] \approx \frac{1}{4}(1-\omega)(T_{\omega}E[r_{\omega}^2]+T_{\omega}E[r_{\omega}^2])$. (13) is the period of time over which the long-term contributions sum to one, since this is the period required for where T_m and T_f are the number of candidates for selec- the population to turn over a generation for those genes tion in each sex and the expectation is for a candidate destined to remain in the population in the long-term. $(i.e., it is not conditional on i being selected). (E[\Delta F]$ Woolliams *et al.* (1999) show this genetic generation is used in Equations 12 and 13, rather than simply ΔF , interval is different from the average age of the parents to emphasize that the result is an expectation over repli- when there are selection advantages between groups cate populations.) (see also Bijma and Woolliams 1999). To balance (8) This result was obtained for $\omega = 0$ by Wray and there is a need to add and subtract terms of magnitude ⁄ $\Delta^2_2C_0(t)$ ($\Delta F/{\rm generation}$) or equivalently $\frac{1}{2}C_0(t)L$ ($\Delta F/{\rm s}$ ⁄ ⁄ $\mathcal{C}_2 CL]^{-1}$, and

$$
E[\Delta F/\text{unit time}] \approx \frac{1}{4}(1-\omega) \sum_{\text{categories } q} X_q E[r_{i(q)}^2], \qquad (14)
$$

Even though the development of the pedigree may assumed. However, Equation 14 clearly shows that the

Since ΔF is proportional to $E[r_i^2]$, the task of predictequilibrium conditions have not been attained by gener- ing ΔF in selected populations would be made easier if ation 2; then for this generation plus a small number tractable and general methods for calculating expected $\sigma_i^2 + \sigma_i^2$ and consequently there is a need to predict tion 4 and $\delta C_u(t-1)$ in Equation 5. Providing *t* is both the mean and variance of the contributions. Comsufficiently large compared to the period of attainment, monly, the prediction of means is a simpler task than the these terms will cancel in Equation 6 since *Cu*(*t*) is a prediction of variances. General methods for predicting convergent series. Thus Equations 10–13 will hold for expected long-term contributions in selected populathe equilibrium values of ω and ΔF . tions have been developed by Woolliams *et al.* (1999). **Overlapping generations:** If ΔF is taken per unit time The objective of the following section is to obtain a $E[r_i^2]$ and consequently for ΔF . The relationship will

tions. The proof uses the result $E[r_i^2] = E_s[r_z^2]$ $E_s[\mu_i^2] + E_s[\sigma_i^2]$, where $\mu_i = E[r_i|s_i]$ and $\sigma_i^2 = Var[r_i|s_i]$, equal to $\frac{1}{2}E_s[r_i^2|s_i]$, since $E_s[\theta_{n,i}] = 2$. Therefore, and the subscript *s* on the *E* indicates that the expectation is being taken over the selective advantages.

Monoecious population: The proof is simplest in the which leads to the result that case of a monoecious diploid population of X parents in discrete generations without selfing. Random mating is assumed ($\omega = 0$). Extension to overlapping genera-

full-sibs). Mass selection is a special case, with $b_1 = b_2 =$ vation. Prediction of $\mu_{l(0)}$ requires the prediction of $\alpha =$ $b_3 = 1$ (or any constant >0). This formulation was used $(\alpha_m, \alpha_f)^T$ and $\beta = (\beta_m^T, \beta_f^T)$. In discrete generations, (α_m, β_f^T) also by Wray *et al.* (1994) in their study of rates of α_f) = $[1/(2X_m)$, $1/(2X_f)$] always. Solutions for β are inbreeding. Every generation, the highest ranking *X*^m obtained applying the method of Woolliams *et al.* sires and X_f dams are selected as parents for the next (1999), using Bulmer's (1980) equilibrium genetic varigeneration. Each sire is mated at random to $d = X_f/X_m$ ances. A summary of equations used is given in appendams and each dam produces a total of n_0 offspring, n_m dix c. For the example $(\alpha_m, \alpha_f) = (0.0250, 0.0083)$, β = male, and n_f female, which are available for selection $(0.0447, 0.0149, 0.0130)$. in the next generation. The unselected base population *Step 2. Rates of inbreeding assuming Poisson variances:* is assumed to have a phenotypic variance of 1 with a From step 1, $\mu_{\ell(m)} = [0.0250 + 0.0447A_{\ell(m)}].$ The exheritability of h_0^2 for the selected trait. Additional notation used for the sib index is shown in Table 2. An $X_m E[\mu^2_{i(m)}] = X_m [0.0250^2 + 0.0447^2 \nu(A_{i(hs)})(1 - X_m^{-1})].$ example is given at each step and this is a selection The $(1 - X_m⁻¹)$ term accounts for variances about the scheme for $X_m = 20$, $X_f = 60$, $n_m = n_f = 4$, with index sample mean of the selected group rather than the true weights $b_1 = 1$, $b_2 = 1.5$, and $b_3 = 2$. The principal mean. parameters for this scheme are presented in Table 3 *i* The terms arising from $X_i E[\mu_i^2_{ij}]$ are calculated analofor easy reference. gously. Since the two selected advantages of the females

TABLE 2 In Wray *et al.* (1994) the selective advantages were **Genetic parameters for a population selected** based on the breeding values $A_{i(x)}$, and this approach is **with a sib index** adopted here but slightly modified. A sire *i* has one selective advantage, namely, its own breeding value plus *X* the average breeding value of its *d* mates (*i.e.*, its mate group) and this aggregate value is denoted by $A_{i(hs)}$. A $P, \overline{P}_{fs}, \overline{P}_{hs}$
 $P, \overline{P}_{fs}, \overline{P}_{hs}$
 (denoted $A_{i(fs)}$). The average breeding value of the full p_m , p_f Selection proportions for males and fe-
sib family from dam *i* is $\frac{1}{2}(A_{i(hs)} + A_{i(fs)})$. Thus, in this hierarchical scheme, $s_{i(m)} = (A_{i(hs)})$, and $s_{i(f)} = (A_{i(hs)})$, $A_{i(s)}$ ^T. The two selective advantages for a dam are inde-
pendent.
Expected long-term genetic contributions were mod-

eled following Wool liams *et al.* (1999) as $E[r_{i(0)}|s_{i(0)}] =$ dams and residual variance $\mu_{i(q)} = \alpha_q + \beta_q^T(s_{i(q)} - \bar{s}_q)$, where $s_{i(q)}$ denotes the vector of selective advantages for a selected individual of sex q expressed as a deviation from the mean of its contemporaries \bar{s}_p , β_q is the vector of regression coefficients of $r_{i(q)}$ on $s_{i(q)} - \bar{s}_q$, α_q is the mean contribution of selected parents of sex q , and ^T denotes the transpose. In the parameterization used, the mean of $A_{i(fs)}$ is always zero. To simplify the notation it is assumed that $A_{i(hs)}$ is already expressed as a deviation from the mean of the contemporary group, and so \bar{s}_q is omitted from this point onwards.

In the initial unselected base population, the phenotypic *Step 1. Prediction of expected contributions:* The prediction of expected genetic contributions is covered in detail by Woolliams *et al.* (1999). The current article only summarizes the procedure for a sib index, without deri-

APPENDIX A: THE EXPECTED MENDELIAN **SAMPLING VARIANCE**

The expected Mendelian sampling variance in generation 1 summed over all alleles in the founders can be
calculated using the following argument. For the prog-
eny of the carrier founder i^* of the allele the gene p selected from parent $i(q)$ has a Poisson distributio frequency has mean $\frac{1}{4}$, *i.e.*, half of the gene frequency $\frac{1}{2}$
in carrier (1/2) plus half of that in mate (0) with $\sigma^2 = \sigma^2$ **∕** in carrier $(\frac{1}{2})$ plus half of that in mate (0), with $\sigma_a^2 = \sigma_{i(\rho)}^2 = \frac{1}{2} \sum_{n} \theta_{n,i(\rho),p} (\eta_p + \gamma_p^2)$ ⁄ $\frac{1}{16}$. For progeny of other parents, $\sigma_a^2 = 0$. Therefore,
for a single allele, the Mendelian sampling variance is $\sigma_b^2 = \frac{1}{2}$ ⁄ for a single allele, the Mendelian sampling variance is $\sigma_{a}^{2} = n_{F}/(16X)$, where n_{F} is the number of offspring of i^* selected in generation 1, and where *X* is the total Then by taking expectations over $s_{i(q)}$ in (B6), and usnumber selected. Summing over all alleles (two per
base individual), and since the sum of the number of
offspring selected over all parents is 2X, the expected
Bijma 1999) that variance is $\frac{1}{4}$. ⁄ $\sum_{i=1}^{k}$

At generation 2 and later, with true random mating the Mendelian sampling variance will be reduced. For dioecious species this will be delayed by a generation through nonrandom mating, and in general the ex-
Thus $\mathbf{1}^T M m = \mathbf{1}^T M v$ and substitution into Equation 17 pected variance is $\frac{1}{4}(1 - \omega)(1 - \Delta F)^{n-1}$ in generation gives the result ⁄ $u > 1$, where ΔF is the rate of inbreeding among the parents. a $\Delta F = \frac{1}{2} \sum_{q} X_q E_s [\mu_{q}^2]$. $$

= $[n(n - 1)X_{q}(X_{q} - 1)]/[T(T - 1)R(p_{q}(p_{FS})], (D3)$ $E[n_{ij}(m)n_{ij}(f)] = [n^{2}X_{m}X_{i}]/[T^{2}R(p_{m}, p_{fs} p_{FS})]$ (D8)

where X_q is the total number of that sex selected and *T* is the total number of candidates, p_q the proportion selected (*i.e.*, X_q/T), and ρ_{FS} the correlation between full-sibs. $R(p, \rho)$ is the ratio $p^2/\Phi(v, v, \rho)$, where $\Phi(v, \chi) \times [n^2]$ v ; ρ) is the upper-quadrant probability that both variables of a standardized bivariate normal distribution The rationale of the term $R(p_m, p_i, \rho)$ as a ratio of probawith correlation coefficient ρ exceed *v*; *v* is defined by bilities for random selection and with correlation ρ re-
 $\Phi(\nu) = 1 - \nu$ and $\Phi(\nu)$ is the distribution function of mains unchanged but has been extended t $\Phi(\nu) = 1 - p$; and $\Phi(\nu)$ is the distribution function of mains unchanged but has been extended to the situation the standard univariate normal distribution. The ratio tion with two sexes with different selection proporti the standard univariate normal distribution. The ratio tion with two sexes with different selection proportions.
is essentially the probability of two sibs being above This ratio is calculated from Mendell and Elston is essentially the probability of two sibs being above the index truncation point when the index correlation (1974) using $R(p_m, p_i, \rho) \approx p_f/\Phi[(i_m \rho - v_i)(1 - k_m \rho^2)^{-1/2}]$, among sibs is zero (as in random selection) divided by which was found by Wray *et al.* (1994) to be the more the probability with correlation o. Burrows (1984) uses accurate implementation of their results (there are two the probability with correlation ρ . Burrows (1984) uses accurate implementation of their results (there are two
tabulated values for the coselection ratio $R(n, \rho)$, but possible implementations since the approximation tabulated values for the coselection ratio $R(p, \rho)$, but possible implementations since the approximated closely by results from asymmetric in male and female parameters). these values can be approximated closely by results from asymmetric in male and female parameters).
Mendel L and Elst on (1974): $R(n_0) = n/\Phi[(i_0 - \Phi])$ To obtain the variances and covariances conditional Mendell and Elston (1974): $R(p, p) = p/\Phi[(i p - 1]$ To obtain the variances and covariances conditional $\psi(1 - k_0^2)^{-1/2}$. This approximation is used through-
upon the selective advantage, the regression model de- ν)(1 - $k\rho^2$)^{-1/2}]. This approximation is used through-
upon the selective advantage, the regression model deout. To allow extension to two sexes we denote $R(p, \rho)$ rived for the expected number of offspring selected is by $R(p, p, \rho)$. [It seems more natural to the authors to used (see appendix c). by $R(p, p, \rho)$. [It seems more natural to the authors to used (see appendix c).
use a term equal to $1/R(p, p, \rho)$ in the formula, which Thus, for a dam family, use a term equal to $1/R(p, p, \rho)$ in the formula, which describes the proportional increase in coselection; however, we have used $R(p, p, \rho)$ to maintain continuity of

notation with Burrows (1984).]
Burrows (1984) derived the additional result to use for the variance of half-sib family sizes. In this article only paternal half-sib families are considered,

$$
E[n_{ij}(q)n_{ik}(q)] = [n^{2}X_{q}(X_{q}-1)]/[T(T-1)R(p_{p} p_{p} p_{k})],
$$
\n(D4) (D1)

where *j* and *k* are distinct mates to a common parent *i*, (D12) and $\rho_{\rm HS}$ is the correlation between half-sibs. Therefore, and for a sire family, for a sire with *d* mates,

$$
E[n_{P}(q)(n_{P}(q) - 1)] = \sum_{j} E[n_{ij}(q)(n_{ij}(q) - 1)]
$$

\n
$$
+ \sum_{j \neq k} E[n_{ij}(q)n_{ik}(q)]
$$

\n
$$
= [d(1 - n^{-1})/R(p_{p} p_{p} p_{F})]
$$

\n
$$
\times [n^{2}X_{j}(X_{j} - 1)]/[T(T - 1)].
$$

\n
$$
= \sum_{j} \sum_{j \neq k} [n_{ij}(q)n_{ik}(q)]
$$
