## Post hoc analysis of the covariance results

The inter-subject variability implied from the covariance analysis (Analysis 2) could be expressed in different ways. For example, if subjects used either the aOT or pOT networks (i.e one was mutually exclusive of the other), then we would expect a negative relationship between aOT and pOT activation across subjects. This was not the case. Instead we found that some subjects activate one network more than the other while others show strong or weak activation in both networks. We therefore categorized our subjects according to their relative activation in aOT and pOT. This allowed us to demonstrate a categorical difference in the degree to which different subject groups activated the aOT and pOT networks respectively.

Subjects were classified into four different groups according to whether their aOT or pOT activation was high (above the mean for all subjects) or low (below the mean for all subjects). The four different subgroups were: (i) Group HH who had high (H) activation in both regions (11 subjects); (ii) Group LL who had low (L) activation in both regions (12 subjects); (iii) Group HL who had high activation in aOT but low activation in pOT (9 subjects); and (iv) Group LH who had low activation in aOT but high activation in pOT (11 subjects). See Figure S1 for more details.

It was the difference between Groups HL and LH that drove the dissociation between aOT and pOT networks. Indeed, a direct comparison of the 9 subjects in Group HL and the 11 subjects in Group LH (using a two sample t-test with no regressors) confirms that Group HL activated the aOT network more than Group LH while Group LH activated the pOT network more than Group HL (see Table S1). Note that this 2 sample t-test with small subject groups is less sensitive than the covariance analysis because (i) subjects varied along a continuum of aOT versus pOT activation (rather than there being a categorical distinction between subject groups), (ii) the covariance analysis identified significant regions in aOT or pOT networks irrespective of the size of their mean main effects (whereas the results of the two sample t-test are dependent on the size of mean differences), and (iii) there were fewer degrees of freedom with the reduction of subjects (20 subjects from the original pool of 43 subjects). Nevertheless, the results of the 2-sample t-test (at p<0.01 uncorrected) support the across-subject correlation findings.

**Figure S1:** scatter plot showing the parameter estimates of aOT versus the parameter estimates of pOT. The four quadrants (HH, LL, Hl and LH) are illustrated. Each subject is represented by one black dot. The horizontal and vertical dashed lines represent the mean over subjects of the parameter estimates of aOT and pOT respectively. Correlation between aOt and pOT is indicated in the top right corner.

**Table S1:** Comparison between HL (high aOT activation but low pOT activation) and LH (low aOT activation but high pOT activation) groups. Effects of interest were reported within the regions listed in Table 2 of the manuscript. Only regions with Z-score  $\geq$  3.0 are reported.

 Table S3: Accuracy [%] and RTs [ms] of 15 subjects during reading irregular words and pseudowords.

Accuracy was 93.3% for irregular words and 94.7% for pseudowords; mean correct response time was 1299 ms ( $\pm$  389) for irregular words and 1274 ms ( $\pm$  401) for pseudowords (t(14) = 0.35, p = 0.73).
