## **SI Materials and Methods**

**Cell Culture.** The BL2 Burkitt's lymphoma cell line was cultured in RPMI medium 1640 containing 10% FCS (vol/vol), 100  $\mu$ M NEAA (Gibco), 1 mM sodium pyruvate, 100 units per mL penicillin, and 100  $\mu$ g/mL streptomycin. BL2- $\Delta$ C-AIDER cells, which are a BL2 clone harboring Jp8BdelER (Jp8Bdel fused with the hormone-binding domain of the estrogen receptor [ER]), were cultured with 0.5  $\mu$ g/mL puromycin. To activate AIDER proteins, 4-hydroxytamoxifen (4-OHT) was added to a concentration of 1  $\mu$ M.

**Microarray.** DNA was labeled according to the Affymetrix sample preparation protocol and hybridized to Human Promoter 1.0R Arrays. Slides were scanned with an Affymetrix GeneChip scanner. Six independent experiments were performed for each sample. Microarray data were analyzed using CisGenome.

**Analysis of Microarray Data.** Normalized signal intensities were generated from Affymetrix CEL files using CisGenome (1). The parameters used to detect peaks are as follows: moving average (MA) is used to combine neighboring probes, false discovery rates is estimated from permutation test, the window boundary is set to 250 bp, the MA cutoff is set to 3, the max allowable gap within a region is set to 200 bp, the max run of insignificant probes with a region is set to 5, the minimum region length is set to 150 bp, and the minimum number of significant probes within a region is set to 5. We retained only peaks where the FDR is <0.3. All probe sequences were mapped to the hg19 genome assembly.

**SOLID Sequencing.** Templated microbeads were prepared according to Applied Biosystem's standard protocol. Sequencing runs were performed on the SOLiD 3 Plus system (Applied Biosystems) under standard conditions.

Analysis of SOLiD DNA-Sequencing Data. Linkers were removed from the sequenced tags by using a custom Perl script, and the resulting tags were mapped to the human genome (assembly hg19) using the Bowtie program with standard parameters (2). Breakage points were summed over 100-bp intervals across the entire genome in 10-bp increments for each control and 4-OHT-treated replicate. Significant differences in breakage frequency were calculated using the EdgeR program (3), with background dispersion values for both conditions calculated over shifting 10,000-bp intervals. This program provided Pvalues and FDR values for each 100-bp interval, measuring the likelihood of observing the differences in breakage points across the two conditions given the selected background breakage rates. Regions with low FDR values overlapping the promoter (defined as 500 bases upstream of the RefSeq-defined transcriptional start site) and gene definitions were extracted. To increase confidence in the potential AID targets, regions with significant P values were clustered via a singlelinkage clustering procedure, which joined any regions within 1 kb of another peak on the genome. The resulting clusters of regions were then overlaid with low-FDR regions, and the most promising candidate genes containing the lowest FDR values (FDR < 0.1), high numbers of P value clusters, or both were selected for further validation testing (Table S2). This layer of additional clustering was chosen to facilitate the testing of genes with the highest likelihood of breakage. Indeed, both the MALAT1 and SNHG3 loci (Fig. S3A) displayed these patterns,

which were likely to be consistent with high levels of AID-induced cleavage activity.

Statistical Parameters of SOLiD DNA-Sequencing Data. In terms of data integrity, our technique is consistent with existing technologies. A summary of the characteristics of the sequenced libraries is provided in Table S8. The read redundancy ranges between 1.23 and 1.28; this redundancy rate is slightly higher than most ChIP-seq experiments (1.05-1.15) but much lower than other sequencing technologies. The slightly higher redundancy rates likely result from high numbers of breakages found in repeat regions (Fig. S5A). Importantly, the low redundancy values argue against problems arising from the number of cycles used, indicating the library does not suffer from amplification bias. An overview annotating the genomic locations of breakage sites in each library is also provided (Fig. S5B). The source of the discrepancies in target identification between this dataset and others instead likely stems from lack of depth. Each sequenced library covers the entire genome at roughly 0.8× coverage. Although the coverage of the as-currently undefined AID-targeted "break-ome" is not known, at present coverage levels, it appears possible to detect regions that are substantially affected by AID-induced breakage while not capturing everything that has been identified.

We have plotted the distribution of the square root of the absolute common dispersion values across the two conditions in all local genome windows which were used to approximate local background breakage rates for comparisons across samples (Fig. S5C). Very few genomic regions exceed an expected error rate of 20% in the measurements. We observe a bimodal distribution in the error rates, with the first peak corresponding to extremely low expected error (<1%) and the second peak found between  $\approx 1-20\%$ . The bimodal distribution implies that the AID breakage in a subset of genome regions is more highly reproducible relative to other regions; interestingly, this is not derived from relative expression values in the two peaks. Regardless, in either peak region the error rates are consistent with existing deep-sequencing techniques and enable robust identification of significant differences between breakage counts across conditions.

**Mutation Analysis.** To analyze SHM mutations, BL2- $\Delta$ C-AIDER cells were treated with 4-OHT (1  $\mu$ M) for 24 h, and the genomic DNA was purified by phenol:chloroform extraction. PCR was performed by using *Pyrobest* or PrimeSTAR GXL DNA polymerase (TaKaRa) with the following amplification conditions: 95 °C for 5 min, 30 cycles at 95 °C for 30 s, 58 °C for 30 s, and 68 °C for 1 min. After purification, the PCR fragments were A-tailed and cloned with the pGEM-T Easy Vector System (Promega). Nucleotide sequences were determined with the ABI PRISM 3130xl Genetic Analyzer (Applied Biosystems). Only unique mutations were counted, and the mutation frequency was calculated from the number of mutations per total bases analyzed.

**REPFIND Analysis.** Analysis with the REPFIND Web server (http:// zlab.bu.edu/repfind/form.html) used the following parameters: *P* value cutoff, 0.0001; minimum repeat length, 3; maximum repeat length, infinity; low complexity filter, on; statistical background, query sequence; order of background Markov model, 1.

**ChIP.** ChIP was performed as described (4).

PNAS PNAS

## Table S8. Summary of general features of the sequenced libraries

PNAS PNAS

Library	Total reads	Total mapped reads	Percent mapped reads	Unique mapping reads	Unique reads, %	Redundancy ratio
OHT(-) rep. 1	83,122,708	51,939,756	62.49	40,459,228	77.90	1.28
OHT(+) rep. 1	84,818,977	52,209,828	61.55	41,546,705	79.58	1.26
OHT(-) rep. 2	82,502,113	53,683,520	65.07	42,994,281	80.09	1.25
OHT(+) rep. 2	83,293,348	51,190,838	61.46	41,686,202	81.43	1.23
