

SUPPLEMENTARY DATA

METHOD S1. Design of the incomplete randomized block experiments

Each block was made of sixteen seedlings from four different maternal families (four seedlings per family). To obtain this design, we proceeded as follows. Each block was randomly assigned to a given position in the glasshouse. Next, sets of four families were randomly assigned to blocks, then seedlings from each family were assigned to each block containing that family, and finally the sixteen seedlings belonging to a block were randomly assigned positions within the block. Seedlings were submitted to daily and seasonal natural variations of irradiance. They were maintained in non-limiting water conditions (i.e., soil water content close to field capacity, i.e. around $0.20 \text{ m}^3 \text{ m}^{-3}$) throughout the experiment (i.e. 24 months) by watering the pots every second or third morning. Homogeneity of the environmental conditions in the glasshouse (i.e. air temperature, air humidity, radiation) was tested twice a year over a 3 week's period. Air temperature and humidity (average $28.6 \pm 2.2 \text{ }^\circ\text{C}$ and $72.7 \pm 8.6\%$, respectively) were recorded at three different locations in the glasshouse using a temperature and relative humidity probe (HMP45, Yaisala, Helsinki, Finland) connected to a CR10X datalogger (Campbell Scientific Inc., Logan, UT, USA). Photosynthetic photon flux density (PPFD) was measured above each block using a linear PAR ceptometer (AccuPar, Decagon Devices, Pullman, WA, USA) and compared with incident photosynthetic photon flux density outside the glasshouse. This allowed calculating a value of relative irradiance for each block and an average relative irradiance in the glasshouse, which was about $14.3 \pm 2.3 \%$ over the study period. To avoid any competition for light among the plants, pots were occasionally turned or their position swapped within the block if necessary to minimise vertical overlap of leaves between seedlings.

METHOD 2. Bayesian model of phenotypic value decomposition

Phenotypic differences among species, habitats-of-provenance and maternal families were detected using a hierarchical linear model including seed mass effects and the three levels of genetic divergence (species, provenance, and families), as shown in the 'conceptual model' figure:

For all individuals, i :

$$Y_{ijklm} \sim N(\text{mean}_{ijklm}, \tau_{\text{res}})$$

$$\text{mean}_{ijklm} = \mu + \alpha_j + \beta_k + \gamma_{kl} + \tau_{klm} + (\varphi_k \times \text{Seed mass}_i)$$

Y corresponds to the individual value for the phenotypic character. τ_{res} corresponds to residual precision (1 / “within-groups” variance) of phenotypic variations. The term α corresponds to the effect of the different years of seed sampling and culture, β corresponds to species effect, γ corresponds to provenance effect within each species (we allow each species to respond differently to soil provenance), and τ corresponds to the effect of maternal family (in terms of mother tree identity) within each species and soil of provenance. Then, the term φ is the regression coefficient between trait value and seed mass. We also defined one parameter per species in order to allow for divergent effects of seed mass variation in the two species. This coefficient may be null, suggesting that intra-specific variations in seed mass does not affect phenotypic variations.

Prior definition:

All parameters were sorted using non-informative priors:

$$\tau_{\text{res}} \sim \text{Gamma}(0.0001, 0.0001)$$

$$\mu \sim N(0.00001, 0.00001)$$

$$\text{for all year } j : \alpha_j \sim N(0.00001, 0.00001)$$

$$\text{for all species } k : \beta_k \sim N(0.00001, 0.00001)$$

$$\text{for all provenance } l \text{ (within each species } k): \gamma_{kl} \sim N(0.00001, 0.00001)$$

$$\text{for all maternal families } m \text{ (within each provenance } l \text{ and species } k): \tau_{klm} \sim N(0.00001, 0.00001)$$

$$\text{for all species } k : \varphi_k \sim N(0.00001, 0.00001)$$

The model was made identifiable by defining constraint $\sum \alpha_j = 0$ for each factor. The model was computed using 1 000 000 iterations with a burning of 100 000 and a thinning of 500. Parameters were estimates with 95% credible interval.

A parameter with 95% credible interval not overlapping 0 indicates that the phenotypic value of the group diverges to the phenotypic mean with a probability of 95%. Two groups identified by the same component (e.g. two habitats within the same species, for a given trait) are considered as different if their 95% credible intervals do not overlap.

METHOD 3. Estimation of heritability (h^2) with a Bayesian two-ways analysis of variance

Heritability was estimated at intra-specific level by estimation of ‘among-family’ exact precision.

For all individuals,

$$\text{Trait}_{ijm} \sim N(\text{mean}_{ijm}, \tau_{\text{res}})$$

$$\text{mean}_{ijm} = \mu + \alpha_j + \tau_m$$

For all years of sampling and culture,

$$\alpha_j \sim N(0, \tau_{\text{year}})$$

For all maternal families,

$$\tau_m \sim N(0, \tau_{\text{progeny}})$$

Prior definition

$$\mu \sim N(0.00001, 0.00001)$$

$$\tau_{\text{res}} \sim \text{Gamma}(0.0001, 0.0001)$$

$$\tau_{\text{years}} \sim \text{Gamma}(0.0001, 0.0001)$$

$$\tau_{\text{progeny}} \sim \text{Gamma}(0.0001, 0.0001)$$

We computed $\sigma_M^2 \sigma_P^2$ where σ_M^2 is the genetic variance “among groups” (inverse of “among groups” precision τ_M), σ_P^2 the total phenotypic variance (sum of the inverse of “among families” precision τ_M plus the inverse of “among years” precision τ_{years} , plus the inverse of residual precision τ_{res}).

The model was computed using 500 000 iterations with a burning of 2000 and a thinning from 20 to 50 depending on the different traits.

TABLE S1. Sampling size. N_{progeny} indicates the number of mother trees (maternal families) and $n_{\text{seedlings}}$ the number of seedlings used in the analysis.
