ABSTRACT

Objectives: The present study sought to assess the relationship between depressive symptomatology and resilience among HIV-infected women and to investigate whether trauma exposure (childhood trauma, other discrete lifetime traumatic events) or the presence of posttraumatic stress symptomatology mediated this relationship.

Design: Cross-sectional study.

Setting: Western Cape, South Africa.

Participants: A convenience sample of 95 HIV-infected women in peri-urban communities in the Western Cape, South Africa. All the women had exposure to moderate to severe childhood trauma as determined by the Childhood Trauma Questionnaire.

Primary and secondary outcome measures: We examined the relationship between depressive symptomatology and resilience and investigated whether trauma exposure or the presence of posttraumatic stress symptomatology mediated this relationship through the Sobel test for mediation and PLS path analysis.

Results: There was a significant negative correlation between depressive symptomatology and resilience ($p = < .01$). PLS path analysis revealed a significant direct effect between depression and resilience. On the Sobel test for mediation, distal (childhood trauma) and proximal traumatic events did not significantly mediate this association ($p = > .05$). However, posttraumatic stress symptomatology significantly mediated the relationship between depression and resilience in trauma exposed women living with HIV.

Conclusions: In the present study, higher levels of resilience resulted in lower levels of self-reported depression. Although causal inferences are not possible, this suggests that in this sample, resilience may act as protective factor against the development of clinical

1
2
3 depression. The results also indicate that posttraumatic stress symptoms (PTSS), which are
4
5 highly prevalent in HIV-infected and trauma exposed individuals and often comorbid with
6
7 depression, may further explain and account for this relationship. Further investigation is
8
9 required to determine if early identification and treatment of PTSS in this population may
10
11 ameliorate the onset and persistence of major depression.

14 15 16 17 18 **ARTICLE SUMMARY**

19 20 21 **Strengths and limitations of this study**

- 22
23
24 • This is the first study investigating the relationship between depressive symptomatology
25
26 and resilience in a sample of trauma exposed HIV-infected individuals and to find evidence
27
28 of a mediating effect of posttraumatic symptoms on this relationship
29
30
- 31
32 • Potential recall bias on the retrospective rating scales may influence the findings.
33
34
- 35
36 • The cross-sectional study design precludes causal inferences and longitudinal assessment of
37
38 this relationship is necessary.
39
40
41
42

43 44 **BACKGROUND**

45
46 In South Africa, an estimated 5.63 million individuals are infected with human
47
48 immunodeficiency virus (HIV). Of these, 3.3 million are females [1]. High rates of intimate
49
50 partner violence (IPV), rape, and childhood abuse have been reported [2-4]. Studies suggest
51
52 high rates of childhood emotional (51.9%), physical (51.1%), and sexual (41.6%) abuse in
53
54 HIV-positive individuals [5]. HIV has become a manageable chronic disease with the
55
56 increased use of highly active antiretroviral therapies (HAART). However, this chronicity is
57
58
59
60

1
2
3 coupled with an increase in the number of lifetime emotional and physical challenges faced
4
5 by infected individuals [6]. Common mental disorders such as depression and anxiety are
6
7 highly prevalent and comorbid with HIV/AIDS. Compared to the general population and
8
9 comparable HIV-negative individuals, evidence suggests that the prevalence of depression is
10
11 two to four fold higher in HIV-infected individuals [7-10]. Prevalence rates of depression in
12
13 HIV-positive individuals range from 5% to 20% across a majority of studies [11]. In South
14
15 African studies, high rates of depression and posttraumatic stress disorder (PTSD) have been
16
17 reported among HIV-infected individuals [12-16]. The most commonly reported psychiatric
18
19 disorders among HIV-positive individuals with a history of childhood maltreatment include
20
21 substance abuse, major depressive disorder, and posttraumatic stress disorder [17].
22
23
24
25

26 Research shows that childhood abuse and exposure to other traumas are among the risk
27
28 factors for the development of adult psychopathology [18-22]. However, not every
29
30 individual who experiences early life stress or other traumatic incidents will develop a
31
32 psychiatric disorder, highlighting the importance of resilience [23, 24]. Human responses to
33
34 stress and trauma differ widely. Some individuals develop psychiatric disorders, such as
35
36 PTSD and depression; others develop psychological symptoms that resolve rapidly, while
37
38 others report no symptoms in response to traumatic stress [25]. Numerous risk and
39
40 protective factors, including developmental, cognitive, psychological (e.g. personality traits,
41
42 coping style, social support) genetic, epigenetic and neurobiological (neurochemistry and
43
44 neural circuitry) mechanisms, have been shown to play a role in how individuals respond to
45
46 stress and trauma [25, 26]. Resilience is a multidimensional construct and is understood as
47
48 an individual's ability to bounce back from hardship and trauma [25]. Resilience refers to a
49
50 person's ability to adapt successfully to acute stress, trauma or more chronic forms of
51
52 adversity [24]. Resilience represents the personal qualities that enable one to thrive in the
53
54
55
56
57
58
59
60

1
2
3 face of adversity [27]. Resilience may be viewed as a measure of stress coping ability and, as
4
5 such, could be an important target of treatment in anxiety, depression, and stress reactions
6
7 [27]. However, there is relatively little awareness about resilience and its relationship to
8
9 these disorders. In non-HIV samples, traumatic experiences such as childhood maltreatment
10
11 and adult life stress, have been reported, among depressed patients, to influence treatment
12
13 response [28, 29]. In patients with PTSD, high resilience has been associated with favourable
14
15 treatment outcomes [30]. Recent data also indicates that in depressed patients resilience
16
17 contributes to more favourable treatment outcomes with the effects of resilience even
18
19 more definitive when combined with low trait anxiety [31].
20
21
22
23

24 To our knowledge, there are no studies investigating the relationship between depressive
25
26 symptomatology and resilience in a sample of trauma exposed HIV-infected individuals. In
27
28 light of this, the present study sought to examine this relationship in a sample of trauma
29
30 exposed HIV-infected women.
31
32
33

34 **METHODS**

37 **Participants**

38
39
40 The study cohort consisted of 95 HIV-positive women who were enrolled in a larger
41
42 prospective cognitive and imaging study. All the women had exposure to childhood trauma
43
44 as defined on the Childhood Trauma Questionnaire (CTQ). Eligibility criteria included:
45
46 willingness and ability to provide written informed consent, ability to read and write in
47
48 either English or Afrikaans at 5th grade level, aged between 18 and 65 years, medically well
49
50 enough to undergo neuropsychological testing and MRI scanning. Exclusions included: a
51
52 current or past history of schizophrenia, bipolar disorder or other psychotic disorders,
53
54 current substance or alcohol abuse or dependence, significant previous head injury,
55
56
57
58
59
60

1
2
3 demonstrated frank dementia on the International HIV Dementia Scale, current seizure
4
5 disorders of any cause, history of CNS infections of neoplasms, hepatitis B positive status,
6
7 and current use or use within the last month of any psychotropic medication.
8
9

10 **Procedure**

11
12
13
14 The study was approved by the ethics committee of Stellenbosch University, South Africa.
15
16 All participants were recruited by a researcher or with the help of doctors and adherence
17
18 counselors from community health care facilities in and around the Cape Town area. All
19
20 participants who consented were screened for eligibility and childhood trauma exposure
21
22 either in person at their clinic or telephonically. Those who met initial screening criteria
23
24 subsequently underwent behavioural, neuromedical, neurocognitive and neuroimaging
25
26 assessments at Stellenbosch University. Participants were reimbursed for their travel costs
27
28 to the University on two separate occasions.
29
30
31
32

33 **Measures**

34
35
36
37 Demographic and clinical characteristics

38
39
40 Age, gender, marital status, ethnicity, years of education and employment status were
41
42 captured. A comprehensive history was obtained from, and a general physical examination
43
44 conducted in, all patients. Virologic markers of disease progression (CD4 lymphocyte count
45
46 and viral loads) were obtained from blood samples.
47
48

49
50
51 Psychiatric morbidity

52
53
54 Current and lifetime psychiatric disorders were evaluated using the MINI- International
55
56 Neuropsychiatric Interview- Plus (M.I.N.I.-Plus) [32].
57
58
59
60

Depression

Participants were assessed for depressive symptomatology using the Center for Epidemiologic Studies Depression Scale (CES-D) [33]. The CES-D is a 20-item widely used self-report instrument designed to measure depressive symptomatology. The scale was specifically designed to measure depressive symptomatology in the general population, unlike previous depression scales which have been predominantly used in clinical populations. The CES-D emphasises the affective component of depressive symptomatology, namely depressed mood. Each item comprises a likert scale ranging from 0 to 3. A total score for the 20 items is obtained, with the lowest possible score being 0 and the highest possible score being 60. Higher scores are indicative of more severe depression.

Traumatic life events

Exposure to traumatic life events were assessed for using the Life Events Checklist (LEC) [34]. The LEC is a widely used measure of exposure to potentially traumatic events. It was developed in order to facilitate the diagnosis of posttraumatic stress disorder (PTSD). One of the LEC's unique features is that it enquires about various types of exposure to each potentially traumatic event. Therefore, the LEC elicits whether the participant experienced, witnessed, or learned of the traumatic event, a feature that other traumatic event measures do not possess. Participants rate their experience of each traumatic event listed on a likert scale. A total score is derived from the sum of experiencing and/or witnessing the event. Higher scores are indicative of the experience of more traumatic life events.

Posttraumatic stress symptomatology

1
2
3 Posttraumatic stress symptomatology was assessed using the Davidson Trauma Scale (DTS)
4
5 [35]. The DTS is a widely used 17-item self-report and measures symptoms of PTSD on
6
7 frequency and severity scales. The items are categorised according to the criteria set out in
8
9 the DSM-IV: criteria B (intrusive re-experiencing) criteria C (avoidance and numbness) and
10
11 criteria D (hyperarousal). For each item, the participant rates the frequency and severity
12
13 during the previous week on 5-point (0 to 4) scales, with the lowest possible score being 0
14
15 and the highest possible score being 136. Higher scores are indicative of more PTSD
16
17 symptoms.
18
19
20
21

22 Childhood trauma

23
24
25 The Childhood Trauma Questionnaire Short Form (CTQ-SF) [36], a 28-item self-report
26
27 inventory that provides valid screening for histories of abuse and neglect was administered.
28
29 It assesses five types of maltreatment including, emotional, physical, and sexual abuse, and
30
31 emotional and physical neglect. These five subscales each consist of 5 items with scores
32
33 ranging from 5 to 25. The overall trauma score ranges from 25 to 125 with higher scores
34
35 indicating higher levels of childhood trauma (score of 25-31 = no trauma, score of 41-51 =
36
37 low to moderate, 56-68 = moderate to severe, and 73-125 = severe to extreme).
38
39
40
41
42

43 Resilience

44
45
46 Resilience was assessed using the Connor Davidson Resilience Scale (CD-RISC) [27, 35]. The
47
48 CD-RISC is a self-report measure of resilience consisting of 25 items. The scale rates
49
50 participants over the past month with a total score of the CD-RISC varying from 0-100. The
51
52 items are scored on a 5 point likert scale, with higher scores reflecting higher resilience.
53
54
55
56
57

59
60

Data Analysis

Data were analysed using the Statistical Package for the Social Sciences (SPSS) for Windows, version 20.0 and Statistica, version 11.0.

Basic statistical analyses were conducted, which included descriptive statistics. Spearman correlation and multiple linear regression analyses were carried out to assess the relationship between the variables of interest.

According to Baron and Kenny (1986), a variable functions as a mediator when it meets the following conditions: (1) variations in the levels of the independent variable (IV) significantly account for variations in the mediator variable (MV) [figure 1, path *a*], (2) variations in the MV significantly account for variations in the dependent variable (DV) [figure 1, path *b*], and (3) when paths *a* and *b* are controlled for, a previous significant relation between the IV and DV is no longer significant, with the strongest demonstration of mediation occurring when path *c* (figure 1) is zero [37]. Rather than hypothesising a direct causal relationship between the IV and DV, a mediational model hypothesises that that IV influences the MV, which in turn influences the DV. In order to assess for a mediation effect, several steps were taken. Firstly, the Sobel test for mediation was conducted to assess whether childhood trauma, traumatic life events, or posttraumatic stress symptoms mediated the relationship between the dependent (depression) and independent variables (resilience). Secondly, to test for mediation, one should conduct three regression equations. Separate coefficients for each equation should be estimated and tested [37]. First, the MV should be regressed on the IV; second, the DV should be regressed on the IV; and third, the DV should be regressed on both the IV and the MV [37]. To establish mediation, the following conditions should be met: First, the IV must affect the MV in the first equation; second, the IV must be shown to

1
2
3 affect the DV in the second equation; and third, the MV must affect the DV in the third
4
5 equation. The effect of the IV on the DV should be less in the third equation than in the
6
7 second. If the IV has no effect when the MV is controlled, then this is indicative of perfect
8
9 mediation [37]. Lastly, a PLS path analysis was performed to confirm the results of the

Figure 1. Mediation model

RESULTS

Demographic characteristics of the sample

Participants were predominantly black (98.9%), Xhosa (African indigenous language) speaking (93.7%) women, with a mean age of 33.6 years (range 21-50). The mean highest level of education was 9.98 years, ranging from 5 to 14 years. The majority were single (73.7%), unemployed (70.5%), and reported a combined annual household income of less than \$1,000 (10 000 ZAR) per year (87.4%).

Clinical characteristics of the sample

The mean CD4 lymphocyte count was 438.40 cells/mm³ (range 25-1529 cells/mm³). The mean HIV viral load was 106,157.05 copies/ml, ranging from below the detectable limit to 3,200,000 copies/ml. The lower limit for detection was 40 copies/ml. The predominant

HIV clade was subtype C. Forty four (46%) of the women were on antiretroviral treatment (ARTs).

Depression, PTSD and resilience scores

The mean score on the CES-D was 17.7, with a minimum of 0 and a maximum of 60. The mean score on the DTS was 25.5, with a minimum of 0 and a maximum of 116. A total of 7 women (6.5%) met criteria for current MDD and 9 (8.4%) for recurrent MDD on the MINI-Plus. Two women (1.9%) met criteria for PTSD on the MINI-Plus. The mean score on the CD-RISC was 81.7 with a minimum of 24 and a maximum of 100, respectively.

Trauma exposure

All women reported experiencing childhood trauma. The mean score on the CTQ was in the moderate to severe range (65.5), with a minimum of 41 and a maximum of 114. However, these women were also exposed to other discrete traumas regarded as index events for the development of PTSD. The commonest traumatic life events reported included: physical assault, transport accident, fire/explosion, life-threatening illness or injury and the sudden unexpected death of a loved one. Table 1 lists all the index traumas reported in this cohort of women.

Table 1. List of traumatic life events experienced (n = 95).

<i>Index trauma (experienced or witnessed)</i>	<i>Sum (n)</i>	<i>Percentage (%)</i>
Natural disaster	15	15.8
Fire/explosion	50	52.7
Transport accident	59	62.1
Serious accident at work, home or while doing sports	23	24.2
Physical assault	69	72.6

Assaulted with a weapon	52	54.7
Sexual assault	35	36.8
Other unwanted/uncomfortable sexual experience	17	17.9
Exposure in a war zone	8	8.5
Captivity (kidnapped, abducted, held hostage)	9	9.5
A life-threatening illness or injury	47	49.5
Exposure to sudden/violent death (murder, suicide)	24	25.3
Sudden or unexpected death of someone close	43	45.2
Serious injury, harm or death you caused to someone else	12	12.7
Badly beaten by parents or guardian as a child	23	24.2
Badly beaten by a spouse or partner	34	35.8
Other life-threatening experience not listed	8	8.5

Reliability analysis

Cronbach alpha coefficients for all measures ranged from good to excellent: CTQ ($\alpha = .73$), LEC ($\alpha = .78$), DTS ($\alpha = .89$), CD-RISC ($\alpha = .94$), CES-D ($\alpha = .96$).

Correlation between variable of interest

Pearson's correlation coefficients were calculated to assess the relationship between all the variables of interest. There was a significant negative correlation between depression (CES-D) and resilience (CD-RISC) scores, $r = -0.28$, $p < 0.01$. In addition, there was a significant negative correlation between posttraumatic stress symptoms (DTS) and resilience (CD-RISC), $r = -0.23$, $p < 0.05$. These correlations suggest that higher levels of resilience resulted in lower levels of self-reported depression and posttraumatic stress symptoms. Moreover, Pearson's correlation coefficients were calculated to assess the relationship between the IV and MV, and the MV and DV. The IV and DV were significantly correlated with two of the presumed MVs, namely childhood trauma (CTQ) and posttraumatic stress symptoms (DTS).

However, traumatic life events (LEC) were not significantly correlated with either the IV or DV, suggesting that this variable is not a mediator (Table 2).

Table 2. Pearson's correlation coefficients for all variables of interest (n = 95).

Variable 1	Variable 2	Pearson r	p value
CTQ	CESD	0.23	0.02
CTQ	LEC	0.12	0.27
CTQ	DTS	-0.01	0.94
CTQ	CDRS	0.22	0.04
CESD	LEC	0.15	0.15
CESD	DTS	0.48	<0.01
CESD	CDRS	-0.28	<0.01
LEC	DTS	0.18	0.08
LEC	CDRS	-0.02	0.84
DTS	CDRS	-0.23	0.03

CDRS = Connor Davidson Resilience Scale; CES-D = Center for Epidemiologic Studies Depression Scale; DTS = Davidson Trauma Scale; CTQ = Childhood Trauma Scale; LE = Life Events Checklist.

Multiple linear regression

Multiple linear regression with depression (CES-D score) as the outcome variable revealed a significant model of 4 factors: childhood trauma ($\beta = .330$, $p = .002$), other trauma exposure ($\beta = .181$, $p = .718$), posttraumatic stress symptomatology ($\beta = .216$, $p = .000$), and resilience ($\beta = -.236$, $p = .007$), of which 3 of the 4 variables were significantly associated with depression (Table 3). This model explains 35% of the variance of depressive symptomatology ($R^2 = 0.35$). As expected, childhood trauma and posttraumatic stress symptoms contributed to depression severity while resilience appeared to reduce it.

Table 3. Regression model for depressive symptomatology (CES-D score) (n = 95).

Variable	<i>df</i>	β	SE of β	<i>p</i>	R^2	Adjusted R^2
Model	4	-	-	.000	.347	.318
Childhood trauma (CTQ)	1	.330	.101	.002		
Other trauma (LEC)	1	.181	.499	.718		
Trauma symptoms (DTS)	1	.216	.045	.000		
Resilience (CD-RISC)	1	-.236	.085	.007		

Sobel test for mediation

To assess for mediation, the Sobel test for mediation was performed. The results showed that neither childhood trauma (CTQ) nor stressful life events (LEC) significantly mediated the relationship between depression and resilience in this sample ($p > 0.05$). However, the results demonstrated that posttraumatic stress symptomatology (DTS) was a significant mediator ($p < 0.05$).

Regression analysis

To confirm whether posttraumatic stress symptomatology (MV) in fact mediated the relationship between depression (DV) and resilience (IV), three separate regression equations were conducted following the guidelines described in the data analysis section. The first regression equation showed that the IV significantly influenced the MV, $p = .027$. The second regression equation showed that the IV significantly influenced the DV, $p = .005$. The third regression equation showed that the MV significantly influenced the DV, $p = .000$. The effect of the IV on the DV was less in the third equation than in the second equation, $p = .005$ vs. $p = .049$. This is indicative of partial mediation. Posttraumatic stress symptoms

accounts for some, but not all, of the relationship between depression and resilience. Partial mediation implies that there is not only a significant relationship between the mediator and the dependent variable, but also some direct relationship between the independent and dependent variable.

PLS path analysis

The PLS path analysis revealed a significant direct effect between depression and resilience ($p < .05$). The PLS path analysis also revealed that the effects via DTS (posttraumatic stress symptoms) were also significant ($p < .05$). This implies that although there is a mediating effect, there is also evidence of a direct effect. The other presumed mediators (CTQ and LEC) were not significant ($p > .05$). See figure 2.

Figure 2. PLS path analysis for all variables of interest.

CDRS = Connor Davidson Resilience Scale; CES-D = Center for Epidemiologic Studies Depression Scale; DTS = Davidson Trauma Scale; CTQ = Childhood Trauma Scale; LE = Life Events Checklist.

DISCUSSION

In this cross-sectional study of 95 HIV-infected women, we found that childhood trauma, posttraumatic stress symptoms and resilience independently predicted depressive symptoms. Childhood trauma and posttraumatic stress symptomatology contributed to depression, while resilience appeared to mitigate it. The results demonstrated a significant association between depression and resilience in this cohort, with resilience acting as a protective buffer. Posttraumatic stress symptoms were found to mediate this relationship and accounted for some, but not all, of the relationship between depression and resilience.

A cut-off score of 16 or greater on the CES-D has been used to identify individuals at risk for clinical depression. Although, the mean score on the CES-D for this cohort was 17.7, this score is still relatively low. Results revealed a significant negative association between depression and resilience in this cohort of women, suggesting that resilience may be acting as a protective buffer against the development of clinically significant depression. The mean score on the CD-RISC was 81.7, suggesting high levels of resilience.

Childhood trauma and posttraumatic stress symptoms independently predicted depressive symptoms but other traumatic life events did not. Mediation analyses demonstrated that childhood trauma did not mediate the relationship between depression and resilience but posttraumatic stress symptoms did. This suggests that it is not the experience of trauma itself that contributes to depression per se, but the psychological manifestation thereof, in this case posttraumatic stress symptoms. A score of 40 and greater has been used to identify individuals with clinically significant PTSD. The mean score on the DTS in this cohort was substantially lower (25.5), once again highlighting the possible role of resilience in this cohort of women. This mediational model suggests that in this cohort, resilience influences

1
2
3 (reduces) posttraumatic stress symptoms, which in turn influences (reduces) depressive
4
5 symptoms. However, this is a partial mediation, suggesting that there is also evidence of a
6
7 direct link between depression and resilience. Resilience appears to act as a protective
8
9 buffer against depression, irrespective of the mediating role of posttraumatic stress
10
11 symptoms.
12
13

14
15 The finding that childhood trauma and posttraumatic stress symptoms were each associated
16
17 with depression is in keeping with other studies. Given that these women all reported early
18
19 life stress and a number of other traumatic life events, this finding was expected. HIV-
20
21 infected individuals are at risk for psychiatric disorders such as depression and PTSD [12-
22
23 16]. In the South African context, PTSD is not an uncommon disorder in individuals with
24
25 HIV/AIDS. In some cases, PTSD is secondary to the diagnosis of HIV/AIDS but in most cases it
26
27 is seen after other traumas [15]. In addition, evidence suggests that major depressive
28
29 disorder is more likely to be associated with PTSD in HIV infected individuals [15].
30
31
32

33
34 Prior studies have examined effects of resilience on adult psychopathology [20, 23] and
35
36 depressive symptom severity [38] in individuals with childhood abuse and/or other trauma
37
38 exposure. However, this is the first study, to our knowledge, to explore the relationship
39
40 between resilience and depression in a cohort of HIV-infected women with childhood
41
42 trauma and to find evidence of a mediating effect of posttraumatic symptoms on this
43
44 relationship. In light of the study findings, it is important to screen not only for depression
45
46 but also for comorbid posttraumatic stress symptoms in HIV-infected individuals and to
47
48 develop interventions that enhance resilience among these individuals.
49
50
51

52
53 The results of the present study should be interpreted in light of the study limitations,
54
55 including potential recall bias on the retrospective rating scales, the cross-sectional study
56
57
58
59
60

1
2
3 design and the potential confounding effect of comorbid psychiatric disorders. Future
4
5 studies with longitudinal assessment of this hypothesis are needed. Understanding how
6
7 resilience can be enhanced is of great importance to not only promoting coping mechanisms
8
9 but also alleviating maladaptive coping and stress responses in common mental illnesses
10
11 such as depression and PTSD [26].

ABSTRACT

Objectives: The present study sought to assess the relationship between depressive symptomatology and resilience among HIV-infected women and to investigate whether trauma exposure (childhood trauma, other discrete lifetime traumatic events) or the presence of posttraumatic stress symptomatology mediated this relationship.

Design: Cross-sectional study.

Setting: Western Cape, South Africa.

Participants: A convenience sample of 95 HIV-infected women in peri-urban communities in the Western Cape, South Africa. All the women had exposure to moderate to severe childhood trauma as determined by the Childhood Trauma Questionnaire.

Primary and secondary outcome measures: We examined the relationship between depressive symptomatology and resilience (the Connor-Davidson Resilience Scale) and investigated whether trauma exposure or the presence of posttraumatic stress symptomatology mediated this relationship through the Sobel test for mediation and PLS path analysis.

Results: There was a significant negative correlation between depressive symptomatology and resilience ($p < .01$). PLS path analysis revealed a significant direct effect between depression and resilience. On the Sobel test for mediation, distal (childhood trauma) and proximal traumatic events did not significantly mediate this association ($p > .05$). However, posttraumatic stress symptomatology significantly mediated the relationship between depression and resilience in trauma exposed women living with HIV.

Conclusions: In the present study, higher levels of resilience were associated with lower levels of self-reported depression. Although causal inferences are not possible, this suggests

1
2
3 that in this sample, resilience may act as protective factor against the development of
4
5 clinical depression. The results also indicate that posttraumatic stress symptoms (PTSS),
6
7 which are highly prevalent in HIV-infected and trauma exposed individuals and often
8
9 comorbid with depression, may further explain and account for this relationship. Further
10
11 investigation is required to determine if early identification and treatment of PTSS in this
12
13 population may ameliorate the onset and persistence of major depression.

20 **ARTICLE SUMMARY**

21 **Strengths and limitations of this study**

- 22
23
24
25
26
27 • This is the first study investigating the relationship between depressive symptomatology
28
29 and resilience in a sample of trauma exposed HIV-infected individuals and to find evidence
30
31 of a mediating effect of posttraumatic symptoms on this relationship
32
33
- 34
35 • Potential recall bias on the retrospective rating scales may influence the findings.
36
37
- 38
39 • The cross-sectional study design precludes causal inferences and longitudinal assessment of
40
41 this relationship is necessary.

BACKGROUND

In South Africa, an estimated 5.63 million individuals are infected with human immunodeficiency virus (HIV). Of these, 3.3 million are females [1]. High rates of intimate partner violence (IPV), rape, and childhood abuse have been reported [2-4]. Studies suggest high rates of childhood emotional (51.9%), physical (51.1%), and sexual (41.6%) abuse in HIV-positive individuals [5]. HIV has become a manageable chronic disease with the increased use of highly active antiretroviral therapies (HAART). However, this chronicity is coupled with an increase in the number of lifetime emotional and physical challenges faced by infected individuals [6]. Common mental disorders such as depression and anxiety are highly prevalent and comorbid with HIV/AIDS. Compared to the general population and comparable HIV-negative individuals, evidence suggests that the prevalence of depression is two to four fold higher in HIV-infected individuals [7-10]. Prevalence rates of depression in HIV-positive individuals range from 5% to 20% across a majority of studies [11]. In South African studies, high rates of depression and posttraumatic stress disorder (PTSD) have been reported among HIV-infected individuals [12-16]. The most commonly reported psychiatric disorders among HIV-positive individuals with a history of childhood maltreatment include substance abuse, major depressive disorder, and posttraumatic stress disorder [17].

Research shows that childhood abuse and exposure to other traumas are among the risk factors for the development of adult psychopathology [18-22]. However, not every individual who experiences early life stress or other traumatic incidents will develop a psychiatric disorder, highlighting the importance of resilience [23, 24]. Human responses to stress and trauma differ widely. Some individuals develop psychiatric disorders, such as PTSD and depression; others develop psychological symptoms that resolve rapidly, while others report no symptoms in response to traumatic stress [25]. Numerous risk and

1
2
3 protective factors, including developmental, cognitive, psychological (e.g. personality traits,
4 coping style, social support) genetic, epigenetic and neurobiological (neurochemistry and
5 neural circuitry) mechanisms, have been shown to play a role in how individuals respond to
6 stress and trauma [25, 26]. Resilience is a multidimensional construct and is understood as
7 an individual's ability to bounce back from hardship and trauma [25]. Resilience refers to a
8 person's ability to adapt successfully to acute stress, trauma or more chronic forms of
9 adversity [24]. Resilience represents the personal qualities that enable one to thrive in the
10 face of adversity [27]. Resilience may be viewed as a measure of stress coping ability and, as
11 such, could be an important target of treatment in anxiety, depression, and stress reactions
12 [27]. However, there is relatively little awareness about resilience and its relationship to
13 these disorders. In non-HIV samples, traumatic experiences such as childhood maltreatment
14 and adult life stress, have been reported, among depressed patients, to influence treatment
15 response [28, 29]. In patients with PTSD, high resilience has been associated with favourable
16 treatment outcomes [30]. Recent data also indicates that in depressed patients resilience
17 contributes to more favourable treatment outcomes with the effects of resilience even
18 more definitive when combined with low trait anxiety [31].

35
36
37
38
39
40
41 To our knowledge, there are no studies investigating the relationship between depressive
42 symptomatology and resilience in a sample of trauma exposed HIV-infected individuals. In
43 light of this, the present study sought to examine this relationship in a sample of trauma
44 exposed HIV-infected women.

45 46 47 48 49 50 51 **METHODS**

52 53 54 **Participants**

1
2
3 A total of 230 HIV-infected and uninfected women, with and without trauma exposure
4
5 consented to participate and were enrolled into a larger prospective cognitive and imaging
6
7 study. Of these, 95 HIV-positive women had exposure to childhood trauma as defined on
8
9 the Childhood Trauma Questionnaire (CTQ) and were included in the present study. A score
10
11 of 41 and higher on the CTQ was used as the cut-off for exposure to childhood trauma.
12
13

14 Eligibility criteria included: willingness and ability to provide written informed consent,
15
16 ability to read and write in either English or Afrikaans at 5th grade level, aged between 18
17
18 and 65 years, medically well enough to undergo neuropsychological testing and MRI
19
20 scanning. Exclusions included: a current or past history of schizophrenia, bipolar disorder or
21
22 other psychotic disorders, current substance or alcohol abuse or dependence, significant
23
24 previous head injury, demonstrated frank dementia on the International HIV Dementia
25
26 Scale, current seizure disorders of any cause, history of CNS infections of neoplasms,
27
28 hepatitis B positive status, and current use or use within the last month of any psychotropic
29
30 medication.
31
32
33
34
35

36 **Procedure**

37
38 The study was approved by the ethics committee of Stellenbosch University, South Africa.
39
40 All participants were recruited by a researcher or with the help of doctors and adherence
41
42 counselors from community health care facilities in and around the Cape Town area. All
43
44 participants who consented were screened for eligibility and childhood trauma exposure
45
46 either in person at their clinic or telephonically. Those who met initial screening criteria
47
48 subsequently underwent behavioural, neuromedical, neurocognitive and neuroimaging
49
50 assessments at Stellenbosch University. Participants were reimbursed for their travel costs
51
52 to the University on two separate occasions.
53
54

Measures

Demographic and clinical characteristics

Age, gender, marital status, ethnicity, years of education and employment status were captured. A comprehensive history was obtained from, and a general physical examination conducted in, all patients. Virologic markers of disease progression (CD4 lymphocyte count and viral loads) were obtained from blood samples.

Psychiatric morbidity

Current and lifetime psychiatric disorders were evaluated using the MINI- International Neuropsychiatric Interview- Plus (M.I.N.I.-Plus) [32].

Depression

Participants were assessed for depressive symptomatology using the Center for Epidemiologic Studies Depression Scale (CES-D) [33]. The CES-D is a 20-item widely used self-report instrument designed to measure depressive symptomatology. The scale was specifically designed to measure depressive symptomatology in the general population, unlike previous depression scales which have been predominantly used in clinical populations. The CES-D emphasises the affective component of depressive symptomatology, namely depressed mood. Each item comprises a likert scale ranging from 0 to 3. A total score for the 20 items is obtained, with the lowest possible score being 0 and the highest possible score being 60. Higher scores are indicative of more severe depression.

Traumatic life events

1
2
3 Exposure to traumatic life events were assessed for using the Life Events Checklist (LEC)
4
5 [34]. The LEC is a widely used measure of exposure to potentially traumatic events. It was
6
7 developed in order to facilitate the diagnosis of posttraumatic stress disorder (PTSD). One of
8
9 the LEC's unique features is that it enquires about various types of exposure to each
10
11 potentially traumatic event. Therefore, the LEC elicits whether the participant experienced,
12
13 witnessed, or learned of the traumatic event, a feature that other traumatic event measures
14
15 do not possess. Participants rate their experience of each traumatic event listed on a likert
16
17 scale. A total score is derived from the sum of experiencing and/or witnessing the event.
18
19 Higher scores are indicative of the experience of more traumatic life events.

21
22
23

24 25 Posttraumatic stress symptomatology 26 27

28 Posttraumatic stress symptomatology was assessed using the Davidson Trauma Scale (DTS)
29
30 [35]. The DTS is a widely used 17-item self-report and measures symptoms of PTSD on
31
32 frequency and severity scales. The items are categorised according to the criteria set out in
33
34 the DSM-IV: criteria B (intrusive re-experiencing) criteria C (avoidance and numbness) and
35
36 criteria D (hyperarousal). For each item, the participant rates the frequency and severity
37
38 during the previous week on 5-point (0 to 4) scales, with the lowest possible score being 0
39
40 and the highest possible score being 136. Higher scores are indicative of more PTSD
41
42 symptoms.
43
44
45
46
47

48 Childhood trauma 49 50

51 The Childhood Trauma Questionnaire Short Form (CTQ-SF) [36], a 28-item self-report
52
53 inventory that provides valid screening for histories of abuse and neglect was administered.
54
55 It assesses five types of maltreatment including, emotional, physical, and sexual abuse, and
56
57
58
59
60

1
2
3 emotional and physical neglect. These five subscales each consist of 5 items with scores
4
5 ranging from 5 to 25. The overall trauma score ranges from 25 to 125 with higher scores
6
7 indicating higher levels of childhood trauma (score of 25-31 = no trauma, score of 41-51 =
8
9 low to moderate, 56-68 = moderate to severe, and 73-125 = severe to extreme).
10
11

12 Resilience

13
14
15 Resilience was assessed using the Connor Davidson Resilience Scale (CD-RISC) [27, 35]. The
16
17 CD-RISC is a self-report measure of resilience consisting of 25 items. The content of the scale
18
19 reflects hardiness, control, commitment, personal or collective goals, change or stress
20
21 viewed as a challenge/opportunity, strengthening effect of stress, past successes,
22
23 recognition of limits to control, engaging the support of others, self-efficacy, optimism,
24
25 action orientation, self-esteem/confidence, adaptability, tolerance of negative affect,
26
27 problem solving skills, humour in the face of stress, patience, faith and secure bonds to
28
29 others. Examples of items include: "I am able to adapt when changes occur", "I have at least
30
31 one close and secure relationship which helps me when I am stressed", "when there are no
32
33 clear solutions to my problems, sometimes fate or God can help", "under pressure I stay
34
35 focused and think clearly", "I try to see the humorous side of things when I am faced with
36
37 problems." The scale rates participants over the past month with a total score of the CD-
38
39 RISC varying from 0-100. The items are scored on a 5 point likert scale, with higher scores
40
41 reflecting higher resilience.

51 Data Analysis

52
53
54
55 Data were analysed using the Statistical Package for the Social Sciences (SPSS) for Windows,
56
57 version 20.0 and Statistica, version 11.0.
58
59
60

1
2
3 Basic statistical analyses were conducted, which included descriptive statistics. Spearman
4
5 correlation and multiple linear regression analyses were carried out to assess the
6
7 relationship between the variables of interest.
8
9

10
11 According to Baron and Kenny (1986), a variable functions as a mediator when it meets the
12
13 following conditions: (1) variations in the levels of the independent variable (IV) significantly
14
15 account for variations in the mediator variable (MV) [figure 1, path *a*], (2) variations in the
16
17 MV significantly account for variations in the dependent variable (DV) [figure 1, path *b*], and
18
19 (3) when paths *a* and *b* are controlled for, a previous significant relation between the IV and
20
21 DV is no longer significant, with the strongest demonstration of mediation occurring when
22
23 path *c* (figure 1) is zero [37]. Rather than hypothesising a direct causal relationship between
24
25 the IV and DV, a mediational model hypothesises that that IV influences the MV, which in
26
27 turn influences the DV. In order to assess for a mediation effect, several steps were taken.
28
29 Firstly, the Sobel test for mediation was conducted to assess whether childhood trauma,
30
31 traumatic life events, or posttraumatic stress symptoms mediated the relationship between
32
33 the dependent (depression) and independent variables (resilience). Secondly, to test for
34
35 mediation, one should conduct three regression equations. Separate coefficients for each
36
37 equation should be estimated and tested [37]. First, the MV should be regressed on the IV;
38
39 second, the DV should be regressed on the IV; and third, the DV should be regressed on
40
41 both the IV and the MV [37]. To establish mediation, the following conditions should be
42
43 met: First, the IV must affect the MV in the first equation; second, the IV must be shown to
44
45 affect the DV in the second equation; and third, the MV must affect the DV in the third
46
47 equation. The effect of the IV on the DV should be less in the third equation than in the
48
49 second. If the IV has no effect when the MV is controlled, then this is indicative of perfect
50

mediation [37]. Lastly, a PLS path analysis was performed to confirm the results of the
aforementioned analyses.

RESULTS

Demographic characteristics of the sample

Participants were predominantly black (98.9%), Xhosa (African indigenous language) speaking (93.7%) women, with a mean age of 33.6 years (range 21-50). The mean highest level of education was 9.98 years, ranging from 5 to 14 years. The majority were single (73.7%), unemployed (70.5%), and reported a combined annual household income of less than \$1,000 (10 000 ZAR) per year (87.4%).

Clinical characteristics of the sample

The mean CD4 lymphocyte count was 438.40 cells/mm³ (range 25-1529 cells/mm³). The mean HIV viral load was 106,157.05 copies/ml, ranging from below the detectable limit to 3,200,000 copies/ml. The lower limit for detection was 40 copies/ml. The predominant HIV clade was subtype C. Forty four (46%) of the women were on antiretroviral treatment (ARTs).

Depression, PTSD and resilience scores

The mean score on the CES-D was 17.7, with a minimum of 0 and a maximum of 60. The mean score on the DTS was 25.5, with a minimum of 0 and a maximum of 116. A total of 7 women (6.5%) met criteria for current MDD and 9 (8.4%) for recurrent MDD on the MINI-Plus. Two women (1.9%) met criteria for PTSD on the MINI-Plus. The mean score on the CD-RISC was 81.7 with a minimum of 24 and a maximum of 100, respectively.

Trauma exposure

All women reported experiencing childhood trauma. The mean score on the CTQ was in the moderate to severe range (65.5), with a minimum of 41 and a maximum of 114. However, these women were also exposed to other discrete traumas regarded as index events for the development of PTSD. The commonest traumatic life events reported included: physical assault, transport accident, fire/explosion, life-threatening illness or injury and the sudden unexpected death of a loved one. Table 1 lists all the index traumas reported in this cohort of women.

Table 1. List of traumatic life events experienced (n = 95).

<i>Index trauma (experienced or witnessed)</i>	<i>Sum (n)</i>	<i>Percentage (%)</i>
Natural disaster	15	15.8
Fire/explosion	50	52.7
Transport accident	59	62.1
Serious accident at work, home or while doing sports	23	24.2
Physical assault	69	72.6
Assaulted with a weapon	52	54.7
Sexual assault	35	36.8
Other unwanted/uncomfortable sexual experience	17	17.9
Exposure in a war zone	8	8.5
Captivity (kidnapped, abducted, held hostage)	9	9.5
A life-threatening illness or injury	47	49.5
Exposure to sudden/violent death (murder, suicide)	24	25.3
Sudden or unexpected death of someone close	43	45.2
Serious injury, harm or death you caused to someone else	12	12.7
Badly beaten by parents or guardian as a child	23	24.2
Badly beaten by a spouse or partner	34	35.8

Other life-threatening experience not listed 8 8.5

Internal consistency

Cronbach alpha coefficients for all measures ranged from good to excellent: CTQ ($\alpha = .73$), LEC ($\alpha = .78$), DTS ($\alpha = .89$), CD-RISC ($\alpha = .94$), CES-D ($\alpha = .96$).

Correlation between variable of interest

Pearson's correlation coefficients were calculated to assess the relationship between all the variables of interest. There was a significant negative correlation between depression (CES-D) and resilience (CD-RISC) scores, $r = -0.28$, $p < 0.01$. In addition, there was a significant negative correlation between posttraumatic stress symptoms (DTS) and resilience (CD-RISC), $r = -0.23$, $p < 0.05$. These correlations suggest that higher levels of resilience resulted in lower levels of self-reported depression and posttraumatic stress symptoms. Moreover, Pearson's correlation coefficients were calculated to assess the relationship between the IV and MV, and the MV and DV. The IV and DV were significantly correlated with two of the presumed MVs, namely childhood trauma (CTQ) and posttraumatic stress symptoms (DTS). However, traumatic life events (LEC) were not significantly correlated with either the IV or DV, suggesting that this variable is not a mediator (Table 2).

Table 2. Pearson's correlation coefficients for all variables of interest (n = 95).

Variable 1	Variable 2	Pearson r	p value
CTQ	CESD	0.23	0.02
CTQ	LEC	0.12	0.27
CTQ	DTS	-0.01	0.94

CTQ	CDRS	0.22	0.04
CESD	LEC	0.15	0.15
CESD	DTS	0.48	<0.01
CESD	CDRS	-0.28	<0.01
LEC	DTS	0.18	0.08
LEC	CDRS	-0.02	0.84
DTS	CDRS	-0.23	0.03

CDRS = Connor Davidson Resilience Scale; CES-D = Center for Epidemiologic Studies Depression Scale; DTS = Davidson Trauma Scale; CTQ = Childhood Trauma Scale; LE = Life Events

Checklist.

Multiple linear regression

Multiple linear regression with depression (CES-D score) as the outcome variable revealed a significant model of 4 factors: childhood trauma ($\beta = .330$, $p = .002$), other trauma exposure ($\beta = .181$, $p = .718$), posttraumatic stress symptomatology ($\beta = .216$, $p = .000$), and resilience ($\beta = -.236$, $p = .007$), of which 3 of the 4 variables were significantly associated with depression (Table 3). This model explains 35% of the variance of depressive symptomatology ($R^2 = 0.35$). As expected, childhood trauma and posttraumatic stress symptoms contributed to depression severity while resilience appeared to reduce it.

Table 3. Regression model for depressive symptomatology (CES-D score) ($n = 95$).

Variable	df	β	SE of β	p	R^2	Adjusted R^2
Model	4	-	-	.000	.347	.318
Childhood trauma (CTQ)	1	.330	.101	.002		
Other trauma (LEC)	1	.181	.499	.718		
Trauma symptoms (DTS)	1	.216	.045	.000		
Resilience (CD-RISC)	1	-.236	.085	.007		

Sobel test for mediation

To assess for mediation, the Sobel test for mediation was performed. The results showed that neither childhood trauma [CTQ] ($z = 1.77$, $p = 0.08$) nor stressful life events [LEC] ($z = -0.19$, $p = 0.84$) significantly mediated the relationship between depression and resilience in this sample. However, the results demonstrated that posttraumatic stress symptomatology (DTS) was a significant mediator ($z = -2.03$, $p = 0.04$).

Regression analysis

To confirm whether posttraumatic stress symptomatology (MV) in fact mediated the relationship between depression (DV) and resilience (IV), three separate regression equations were conducted following the guidelines described in the data analysis section. The first regression equation showed that the IV significantly influenced the MV, ($\beta = -.226$, $p = .027$). The second regression equation showed that the IV significantly influenced the DV, ($\beta = -.283$, $p = .005$). The third regression equation showed that the MV significantly influenced the DV, ($\beta = .442$, $p = .000$). The effect of the IV on the DV was less in the third equation than in the second equation, $\beta = -.183$ ($p = .049$) vs. $\beta = -.283$ ($p = .005$). This is indicative of partial mediation. Posttraumatic stress symptoms accounts for some, but not all, of the relationship between depression and resilience. Partial mediation implies that there is not only a significant relationship between the mediator and the dependent variable, but also some direct relationship between the independent and dependent variable.

PLS path analysis

1
2
3 The PLS path analysis revealed a significant direct effect between depression and resilience
4
5 ($p < .05$). The PLS path analysis also revealed that the effects via DTS (posttraumatic stress
6
7 symptoms) were also significant ($p < .05$). This implies that although there is a mediating
8
9 effect, there is also evidence of a direct effect. The other presumed mediators (CTQ and
10
11 LEC) were not significant ($p > .05$). See figure 2.
12
13

14 15 **DISCUSSION**

16
17 In this cross-sectional study of 95 HIV-infected women, we found that childhood trauma,
18
19 posttraumatic stress symptoms and resilience independently predicted depressive
20
21 symptoms. Childhood trauma and posttraumatic stress symptomatology contributed to
22
23 depression, while resilience appeared to mitigate it. The results demonstrated a significant
24
25 association between depression and resilience in this cohort, with resilience acting as a
26
27 protective buffer. Posttraumatic stress symptoms were found to mediate this relationship
28
29 and accounted for some, but not all, of the relationship between depression and resilience.
30
31
32

33
34 A cut-off score of 16 or greater on the CES-D has been used to identify individuals at risk for
35
36 clinical depression. Although, the mean score on the CES-D for this cohort was 17.7, this
37
38 score is still relatively low. Results revealed a significant negative association between
39
40 depression and resilience in this cohort of women, suggesting that resilience may be acting
41
42 as a protective buffer against the development of clinically significant depression. The mean
43
44 score on the CD-RISC was 81.7, suggesting high levels of resilience.
45
46
47

48
49 Childhood trauma and posttraumatic stress symptoms independently predicted depressive
50
51 symptoms but other traumatic life events did not. Mediation analyses demonstrated that
52
53 childhood trauma did not mediate the relationship between depression and resilience but
54
55 posttraumatic stress symptoms did. This suggests that it is not the experience of trauma
56
57
58
59
60

1
2
3 itself that contributes to depression per se, but the psychological manifestation thereof, in
4
5 this case posttraumatic stress symptoms. A score of 40 and greater has been used to
6
7 identify individuals with clinically significant PTSD. The mean score on the DTS in this cohort
8
9 was substantially lower (25.5), once again highlighting the possible role of resilience in this
10
11 cohort of women. This mediational model suggests that in this cohort, resilience influences
12
13 (reduces) posttraumatic stress symptoms, which in turn influences (reduces) depressive
14
15 symptoms. However, this is a partial mediation, suggesting that there is also evidence of a
16
17 direct link between depression and resilience. Resilience appears to act as a protective
18
19 buffer against depression, irrespective of the mediating role of posttraumatic stress
20
21 symptoms.
22
23
24
25
26

27 The finding that childhood trauma and posttraumatic stress symptoms were each associated
28
29 with depression is in keeping with other studies. Given that these women all reported early
30
31 life stress and a number of other traumatic life events, this finding was expected. HIV-
32
33 infected individuals are at risk for psychiatric disorders such as depression and PTSD [12-16].
34
35 In the South African context, PTSD is not an uncommon disorder in individuals with
36
37 HIV/AIDS. In some cases, PTSD is secondary to the diagnosis of HIV/AIDS but in most cases it
38
39 is seen after other traumas [15]. In addition, evidence suggests that major depressive
40
41 disorder is more likely to be associated with PTSD in HIV infected individuals [15].
42
43 Prior studies have examined effects of resilience on adult psychopathology [20, 23] and
44
45 depressive symptom severity [38] in individuals with childhood abuse and/or other trauma
46
47 exposure. However, this is the first study, to our knowledge, to explore the relationship
48
49 between resilience and depression in a cohort of HIV-infected women with childhood
50
51 trauma and to find evidence of a mediating effect of posttraumatic symptoms on this
52
53
54
55
56
57
58
59
60

1
2
3 relationship. In light of the study findings, it is important to screen not only for depression
4
5 but also for comorbid posttraumatic stress symptoms in HIV-infected individuals and to
6
7 develop interventions that enhance resilience among these individuals.
8
9

10 The results of the present study should be interpreted in light of the study limitations,
11
12 including potential recall bias on the retrospective rating scales, the cross-sectional study
13
14 design and the potential confounding effect of comorbid psychiatric disorders. In addition,
15
16 no data on non-traumatic everyday stressful life events were captured.
17
18
19

20 Future studies with longitudinal assessment of this hypothesis are needed. Understanding
21
22 how resilience can be enhanced is of great importance to not only promoting coping
23
24 mechanisms but also alleviating maladaptive coping and stress responses in common
25
26 mental illnesses such as depression and PTSD [26].

ABSTRACT

Objectives: The present study sought to assess the relationship between depressive symptomatology and resilience among HIV-infected women and to investigate whether trauma exposure (childhood trauma, other discrete lifetime traumatic events) or the presence of posttraumatic stress symptomatology mediated this relationship.

Design: Cross-sectional study.

Setting: Western Cape, South Africa.

Participants: A convenience sample of 95 HIV-infected women in peri-urban communities in the Western Cape, South Africa. All the women had exposure to moderate to severe childhood trauma as determined by the Childhood Trauma Questionnaire.

Primary and secondary outcome measures: We examined the relationship between depressive symptomatology and resilience ([the Connor-Davidson Resilience Scale](#)) and investigated whether trauma exposure or the presence of posttraumatic stress symptomatology mediated this relationship through the Sobel test for mediation and PLS path analysis.

Results: There was a significant negative correlation between depressive symptomatology and resilience ($p < .01$). PLS path analysis revealed a significant direct effect between depression and resilience. On the Sobel test for mediation, distal (childhood trauma) and proximal traumatic events did not significantly mediate this association ($p > .05$). However, posttraumatic stress symptomatology significantly mediated the relationship between depression and resilience in trauma exposed women living with HIV.

Conclusions: In the present study, higher levels of resilience [resulted in were associated with](#) lower levels of self-reported depression. Although causal inferences are not possible, this

1
2
3 suggests that in this sample, resilience may act as protective factor against the development
4
5 of clinical depression. The results also indicate that posttraumatic stress symptoms (PTSS),
6
7 which are highly prevalent in HIV-infected and trauma exposed individuals and often
8
9 comorbid with depression, may further explain and account for this relationship. Further
10
11 investigation is required to determine if early identification and treatment of PTSS in this
12
13 population may ameliorate the onset and persistence of major depression.

20 **ARTICLE SUMMARY**

21 **Strengths and limitations of this study**

- 22
23
24
25
26
27 • This is the first study investigating the relationship between depressive symptomatology
28
29 and resilience in a sample of trauma exposed HIV-infected individuals and to find evidence
30
31 of a mediating effect of posttraumatic symptoms on this relationship
32
33
- 34
35 • Potential recall bias on the retrospective rating scales may influence the findings.
36
37
- 38
39 • The cross-sectional study design precludes causal inferences and longitudinal assessment of
40
41 this relationship is necessary.
42
43
44

45 **BACKGROUND**

46
47 In South Africa, an estimated 5.63 million individuals are infected with human
48
49 immunodeficiency virus (HIV). Of these, 3.3 million are females [1]. High rates of intimate
50
51 partner violence (IPV), rape, and childhood abuse have been reported [2-4]. Studies suggest
52
53 high rates of childhood emotional (51.9%), physical (51.1%), and sexual (41.6%) abuse in
54
55 HIV-positive individuals [5]. HIV has become a manageable chronic disease with the
56
57
58
59
60

1
2
3 increased use of highly active antiretroviral therapies (HAART). However, this chronicity is
4
5 coupled with an increase in the number of lifetime emotional and physical challenges faced
6
7 by infected individuals [6]. Common mental disorders such as depression and anxiety are
8
9 highly prevalent and comorbid with HIV/AIDS. Compared to the general population and
10
11 comparable HIV-negative individuals, evidence suggests that the prevalence of depression is
12
13 two to four fold higher in HIV-infected individuals [7-10]. Prevalence rates of depression in
14
15 HIV-positive individuals range from 5% to 20% across a majority of studies [11]. In South
16
17 African studies, high rates of depression and posttraumatic stress disorder (PTSD) have been
18
19 reported among HIV-infected individuals [12-16]. The most commonly reported psychiatric
20
21 disorders among HIV-positive individuals with a history of childhood maltreatment include
22
23 substance abuse, major depressive disorder, and posttraumatic stress disorder [17].
24
25
26
27

28
29 Research shows that childhood abuse and exposure to other traumas are among the risk
30
31 factors for the development of adult psychopathology [18-22]. However, not every
32
33 individual who experiences early life stress or other traumatic incidents will develop a
34
35 psychiatric disorder, highlighting the importance of resilience [23, 24]. Human responses to
36
37 stress and trauma differ widely. Some individuals develop psychiatric disorders, such as
38
39 PTSD and depression; others develop psychological symptoms that resolve rapidly, while
40
41 others report no symptoms in response to traumatic stress [25]. Numerous risk and
42
43 protective factors, including developmental, cognitive, psychological (e.g. personality traits,
44
45 coping style, social support) genetic, epigenetic and neurobiological (neurochemistry and
46
47 neural circuitry) mechanisms, have been shown to play a role in how individuals respond to
48
49 stress and trauma [25, 26]. Resilience is a multidimensional construct and is understood as
50
51 an individual's ability to bounce back from hardship and trauma [25]. Resilience refers to a
52
53 person's ability to adapt successfully to acute stress, trauma or more chronic forms of
54
55
56
57
58
59
60

adversity [24]. Resilience represents the personal qualities that enable one to thrive in the face of adversity [27]. Resilience may be viewed as a measure of stress coping ability and, as such, could be an important target of treatment in anxiety, depression, and stress reactions [27]. However, there is relatively little awareness about resilience and its relationship to these disorders. In non-HIV samples, traumatic experiences such as childhood maltreatment and adult life stress, have been reported, among depressed patients, to influence treatment response [28, 29]. In patients with PTSD, high resilience has been associated with favourable treatment outcomes [30]. Recent data also indicates that in depressed patients resilience contributes to more favourable treatment outcomes with the effects of resilience even more definitive when combined with low trait anxiety [31].

To our knowledge, there are no studies investigating the relationship between depressive symptomatology and resilience in a sample of trauma exposed HIV-infected individuals. In light of this, the present study sought to examine this relationship in a sample of trauma exposed HIV-infected women.

METHODS

Participants

A total of 230 HIV-infected and uninfected women, with and without trauma exposure consented to participate and were enrolled into a larger prospective cognitive and imaging study. Of these, 95 HIV-positive women had exposure to childhood trauma as defined on the Childhood Trauma Questionnaire (CTQ) and were included in the present study. A score of 41 and higher on the CTQ was used as the cut-off for exposure to childhood trauma.

Eligibility criteria included: willingness and ability to provide written informed consent, ability to read and write in either English or Afrikaans at 5th grade level, aged between 18

1
2
3 and 65 years, medically well enough to undergo neuropsychological testing and MRI
4
5 scanning. Exclusions included: a current or past history of schizophrenia, bipolar disorder or
6
7 other psychotic disorders, current substance or alcohol abuse or dependence, significant
8
9 previous head injury, demonstrated frank dementia on the International HIV Dementia
10
11 Scale, current seizure disorders of any cause, history of CNS infections of neoplasms,
12
13 hepatitis B positive status, and current use or use within the last month of any psychotropic
14
15 medication.
16
17
18
19

20 Procedure

21
22
23 The study was approved by the ethics committee of Stellenbosch University, South Africa.
24
25 All participants were recruited by a researcher or with the help of doctors and adherence
26
27 counselors from community health care facilities in and around the Cape Town area. All
28
29 participants who consented were screened for eligibility and childhood trauma exposure
30
31 either in person at their clinic or telephonically. Those who met initial screening criteria
32
33 subsequently underwent behavioural, neuromedical, neurocognitive and neuroimaging
34
35 assessments at Stellenbosch University. Participants were reimbursed for their travel costs
36
37 to the University on two separate occasions.
38
39
40
41
42

43 Measures

44 Demographic and clinical characteristics

45
46
47 Age, gender, marital status, ethnicity, years of education and employment status were
48
49 captured. A comprehensive history was obtained from, and a general physical examination
50
51 conducted in, all patients. Virologic markers of disease progression (CD4 lymphocyte count
52
53 and viral loads) were obtained from blood samples.
54
55
56
57
58
59
60

Psychiatric morbidity

Current and lifetime psychiatric disorders were evaluated using the MINI- International Neuropsychiatric Interview- Plus (M.I.N.I.-Plus) [32].

Depression

Participants were assessed for depressive symptomatology using the Center for Epidemiologic Studies Depression Scale (CES-D) [33]. The CES-D is a 20-item widely used self-report instrument designed to measure depressive symptomatology. The scale was specifically designed to measure depressive symptomatology in the general population, unlike previous depression scales which have been predominantly used in clinical populations. The CES-D emphasises the affective component of depressive symptomatology, namely depressed mood. Each item comprises a likert scale ranging from 0 to 3. A total score for the 20 items is obtained, with the lowest possible score being 0 and the highest possible score being 60. Higher scores are indicative of more severe depression.

Traumatic life events

Exposure to traumatic life events were assessed for using the Life Events Checklist (LEC) [34]. The LEC is a widely used measure of exposure to potentially traumatic events. It was developed in order to facilitate the diagnosis of posttraumatic stress disorder (PTSD). One of the LEC's unique features is that it enquires about various types of exposure to each potentially traumatic event. Therefore, the LEC elicits whether the participant experienced, witnessed, or learned of the traumatic event, a feature that other traumatic event measures do not possess. Participants rate their experience of each traumatic event listed on a likert

1
2
3 scale. A total score is derived from the sum of experiencing and/or witnessing the event.
4

5 Higher scores are indicative of the experience of more traumatic life events.
6
7

8 Posttraumatic stress symptomatology 9

10
11 Posttraumatic stress symptomatology was assessed using the Davidson Trauma Scale (DTS)
12 [35]. The DTS is a widely used 17-item self-report and measures symptoms of PTSD on
13
14 frequency and severity scales. The items are categorised according to the criteria set out in
15
16 the DSM-IV: criteria B (intrusive re-experiencing) criteria C (avoidance and numbness) and
17
18 criteria D (hyperarousal). For each item, the participant rates the frequency and severity
19
20 during the previous week on 5-point (0 to 4) scales, with the lowest possible score being 0
21
22 and the highest possible score being 136. Higher scores are indicative of more PTSD
23
24 symptoms.
25
26
27
28
29

30 Childhood trauma 31

32
33 The Childhood Trauma Questionnaire Short Form (CTQ-SF) [36], a 28-item self-report
34
35 inventory that provides valid screening for histories of abuse and neglect was administered.
36
37 It assesses five types of maltreatment including, emotional, physical, and sexual abuse, and
38
39 emotional and physical neglect. These five subscales each consist of 5 items with scores
40
41 ranging from 5 to 25. The overall trauma score ranges from 25 to 125 with higher scores
42
43 indicating higher levels of childhood trauma (score of 25-31 = no trauma, score of 41-51 =
44
45 low to moderate, 56-68 = moderate to severe, and 73-125 = severe to extreme).
46
47
48
49
50

51 Resilience 52

53
54
55 Resilience was assessed using the Connor Davidson Resilience Scale (CD-RISC) [27, 35]. The
56

57 CD-RISC is a self-report measure of resilience consisting of 25 items. [The content of the scale](#)
58
59
60

1
2
3 reflects hardiness, control, commitment, personal or collective goals, change or stress
4
5 viewed as a challenge/opportunity, strengthening effect of stress, past successes,
6
7 recognition of limits to control, engaging the support of others, self-efficacy, optimism,
8
9 action orientation, self-esteem/confidence, adaptability, tolerance of negative affect,
10
11 problem solving skills, humour in the face of stress, patience, faith and secure bonds to
12
13 others. Examples of items include: "I am able to adapt when changes occur", "I have at least
14
15 one close and secure relationship which helps me when I am stressed", "when there are no
16
17 clear solutions to my problems, sometimes fate or God can help", "under pressure I stay
18
19 focused and think clearly", "I try to see the humorous side of things when I am faced with
20
21 problems." The scale rates participants over the past month with a total score of the CD-
22
23
24
25
26
27 RISC varying from 0-100. The items are scored on a 5 point likert scale, with higher scores
28
29 reflecting higher resilience.
30
31
32

33 **Data Analysis**

34
35
36
37 Data were analysed using the Statistical Package for the Social Sciences (SPSS) for Windows,
38
39 version 20.0 and Statistica, version 11.0.
40

41
42 Basic statistical analyses were conducted, which included descriptive statistics. Spearman
43
44 correlation and multiple linear regression analyses were carried out to assess the
45
46 relationship between the variables of interest.
47
48

49
50 According to Baron and Kenny (1986), a variable functions as a mediator when it meets the
51
52 following conditions: (1) variations in the levels of the independent variable (IV) significantly
53
54 account for variations in the mediator variable (MV) [figure 1, path *a*], (2) variations in the
55
56 MV significantly account for variations in the dependent variable (DV) [figure 1, path *b*], and
57
58
59
60

1
2
3 (3) when paths *a* and *b* are controlled for, a previous significant relation between the IV and
4
5 DV is no longer significant, with the strongest demonstration of mediation occurring when
6
7 path *c* (figure 1) is zero [37]. Rather than hypothesising a direct causal relationship between
8
9 the IV and DV, a mediational model hypothesises that that IV influences the MV, which in
10
11 turn influences the DV. In order to assess for a mediation effect, several steps were taken.
12
13 Firstly, the Sobel test for mediation was conducted to assess whether childhood trauma,
14
15 traumatic life events, or posttraumatic stress symptoms mediated the relationship between
16
17 the dependent (depression) and independent variables (resilience). Secondly, to test for
18
19 mediation, one should conduct three regression equations. Separate coefficients for each
20
21 equation should be estimated and tested [37]. First, the MV should be regressed on the IV;
22
23 second, the DV should be regressed on the IV; and third, the DV should be regressed on
24
25 both the IV and the MV [37]. To establish mediation, the following conditions should be
26
27 met: First, the IV must affect the MV in the first equation; second, the IV must be shown to
28
29 affect the DV in the second equation; and third, the MV must affect the DV in the third
30
31 equation. The effect of the IV on the DV should be less in the third equation than in the
32
33 second. If the IV has no effect when the MV is controlled, then this is indicative of perfect
34
35 mediation [37]. Lastly, a PLS path analysis was performed to confirm the results of the
36
37

Figure 1. Mediation model

RESULTS

Demographic characteristics of the sample

Participants were predominantly black (98.9%), Xhosa (African indigenous language) speaking (93.7%) women, with a mean age of 33.6 years (range 21-50). The mean highest level of education was 9.98 years, ranging from 5 to 14 years. The majority were single (73.7%), unemployed (70.5%), and reported a combined annual household income of less than \$1,000 (10 000 ZAR) per year (87.4%).

Clinical characteristics of the sample

The mean CD4 lymphocyte count was 438.40 cells/mm³ (range 25-1529 cells/mm³). The mean HIV viral load was 106,157.05 copies/ml, ranging from below the detectable limit to 3,200,000 copies/ml. The lower limit for detection was 40 copies/ml. The predominant HIV clade was subtype C. Forty four (46%) of the women were on antiretroviral treatment (ARTs).

Depression, PTSD and resilience scores

The mean score on the CES-D was 17.7, with a minimum of 0 and a maximum of 60. The mean score on the DTS was 25.5, with a minimum of 0 and a maximum of 116. A total of 7 women (6.5%) met criteria for current MDD and 9 (8.4%) for recurrent MDD on the MINI-Plus. Two women (1.9%) met criteria for PTSD on the MINI-Plus. The mean score on the CD-RISC was 81.7 with a minimum of 24 and a maximum of 100, respectively.

Trauma exposure

All women reported experiencing childhood trauma. The mean score on the CTQ was in the moderate to severe range (65.5), with a minimum of 41 and a maximum of 114. However, these women were also exposed to other discrete traumas regarded as index events for the development of PTSD. The commonest traumatic life events reported included: physical assault, transport accident, fire/explosion, life-threatening illness or injury and the sudden unexpected death of a loved one. Table 1 lists all the index traumas reported in this cohort of women.

Table 1. List of traumatic life events experienced (n = 95).

<i>Index trauma (experienced or witnessed)</i>	<i>Sum (n)</i>	<i>Percentage (%)</i>
Natural disaster	15	15.8
Fire/explosion	50	52.7
Transport accident	59	62.1
Serious accident at work, home or while doing sports	23	24.2
Physical assault	69	72.6
Assaulted with a weapon	52	54.7
Sexual assault	35	36.8
Other unwanted/uncomfortable sexual experience	17	17.9
Exposure in a war zone	8	8.5
Captivity (kidnapped, abducted, held hostage)	9	9.5
A life-threatening illness or injury	47	49.5
Exposure to sudden/violent death (murder, suicide)	24	25.3
Sudden or unexpected death of someone close	43	45.2
Serious injury, harm or death you caused to someone else	12	12.7
Badly beaten by parents or guardian as a child	23	24.2
Badly beaten by a spouse or partner	34	35.8
Other life-threatening experience not listed	8	8.5

Reliability analysis Internal consistency

Cronbach alpha coefficients for all measures ranged from good to excellent: CTQ ($\alpha = .73$), LEC ($\alpha = .78$), DTS ($\alpha = .89$), CD-RISC ($\alpha = .94$), CES-D ($\alpha = .96$).

Correlation between variable of interest

Pearson's correlation coefficients were calculated to assess the relationship between all the variables of interest. There was a significant negative correlation between depression (CES-D) and resilience (CD-RISC) scores, $r = -0.28$, $p = < 0.01$. In addition, there was a significant negative correlation between posttraumatic stress symptoms (DTS) and resilience (CD-RISC), $r = -0.23$, $p = < 0.05$. These correlations suggest that higher levels of resilience resulted in lower levels of self-reported depression and posttraumatic stress symptoms. Moreover, Pearson's correlation coefficients were calculated to assess the relationship between the IV and MV, and the MV and DV. The IV and DV were significantly correlated with two of the presumed MVs, namely childhood trauma (CTQ) and posttraumatic stress symptoms (DTS). However, traumatic life events (LEC) were not significantly correlated with either the IV or DV, suggesting that this variable is not a mediator (Table 2).

Table 2. Pearson's correlation coefficients for all variables of interest (n = 95).

Variable 1	Variable 2	Pearson r	p value
CTQ	CESD	0.23	0.02
CTQ	LEC	0.12	0.27
CTQ	DTS	-0.01	0.94

CDRS = Connor Davidson Resilience Scale; CES-D = Center for Epidemiologic Studies Depression Scale; DTS = Davidson Trauma Scale; CTQ = Childhood Trauma Scale; LE = Life Events Checklist.

Multiple linear regression

Multiple linear regression with depression (CES-D score) as the outcome variable revealed a significant model of 4 factors: childhood trauma ($\beta = .330$, $p = .002$), other trauma exposure ($\beta = .181$, $p = .718$), posttraumatic stress symptomatology ($\beta = .216$, $p = .000$), and resilience ($\beta = -.236$, $p = .007$), of which 3 of the 4 variables were significantly associated with depression (Table 3). This model explains 35% of the variance of depressive symptomatology ($R^2 = 0.35$). As expected, childhood trauma and posttraumatic stress symptoms contributed to depression severity while resilience appeared to reduce it.

Table 3. Regression model for depressive symptomatology (CES-D score) (n = 95).

Variable	df	β	SE of β	p	R^2	Adjusted R^2
Model	4	-	-	.000	.347	.318
Childhood trauma (CTQ)	1	.330	.101	.002		
Other trauma (LEC)	1	.181	.499	.718		
Trauma symptoms (DTS)	1	.216	.045	.000		
Resilience (CD-RISC)	1	-.236	.085	.007		

Sobel test for mediation

To assess for mediation, the Sobel test for mediation was performed. The results showed that neither childhood trauma [CTQ] ($z = 1.77, p = 0.08$) nor stressful life events [LEC] ($z = -0.19, p = 0.84$) significantly mediated the relationship between depression and resilience in this sample ($p > 0.05$). However, the results demonstrated that posttraumatic stress symptomatology (DTS) was a significant mediator ($z = -2.03, p = 0.04$ ~~$p < 0.05$~~).

Regression analysis

To confirm whether posttraumatic stress symptomatology (MV) in fact mediated the relationship between depression (DV) and resilience (IV), three separate regression equations were conducted following the guidelines described in the data analysis section.

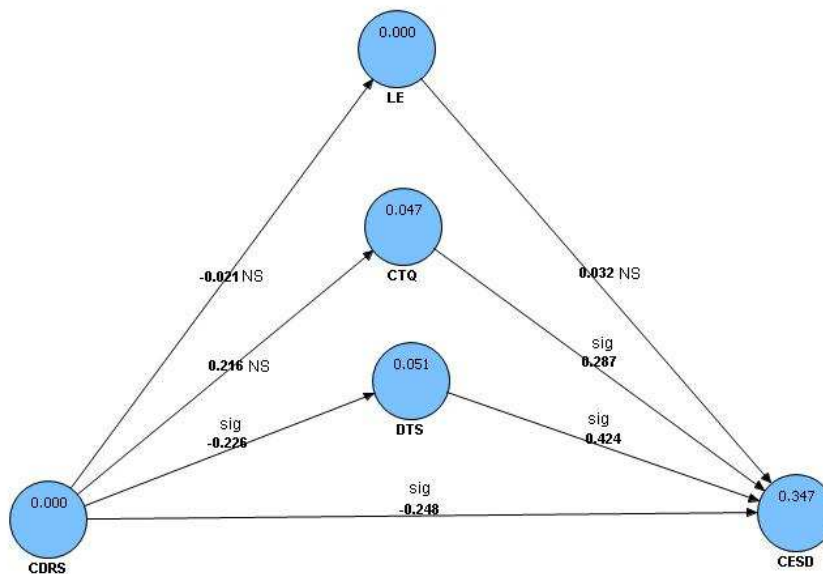

The first regression equation showed that the IV significantly influenced the MV, ($\beta = -.226, p = .027$). The second regression equation showed that the IV significantly influenced the DV, ($\beta = -.283, p = .005$). The third regression equation showed that the MV significantly influenced the DV, ($\beta = .442, p = .000$). The effect of the IV on the DV was less in the third equation than in the second equation, $\beta = -.183 (p = .049)$ vs. $\beta = -.283 (p = .005)$. This is indicative of partial mediation. Posttraumatic stress symptoms accounts for some, but not all, of the relationship between depression and resilience. Partial mediation implies that there is not only a significant relationship between the mediator and the dependent variable, but also some direct relationship between the independent and dependent variable.

PLS path analysis

The PLS path analysis revealed a significant direct effect between depression and resilience ($p < .05$). The PLS path analysis also revealed that the effects via DTS (posttraumatic stress

symptoms) were also significant ($p < .05$). This implies that although there is a mediating effect, there is also evidence of a direct effect. The other presumed mediators (CTQ and LEC) were not significant ($p > .05$). See figure 2.

Figure 2. PLS path analysis for all variables of interest.

CDRS = Connor Davidson Resilience Scale; CES-D = Center for Epidemiologic Studies Depression Scale; DTS = Davidson Trauma Scale; CTQ = Childhood Trauma Scale; LE = Life Events Checklist.

DISCUSSION

In this cross-sectional study of 95 HIV-infected women, we found that childhood trauma, posttraumatic stress symptoms and resilience independently predicted depressive symptoms. Childhood trauma and posttraumatic stress symptomatology contributed to depression, while resilience appeared to mitigate it. The results demonstrated a significant association between depression and resilience in this cohort, with resilience acting as a protective buffer. Posttraumatic stress symptoms were found to mediate this relationship and accounted for some, but not all, of the relationship between depression and resilience.

1
2
3 A cut-off score of 16 or greater on the CES-D has been used to identify individuals at risk for
4
5 clinical depression. Although, the mean score on the CES-D for this cohort was 17.7, this
6
7 score is still relatively low. Results revealed a significant negative association between
8
9 depression and resilience in this cohort of women, suggesting that resilience may be acting
10
11 as a protective buffer against the development of clinically significant depression. The mean
12
13 score on the CD-RISC was 81.7, suggesting high levels of resilience.
14
15

16
17
18 Childhood trauma and posttraumatic stress symptoms independently predicted depressive
19
20 symptoms but other traumatic life events did not. Mediation analyses demonstrated that
21
22 childhood trauma did not mediate the relationship between depression and resilience but
23
24 posttraumatic stress symptoms did. This suggests that it is not the experience of trauma
25
26 itself that contributes to depression per se, but the psychological manifestation thereof, in
27
28 this case posttraumatic stress symptoms. A score of 40 and greater has been used to
29
30 identify individuals with clinically significant PTSD. The mean score on the DTS in this cohort
31
32 was substantially lower (25.5), once again highlighting the possible role of resilience in this
33
34 cohort of women. This mediational model suggests that in this cohort, resilience influences
35
36 (reduces) posttraumatic stress symptoms, which in turn influences (reduces) depressive
37
38 symptoms. However, this is a partial mediation, suggesting that there is also evidence of a
39
40 direct link between depression and resilience. Resilience appears to act as a protective
41
42 buffer against depression, irrespective of the mediating role of posttraumatic stress
43
44 symptoms.
45
46
47
48
49

50
51
52 The finding that childhood trauma and posttraumatic stress symptoms were each associated
53
54 with depression is in keeping with other studies. Given that these women all reported early
55
56 life stress and a number of other traumatic life events, this finding was expected. HIV-
57
58
59
60

1
2
3 infected individuals are at risk for psychiatric disorders such as depression and PTSD [12-16].

4
5 In the South African context, PTSD is not an uncommon disorder in individuals with
6
7 HIV/AIDS. In some cases, PTSD is secondary to the diagnosis of HIV/AIDS but in most cases it
8
9 is seen after other traumas [15]. In addition, evidence suggests that major depressive
10
11 disorder is more likely to be associated with PTSD in HIV infected individuals [15].
12

13
14 Prior studies have examined effects of resilience on adult psychopathology [20, 23] and
15
16 depressive symptom severity [38] in individuals with childhood abuse and/or other trauma
17
18 exposure. However, this is the first study, to our knowledge, to explore the relationship
19
20 between resilience and depression in a cohort of HIV-infected women with childhood
21
22 trauma and to find evidence of a mediating effect of posttraumatic symptoms on this
23
24 relationship. In light of the study findings, it is important to screen not only for depression
25
26 but also for comorbid posttraumatic stress symptoms in HIV-infected individuals and to
27
28 develop interventions that enhance resilience among these individuals.
29
30
31

32
33 The results of the present study should be interpreted in light of the study limitations,
34
35 including potential recall bias on the retrospective rating scales, the cross-sectional study
36
37 design and the potential confounding effect of comorbid psychiatric disorders. In addition,
38
39 no data on non-traumatic everyday stressful life events were captured.
40
41
42

43
44 Future studies with longitudinal assessment of this hypothesis are needed. Understanding
45
46 how resilience can be enhanced is of great importance to not only promoting coping
47
48 mechanisms but also alleviating maladaptive coping and stress responses in common
49
50 mental illnesses such as depression and PTSD [26].
