

THE LANCET

Supplementary appendix

This appendix formed part of the original submission and has been peer reviewed.
We post it as supplied by the authors.

Supplement to: Kassebaum NJ, Bertozzi-Villa A, Coggeshall MS, et al. Global, regional, and national levels and causes of maternal mortality during 1990–2013: a systematic analysis for the Global Burden of Disease Study 2013. *Lancet* 2014; published online May 2. [http://dx.doi.org/10.1016/S0140-6736\(14\)60696-6](http://dx.doi.org/10.1016/S0140-6736(14)60696-6).

Appendix to Global, regional, and national levels and causes of maternal mortality during 1990-2013: a systematic analysis for the Global Burden of Disease Study 2013

This appendix provides more methodological detail on the maternal mortality estimation process, details on DisMod-MR 2.0 implementation, and country tables of numbers of deaths for five-year age-groups from 1990 to 2013.

1. Supplemental Methods: Maternal Mortality Estimation

1.1 Data

Appendix Table 1 provides the sources of data used for each country for computation of the MMR. These have been identified through multiple mechanisms. As part of the GBD 2013, we systematically collate vital registration data reported by countries directly on their websites or through reports and reported to the World Health Organisation. Through the network of collaborators working on the GBD 2013 various other national sources have been identified and included in the study. 73 separate country surveys released up through March 1st 2014 have been analysed. Where microdata have not been reported, we have used results in DHS reports. We have searched websites, the Global Health Data Exchange and international compendiums such as IPUMS for census data that included questions on pregnancy related death. We updated the literature reviews conducted by Hogan et al and Lozano et al. We identified country-specific maternal mortality studies using the country name and “maternal mortality” or “maternal death” or “MMR” in PubMed. This search produced 793 results. The results were screened by title and abstract. After this screening a total of 88 articles were obtained in full text format for further review. Of those reviewed, 40 were excluded as not having relevant data to inform mortality estimation and 48 were extracted for inclusion in the database. A flow chart of this review is shown in Appendix Figure 1.

Appendix Table 2 tabulates all ICD-9 and ICD-10 codes as assigned to maternal conditions. Of note, ICD-10 but not ICD-9 includes late maternal deaths between 6 weeks and 1 year after termination.¹ MDG guidance for cross-country comparisons of the MMR recommends that all HIV-related deaths during pregnancy or within 6 weeks should be included in the MMR but the UN group estimating maternal mortality uses only 50% of these deaths in their estimation.²⁻⁴ For vital registration and verbal autopsy data, maternal deaths are often misclassified as other underlying causes. In the GBD 2013, deaths assigned to causes that are unlikely to be underlying causes of death are reassigned using standardised algorithms.⁵ The causes of death that are in part re-assigned to maternal causes are shown in Appendix Table 3.⁶ DHS and RHS micro-data on sibling deaths that were pregnancy-related were re-analysed by single year using Gakidou-King weights to deal with potential survivor bias.⁷ Where different DHS surveys provided data on reproductive aged deaths and the number that were pregnancy related for the same year, we have pooled results for that year to reduce stochastic measurement error. To deal with problems of zero counts in vital registration or sibling histories for a given age-group in a given year, we use a Bayesian noise reduction algorithm. For this algorithm, we assume a normal prior and a normal data likelihood. We estimate the normal prior for a given country series of data such as vital registration for a revision of the ICD or sequence of DHS surveys in a country by estimating a negative binomial for the fraction of deaths in each age-group due to maternal causes with dummy variables for age and year. These regressions are country specific so borrowing strength over age is only within a data type in a country. The variance of the prior, τ^2 , is estimated from the negative binomial regression taking into account the variance-covariance matrix of the regression coefficients. For the data variance, we use the Wilson approximation which provides an estimate of σ^2 even in cases with a zero count of maternal deaths. The posterior estimate for each data points is

$$\text{Mean} = \left(\frac{\tau^2}{\tau^2 + \sigma^2} X + \frac{\sigma^2}{\tau^2 + \sigma^2} \mu \right)$$
$$\text{Variance} = \left(\frac{\tau^2 \sigma^2}{\tau^2 + \sigma^2} \right)$$

Where X is the mean of the data and μ is the mean of the prior. This approach to noise reduction avoids the problem that zero counts in a ln rates model or a logit cause fraction model will be dropped from the regression and lead to upward bias in the estimates. This is particularly important in two settings: high-income countries with small numbers of maternal deaths and in the analysis of sibling history data where for any given age-group in any given year the number of deaths reported in the survey that are pregnancy-related or the number of deaths from all causes in that age group may be small.

1.2 Modeling

Following Lozano et al and the GBD 2010, we use CODEm to model maternal mortality.^{8,9} The Cause of Death Ensemble Model (CODEm) is based on five general principles: identifying all available data, maximising the comparability and quality of the dataset, developing a diverse set of plausible models, assessing the predictive validity of each plausible individual model and of ensemble models, and choosing the model or ensemble model with the best performance in out-of-sample predictive analysis.¹⁰ Specifically, CODEm explores a large variety of possible models to estimate trends in causes of death. Possible models are identified using a covariate selection algorithm that yields many plausible combinations of covariates which are then run through four model classes. The model classes include mixed effects linear models and spatiotemporal GPR models for cause fractions and death rates. All models for each cause of death are then assessed using out-of-sample predictive validity and combined into an ensemble with optimal out-of-sample predictive performance.

We first identified a range of plausible covariates for maternal conditions based on the published literature. We divided these covariates into three groups based on the strength of epidemiological evidence: 1) Level 1 covariates for which there is strong evidence and a biologically plausible pathway, 2) Level 2 covariates for which there is some evidence but with a less direct causal pathway, and 3) Level 3 covariates where there is general correlation evidence for a relationship as observed in previous time series or cross-sectional studies. Appendix Table 4 lists the candidate covariates, priors, and levels for the overall maternal conditions CODEm model based on physician judgment and literature review of risk factors related to maternal conditions.

For a covariate to be included, we needed to have a comparable, complete time series for 1980 - 2010.

Transformations were performed based on the observed relationship between rates or cause fractions and the covariate of interest untransformed or transformed – if the relationship between the transformed covariate and the rate or cause fraction was more linear than the relationship between the untransformed covariate, the transformation was included. We used the natural log transformation of total fertility rate, neonatal death rate, and lag-distributed income as the result of such analyses. On the basis of this published work and previous theory, we selected age-specific fertility rate (ASFR), log transformed total fertility rate, in-facility delivery, skilled birth attendance, antenatal care visit coverage, education, HIV prevalence, log-transformed neonatal death rate, malnutrition levels, log transformed lag-distributed income (LDI) per capita and health system access (an aggregate measure of hospital beds per capita, in-facility deliveries, vaccination coverage, and other health system indicators produced by IHME).^{11–15}

In the first step, we run regressions for all possible combinations of Level 1 covariates. We run regressions for models where the dependent variable is the rate in logarithmic scale by age and models where the dependent variable is logit cause fraction by age. All models, where the signs for all covariates in that model are in the expected direction and the coefficient is significant at the $p < .05$ level, are retained. Level two and three covariates are then added to these models using a forward stepwise technique which is not order dependent. This is achieved by starting the forward stepwise evaluation for each base model over for each category two covariate. Models which are subsets of other models at levels two or three were dropped. A total of 325 unique combinations of covariates (114 for cause fractions, 211 for death rates) were kept where the coefficient for a covariate was significant at the $p < 0.05$ level and in the expected direction. Counting the covariates' being run as both simple mixed effects and spatiotemporal models, this resulted in a total pool of 650 retained component models, out of 15 312 component models tested.

As per Lozano et al, the ability of each of these models to make accurate predictions is formally evaluated.⁸ We created 50 train-test-test splits. For each of these datasets, we randomly assign 70% of the data to the train set, 15% to the test 1 set, and the last 15% to test 2. The assignment of the data to train and test is implemented so that the pattern of holding out the data for the test datasets mimics the pattern of missingness in the full dataset. For each train dataset, we re-estimate each of the proposed models including both the linear model and the spatial-temporal model. We use the results of the models estimated on the training data alone to predict for the first test set. The test data have not been included in the model estimation; the performance of each model is therefore being evaluated out-of-sample. In this way, the out-of-sample predictions for the test set are a fair test of how each model will perform for maternal mortality where the data are sparse or missing.

Predictive validity was evaluated using three metrics. First, we evaluated how well each model predicts age-specific death rates using the RMSE of the natural log of the death rate. Log death rates are comparable across age-groups so that we were able to pool results from model performance across age groups with quite different underlying rates. Second, we also want models that predict accurate trends. To do this, for the test data, we compared the predicted slope for every time interval from 1 to 5 years and compared it to the slope from the held out data. We computed the RMSE for the predicted slope. Finally, we also wanted models that generate plausible prediction intervals so we computed the percent of the data in the test set included in the 95% prediction interval. The prediction interval was based both on the uncertainty in the predicted death rate and the data variance for each observation.

Following Lozano et al, the best overall results in terms of RMSE and trend were yielded by the ensemble model with a Psi value of 1.22.⁸ This value of Psi results in draws ranging from 180 for the top performing model to 0 for the worst performer, as detailed in Appendix Table 5. For comparison it also shows the results for the best single model. The best component model was a spatiotemporal model on the logit of the cause fractions, with education (years per capita), total fertility rate (log-transformed) and lag distributed income per capita (log-transformed) as the component covariates. The ensemble model has slightly better predictive validity on both RMSE and the trend test, particularly out-of-sample. In addition, the coverage of the ensemble model is larger than that of the component model. This finding is in line with the published literature on ensemble models which in general tend to have more accurate uncertainty intervals. We should note, however, that the coverage of the uncertainty interval is in excess of 98.3% suggesting that we have overestimated uncertainty intervals.

Models were initially run with no outliers marked. Based on the estimates produced by these initial models and corresponding combined RMSE and trend test scores from that ensemble model, we carefully examined all data from each site-year to look for outliers. Criteria for considering data to be outliers were as follows: 1) The source reported maternal deaths systematically and significantly lower than other data sources for the same site-year; 2) Individual data points that, because they were the sole data from that site-year, were seen to impart obvious inconsistencies in time or age trend to the model; and 3) Data from selected age groups or years where despite the VR and DHS smoothing algorithms had implausible cause fractions or death rates.

1.3 Age-Specific Fertility Rate Estimation, ages 10-14

Age-specific fertility rate estimates were available from the United Nations Population Division (UNPOP) for ages 15-49. To estimate ASFR for the 10-14 age group, we set fertility in ages 5-9 equal to 0. Then fit country-year specific local polynomials of degree 1 with a Gaussian kernel on fertility rate across ages.¹⁶ We then used a direct plug-in method to choose the bandwidth and if this fails to produce a bandwidth estimate, set the bandwidth equal to 2.¹⁷ We used the resulting estimates for ages 10-14 only and retain the original point estimates for the other ages. If this local polynomial procedure results in negative ASFR, then we instead use a linear interpolation between the nearest ages. After all of this, we adjust ASFR for ages 10-14 by adjusting for menarchal age as determined by three recent studies.¹⁸⁻²⁰

1.4 HIV Correction

As noted in the body of the text, we have made no changes to the approach for dealing with misclassification of maternal deaths in vital registration data. We have, however, modified the method used for estimating the number of maternal deaths associated with HIV. Many studies have failed to find increased mortality in HIV+ pregnant mothers, but those who have advanced HIV are known to have increased baseline mortality. Previously we have not distinguished between deaths in HIV+ women that were caused by pregnancy and those for which the pregnancy was incidental to their death. In order to more explicitly quantify the contribution of pregnancy to death in HIV+ women, and therefore more accurately estimate the maternal death count, we completed two additional analyses. First, we determined the population attributable fraction (PAF) of HIV to pregnancy-related death. Second, we determined the proportion of pregnancy-related deaths in HIV-positive persons that are aggravated by pregnancy and are therefore by definition maternal deaths.

$$PAF = \frac{p * (RR - 1)}{1 + p * (RR - 1)}$$

Where *PAF* is the population attributable fraction, *p* denotes the prevalence of HIV in pregnancy, and RR is relative risk of mortality in HIV+ vs HIV- pregnant females.

For the first part of the analysis, we used the paper published by Calvert and Ronsmans to identify sources that could inform Step 1 of our HIV-correction analysis. We independently reviewed each of the component studies in Calvert and Ronsmans' review and extracted data directly, not from the systematic review paper. We only identified one additional study that was not used in Calvert and Ronsmans' analysis. We have, however, not used all the studies included in that review. Specific details are as follows: 1) Figueroa-Damian, et.al was excluded for not including any postpartum deaths at all. 2) In the case of Ryder, et. al. and Zvandasara, et.al. we excluded those deaths > 12 months after delivery. 3) We excluded the results from Chilongozi, et. al. from the site that did not include any HIV negative patients. 4) Leroy, et.al. was not in the bibliography. We could not locate it for review so it was excluded. 5) Kourtis et. al. was extracted with adjustment of the denominator based on the average number of hospitalisations per delivery in each group. 6) Ticconi, et. al. was excluded for being both non-representative and including subgroup data from mothers with malaria infection. A total 21 sources were included in our analysis of the increased mortality risk of HIV+ versus HIV- women in pregnancy.²¹ We performed DerSimonian-Laird random effects meta-analysis to derive a pooled estimate of RR of death during pregnancy given HIV positivity.²² The pooled effect size was 6·40 (95% UI 3·98 – 10·29) which was then used to calculate an HIV PAF for each country, age group and year. Prevalence of HIV in pregnancy estimates came from the UNAIDS Spectrum database, which incorporates observed age-dependent differences in fertility amongst HIV positive women to predict HIV prevalence in pregnancy. Spectrum predicts HIV-positive 15-19 year olds have fertility of 1·2 times that of HIV-negative. For ages 20-24 the ratio is 0·76, decreasing eventually to 0·47 in 45–49 year olds.

The country-year-age group-specific PAF was applied to the entire envelope of maternal deaths that was estimated by CODEm. In order to determine the proportion of those HIV-related deaths that were attributable to maternal causes, we performed a second systematic literature review. This time we sought evidence for the excess mortality risk of pregnancy in those women who are already HIV positive. Most studies have failed to find such an effect, but most also did not stratify their study population by stage of HIV or ART status. Only two studies did this stratification, with a pooled effect size of 1·13 (95% UI 0·73 – 1·77).^{23,24}

1.5 CoDCorrect

To ensure consistent our estimates of maternal mortality are consistent with all other causes for every country, age, sex and year group, we employed a simple algorithm called CoDCorrect. At the level of each draw from the posterior distribution of each cause, we proportionally rescaled every cause such that the sum of the cause-specific estimates equaled the number of deaths from all causes generated from the demographic analysis.²⁵

2. Supplemental Methods: Maternal Causes and Timing of Death

2.1 Data

We modeled aetiology of maternal death for six causes in GBD 2010: maternal haemorrhage, maternal sepsis, hypertensive disorders of pregnancy, obstructed labor, abortion, and “other maternal conditions”. For this analysis we have expanded to nine causes including the first five above as well as “other direct maternal conditions”, “other indirect maternal conditions”, late maternal death and HIV. Our general approach was the same as used for GBD 2010. In that analysis, we used data from a combination of vital registration, verbal autopsy, burial, census, sibling history, and surveillance sources. We updated these datasets with systematic literature review, searching for maternal mortality studies by cause with the terms “maternal mortality”, “maternal death”, “MM”, or “confidential enquiry,” or “obstetric” or “pregnancy” and “aetiology” or “cause pattern” and “death” or “mortality.” The cause-specific literature review yielded 1217 results. 171 were reviewed in full text. A total of 110 were excluded for not having relevant data. 61 articles were found to have relevant data and were included in the database.

We have not previously estimated timing of maternal death, but given the relevance to policy and planning of potential interventions, decided to include it in this analysis. Vital registration and census data collection systems do not collate this sort of data, so we relied on systematic literature review. We used the terms “maternal mortality” to search for studies on the timing of maternal deaths in PubMed, and 8076 studies were reviewed. 629 articles were obtained in full text form and reviewed for inclusion. 142 were found to have data on the timing of maternal deaths, and were extracted for inclusion, while 487 others lacked relevant data and were excluded from analysis.

A flow chart illustrating both of these literature reviews is illustrated in Appendix Figure 1.

All vital registration and sample registration data that provided ICD-coded detail for causes of maternal mortality were included as well. To increase the precision of input data, we combined each two year period (e.g. 1980 and 1981) into a single datum, we excluded any site-year where the total number of maternal deaths was less than ten, and excluded those data with a maternal cause-fraction of less than 3% or greater than 45%, respectively the highest and lowest cause fractions found in the literature for any subcause. This processing resulted in a total of 943 distinct site-years (1886 site-years prior to pooling) of data available for modeling causes of maternal death.

2.2 Modeling of timing and causes of maternal death

We used DisMod-MR 2.0 to model the data on the causes and timing of maternal death. The fundamentals of DisMod-MR 2.0 are outlined below. The study-level covariates and country-level covariates used for each model are shown in Appendix Table 7.

2.3 DisMod-MR 2.0 description and implementation

DisMod-MR was developed for the GBD2010 study to deal with the many challenges in estimating the prevalence of non-fatal health outcomes and risk factor exposures. The information gathered by systematic reviews of published studies, grey literature sources and survey data varied tremendously for each outcome of interest in terms of the volume of data, methods used to collect the data, geographical and temporal coverage, and the type of epidemiological parameter. The goal was to find the true variation in the occurrence of diseases and risk factors for every country and over time.

Estimates of prevalence (or any of the other epidemiological parameters of interest: incidence, remission, duration and risk of mortality) for the same populations often varied by much more than would be expected based on sampling error. Differences in data collection methods such as sampling design, case definitions, measurement instruments and implementation issues, contributed to large non-sampling error. There are two approaches to deal with this heterogeneity. One could set criteria for the optimal measurement of each disease parameter of interest and include only those studies that meet that high standard. This would make measurements comparable but would leave out the vast majority of information available. In GBD, the preferred approach is to make use of all available data that meets a minimum standard of acceptable quality and address major differences in measurement methods by adjusting data for any systematic bias introduced by a study quality characteristic relative to a chosen reference value. This was done by identifying for each disease or risk factor exposure the important study characteristics that can help explain the variation in measurements and flag data points that deviate from the chosen, optimal, reference value with a covariate. DisMod-MR then estimated a coefficient for each chosen study covariate and adjusted the data accordingly.

To help make estimates for countries and time periods for which little or no data were available, DisMod-MR would predict based on country characteristics and random effects on super-region, region and country. For this purpose a database of country covariates for 93 topic areas and 242 variants thereof was created. Missing data were filled in using Gaussian process or space-time regression methods to ensure a complete set of values for each covariate for

every country and every year from 1980 to present. If no country covariates were specified and no data were available, a country estimate would revert to the average of a region, super-region or the world.

DisMod-MR dealt with any specification of age ranges by which data were available to produce estimates by the 20 standard GBD age groups. It also allowed the user to add strong prior knowledge on the age at onset or age pattern of prevalence or incidence such as restricting the occurrence of pre-menstrual syndrome to fertile ages or stipulating that there are no cases of Parkinson's disease before age 30. All these functions were new in DisMod-MR compared to earlier DisMod version used in previous GBD studies which required an analyst to choose one particular data source for a given disease parameter rather than being able to evaluate all available data. Hence the tool was renamed DisMod-MR, the suffix indicating the important meta-regression component. DisMod-MR also accommodated the main functionality of the earlier DisMod tools, i.e. confronting the data from different disease parameters and forcing consistency between these based on differential equations that determine the flow of cases in a stable population between those disease-free and prevalent cases of disease (through incidence or remission) and those in either category that die from other causes (other-cause mortality) and the disease of interest (cause-specific mortality).

To accommodate all functions, DisMod-MR was designed as a Bayesian meta-regression tool using a generalised negative binomial model with fixed effects on age, study and country level covariates as well as random intercepts for country, region and super-region. Greater detail on DisMod-MR has been published in a web-appendix to the paper on non-fatal health outcomes in GBD2010.²⁶

While DisMod-MR successfully addressed many of the major challenges in the estimation of non-fatal health outcomes and risk factor exposures it had a number of drawbacks which we have tried to solve for GBD 2013 by creating an updated version of the tool, DisMod-MR 2.0. The biggest drawback was the computing time required. Each disease model needed to run between 4 and 24 hours on a large computer cluster to produce results for all countries and three time periods (1990, 2005 and 2010). Moreover because of computational constraints a decision had to be made to restrict the consistency checks at the level of 21 regions only. To make country estimates, the relevant fixed effects on study and country covariates and the random effects for each country were applied. While this produced defensible estimates of prevalence it did not guarantee coherence between prevalence and other disease parameters such as incidence and excess mortality rates at the country level.

The code for DisMod-MR 2.0 was rewritten and optimised to run up to 50 times faster than DisMod-MR. A decision was also made to shift to an offset log-normal rather than a negative binomial model as this is easier to implement and because predictive validity tests carried out in DisMod-MR indicated that the statistical properties the two types of models were at least equivalent.

The much faster running time of the core computational engine in DisMod-MR 2.0 allows us to better evaluate all the data through a geographical cascade of four levels. At first, all the world's data are evaluated to estimate the fixed effects on age, sex, study level and country level covariates as well as a first pass at estimating the random effects for countries, regions and super-regions. The outputs of the global level are then used as prior information for the next, super-region level of the cascade. A single age pattern for both sexes and all years of interest is created with uncertainty bounds. All data points that are marked as pertaining to both sexes or flagged with a covariate for a study characteristic (e.g. a less than optimal case definition or a low response rate) are adjusted at this stage to reflect what the likely value would have been if the study had specified sex and/or used the reference study characteristic. The data are also split up between super-regions and, optionally, by time period and sex. Using the global prior and the adjusted data values for each super-region are re-estimated using the same core computational engine. While there is flexibility whether to re-assess fixed effects on sex or study level covariates at this level, the default option is to adjust the data by the sex and study-level covariates after the global level fit, only. At each successive level of the cascade the fixed effects on country-level covariates are re-evaluated and centered on the average of values for the countries that make up a super-region or region. Similarly, random effects are re-evaluated

for just the countries in a given geography. It logically follows that no fixed or random effects are re-evaluated at country level. After fitting the model to each of the super-regions, the results are fed as priors to the region-specific fits and finally, region fits are used as a prior when modelling a country's results for a particular time period.

A new interface was created to draw relevant data for each disease, sequela or risk factor to be modelled, to apply all the default and optional settings and to visualise results. The analyst has a lot of choice to set model parameters to suit any given disease or risk factor of interest. There is a setting to define the age mesh point at which DisMod-MR 2.0 does its calculations. The default setting is to use 21 age mesh points that define the 20 GBD standard age groups. For each study-level and country-level covariate the analyst can set a reference value and upper and lower values for the coefficients. The inclusion of cause-specific mortality rates by age and sex from GBD's mortality estimates is optional. An alternative method of informing a model with mortality data is by using the log of the age-standardised mortality rate as a country-level covariate. Other examples of the basic settings include a value for the parameter that determines the amount of smoothing over the age curve and is denoted by Greek letter 'xi' (ξ); the value of the offset for the lognormal ('eta' or η) for which the default setting is at one per cent of the median of available data values for a parameter or 0.0001 in case there are no data for that parameter; and a range of values for the parameter 'zeta' (ζ) that determines how much 'noise' the analyst allows DisMod-MR 2.0 to estimate for a parameter. The latter function is useful to the analyst. When DisMod-MR 2.0 estimates zeta close to the upper threshold it indicates there is a lot of noise in the data or it may be an indication that there are data entry errors that deserve attention.

Analysts have the choice of using a Gaussian, log-Gaussian, Laplace or Log-Laplace likelihood function in DisMod-MR 2.0. The default log-Gaussian equation for the data likelihood is:

$$-\log[p(y_j|\Phi)] = \log(\sqrt{2\pi}) + \log(\delta_j + s_j) + \frac{1}{2} \left(\frac{\log(a_j + \eta_j) - \log(m_j + \eta_j)}{\delta_j + s_j} \right)^2$$

where, y_j is a 'measurement value' (i.e. data point); Φ denotes all model random variables; η_j is the offset value, eta, for a particular 'integrand' (prevalence, incidence, remission, excess mortality rate, with-condition mortality rate, cause-specific mortality rate, relative risk or standardised mortality ratio) and a_j is the adjusted measurement for data point j , defined by:

$$a_j = e^{(-u_j - c_j)} y_j$$

where u_j is the total 'area effect' (i.e. the sum of the random effects at three levels of the cascade: super-region, region and country) and c_j is the total covariate effect (i.e. the mean combined fixed effects for sex, study level and country level covariates), defined by:

$$c_j = \sum_{k=0}^{K[I(j)]-1} \beta_{I(j),k} \hat{X}_{k,j}$$

with standard deviation

$$s_j = \sum_{l=0}^{L[I(j)]-1} \zeta_{I(j),l} \hat{s}_{k,j}$$

where k denotes the mean value of each data point in relation to a covariate (also called x-covariate); $I(j)$ denotes a data point for a particular integrand, j ; $\beta_{I(j),k}$ is the multiplier of the k^{th} x-covariate for the i^{th} integrand; $\hat{X}_{k,j}$ is the covariate value corresponding to the data point j for covariate k ; l denotes the standard deviation of each data point

in relation to a covariate (also called z-covariate); $\zeta_{l(j),k}$ is the multiplier of the l^{th} z-covariate for the i^{th} integrand; and δ_j is the standard deviation for adjusted measurement j , defined by:

$$\delta_j = \log[y_j + e^{(-u_j - c_j)}\eta_j + c_j] - \log[y_j + e^{(-u_j - c_j)}\eta_j]$$

Where m_j denotes the model for the j^{th} measurement, not counting effects or measurement noise and defined by:

$$m_j = \frac{1}{B(j) - A(j)} \int_{A(j)}^{B(j)} I_j(a) da$$

where $A(j)$ is the lower bound of the age range for a data point; $B(j)$ is the upper bound of the age range for a data point; and $I(j)$ denotes the function of age corresponding to the integrand for data point j .

3. Supplemental Results

Total maternal deaths by underlying cause for 188 countries in 2013 are shown in Appendix Table 8.

Appendix Figure 2 illustrates input data and CODEm model results before and after HIV correction for 188 countries.

Appendix Table 4: Covariates used in CODEm

Appendix Table 4: Covariates used in CODEm		
Covariate	Direction	Level
Age-specific fertility rate	1	1
Total fertility rate	1	1
Age-standardized HIV death rate for females 15-49	1	1
Neonatal death rate	1	1
Lag-distributed GDP per capita	-1	3
Proportion of deliveries occurring in facilities	-1	1
Proportion of deliveries performed by skilled birth attendants	-1	1
Coverage of 4 visits of antenatal care	-1	2
Malnutrition in children under 5 years (proportion > 2SD below mean weight for age)	1	2
Health system access	-1	2

Appendix Table 5: CODEm sub-model performance

Overall Rank	Model type	Dependent variable	Covariates	Root Mean Squared Error		Trend Test		Draws
				Test 1	Rank	Test 1	Rank

Appendix Table 7: Study level and country level covariates used to model aetiology and timing of maternal death in DisMod-MR 2.0

DisMod model	Study covariates	Country covariates
Abortive outcome	Data source only specified direct causes Data source did not specify "late maternal"	Legality of abortion (0 - 7: 0 = always illegal, 7 = always legal)
Hypertensive disorders of pregnancy	Data source only specified direct causes Data source did not specify "late maternal"	None
Maternal haemorrhage	Data source only specified direct causes Data source did not specify "late maternal"	Logit(proportion of pregnancies with in-facility delivery)
Sepsis	Data source only specified direct causes Data source did not specify "late maternal"	Ln(Lag distributed income)
Obstructed labor	Data source only specified direct causes Data source did not specify "late maternal"	Proportion of pregnancies with in-facility delivery
Other direct causes	Data source only specified direct causes Data source did not specify "late maternal"	Ln(Lag distributed income)
Other indirect causes	Study specified HIV as a subtype of indirect Data source did not specify "late maternal"	None
HIV	N/A	N/A
Late maternal death	None	Logit(proportion of pregnancies with in-facility delivery) Ln(Lag distributed income)
Timing - Antepartum	None	Proportion of pregnancies with 4 antenatal care visits
Timing - Intrapartum	None	Logit(proportion of pregnancies with in-facility delivery) Ln(Lag distributed income)
Timing - Postpartum	None	Logit(proportion of pregnancies with in-facility delivery) Ln(Lag distributed income)
Timing - Late	None	Logit(proportion of pregnancies with in-facility delivery) Ln(Lag distributed income)

Appendix Table 8. Global and regional maternal deaths by cause and timing, 1990

	Cause of death										Timing of death				
	Abortion	Haemorrhage	Hypertension	Obstructed labor	Sepsis	Late	Other direct	Indirect	HIV	Antepartum	Intra-partum	Post-partum	late
