

SHORT REPORT

Neuropsychological profile linked to low dopamine: in Alzheimer's disease, major depression, and Parkinson's disease

Nicola Wolfe, Douglas I Katz, Martin L Albert, Abraham Almozlino, Raymon Durso, Marcia C Smith, Ladislav Volicer

Abstract

A distinct pattern of neuropsychological deficits was associated with low homovanillic acid (HVA) in the cerebrospinal fluid of 21 patients with: Alzheimer's disease (9), Parkinson's disease (8) and major depressive disorders (4). Regardless of clinical diagnosis, patients with low HVA were slower on a test of efficiency of processing timed information, and showed greater benefit from semantic structure on a verbal fluency task than patients with high HVA. However, low HVA subjects were not significantly impaired on confrontation naming (Boston Naming Test). Across three diagnostic groups, patients with lower HVA also tended to have more extrapyramidal motor signs and were significantly more depressed. These results demonstrate a significant relationship between specific neurobehavioural deficits and dopaminergic activity which cuts across traditional diagnostic categories.

Based on a description of the role of dopamine in dementia by Bachman and Albert,¹ we suspected that patients with dopamine deficiency might exhibit a characteristic neurobehavioural profile that cuts across the traditional diagnostic categories of Alzheimer's disease, Parkinson's disease, and major depressive disorders. Low dopamine has been associated with extrapyramidal motor signs, cognitive impairment and depression within each of these disorders. We suspected that low dopamine could be a common neurochemical pathology which accounts for similarities observed across these diagnostic groups. In this pilot study, we tested the hypothesis that regardless of diagnosis, subjects with low cerebrospinal fluid (CSF) homovanillic acid (HVA) would exhibit a syndrome consisting of the following: Parkinsonian motor signs, slowed cognition (bradyphrenia), and depression.

Patients and methods

We evaluated twenty one male inpatients with

diagnoses of dementia of the Alzheimer type (9) (ADDA-NINCDS criteria),² Parkinson's disease (8) (clinical consensus by two neurologists on (a) the presence of at least three of the four cardinal features: resting tremor, rigidity, bradykinesia, postural instability, and (b) absence of other known aetiologies of extrapyramidal symptoms), or major depressive disorder (4) (DSMIII).³ Exclusion criteria for all patients were: evidence of structural lesion on CT scan, Hachinski Ischaemia Score greater than 4, or history of seizure. Neuropsychological testing included the following range of tests: the Mini-Mental State Test (MMS), a standard index of overall cognitive ability, and the Varied Interval Summation Task (VIST), a simplified version of the Paced Auditory Serial Addition Task⁴ designed to measure efficiency of processing speeded information. In this test, subjects hear a number (between 3 and 9) followed by a random series of the numbers 1 or 2. The task is to add the series and report the sum after the tenth number. The interstimulus interval ranges from 5s on the first trial to 0.7s on the last. Thus successive trials increase the rate of presentation of stimuli, but the verbal response is not timed. The test score is the total number of successful trials. A pilot study of this instrument (Katz, unpublished data) showed it to be sensitive to efficiency of processing speeded information and to attentional deficits.

The Controlled Oral Word Association Test (FAS) of verbal fluency⁵ was used to assess benefit from semantic structure in word list generation. Benefit from structure was calculated as: number of correct responses in Semantic Categories (animals, fruits and vegetables, first names); number of correct responses in Phonemic Categories (starting with first letter F, A, and S successively)/(Total correct responses). The Boston Naming Test (BNT) (30 item version) was included as an index of language function predicted to be uncorrelated with dopamine deficiency. Extrapyramidal motor signs were assessed with the Parkinson's Disease Motor Performance Scale (PDS), based on the scale by Duvoisin⁶; and affect was measured with the Hamilton Depression Rating Scale (HDRS).

Figure Cognitive profiles of patients with low versus high CSF HVA.

Results in patients with lower HVA ($n = 9$), compared to high HVA ($n = 12$). Statistically significant differences: * $p < 0.025$, ** $p < 0.01$ (one-tailed).

*Benefit from semantic structure was computed as: (number correct using semantic categories minus number correct using phonemic categories) / (total correct responses). Data in Table.

Lumbar puncture was performed using standard clinical procedure with the patient in the lateral recumbent position at 9 am after the patient had fasted and remained in bed from midnight of the previous day. CSF was quick frozen at the bedside and stored at -70°C until the day of assay. HVA in the 7–9th cc was measured by high pressure liquid chromatography based on the method described by Matson *et al*⁷ using absolute coulometric detection with high selectivity and resolution. HVA levels obtained were comparable with other studies.⁸

Most patients were not taking drugs, but 14% (3/21) had received major tranquilisers (minimum washout period 10 days) and 19% (4/21) had previously received levodopa therapy (Sinemet for Parkinson's disease minimum washout period two days). The length of the washout period was not significantly correlated with CSF HVA in these patients, however, the number of these patients is too small to rule out the possibility of residual drug effects. Age and education were not significantly different across the diagnostic groups.

Results

The mean (SD) cerebrospinal fluid HVA levels were: 40.9 (17.1) ng/ml for Alzheimer's disease, 34.6 (16) ng/ml for Parkinson's disease, and 29.9 (17.2) ng/ml for major depression. To define the pattern of cognitive deficits associated with dopamine deficiency, we compared patients with "low HVA" (9) to those

with "high HVA" (12). Raw scores were residualised to correct for baseline differences in group means.⁹ (Group effect = grand mean–group mean). The "low HVA" subset of patients, defined as those with HVA level below the mean of residualised scores included four with Alzheimer's disease, three with Parkinson's disease and two with major depressive disorder. The "low HVA" patients, regardless of clinical diagnosis, exhibited a distinctive pattern of performance on the neuropsychological tests selected to assess bradyphrenia, ability to benefit from structured tasks, and anomia (fig, table).

On the efficiency of processing speeded information (VIST), patients with low HVA performed significantly worse compared with high HVA patients ($t(16) = -2.31, p < 0.025$) (one-tailed t -tests were used to test this directional hypothesis). On the Verbal Fluency Task, subjects with low HVA displayed significantly greater benefit from the structured condition compared with the unstructured condition ($t(16) = 2.86, p < 0.01$, one-tailed). Patients in the low HVA group had slightly lower overall Mini Mental State Scores ($t(16) = -2.19, p < 0.025$, one-tailed). However, cognitive impairment in patients with low CSF HVA was not present in all domains. For example, scores on confrontation naming (Boston Naming Test) were not significantly impaired in patients with lower HVA compared with the high HVA group. Subjects in the low HVA group also had a significantly greater number of Parkinsonian motor features ($t(16) = 2.31, p < 0.025$, one-tailed) and more depression ($t(16) = 2.08, p < 0.05$, one-tailed).

Discussion

In this study, patients with low CSF HVA, regardless of clinical diagnostic category, exhibited a characteristic profile of cognitive deficits, depressive symptoms, and extrapyramidal motor signs. Other investigators have described aspects of this neurobehavioural profile in subgroups of patients in each clinical category.^{8,10} This analysis draws together these aspects.

Research on cognitive deficits in Parkinson's disease provides the best comparison to the neuropsychological pattern described in the current study. Bachman and Albert¹ emphasised the pattern of slowed thinking, impaired

Table Cognitive profiles of patients with low versus high CSF HVA

	High HVA ($n = 12$)	Low HVA ($n = 9$)
Mini Mental State (MMS)	23.7, 5.45 (79.0, 18.2)	18.9, 4.2†† (63.0, 14.0)
Varied Interval Summation Task (VIST)*	7.8, 3.16 (55.7, 22.5)	4.89, 2.42†† (34.9, 17.3)
Verbal Fluency (FAS)** (Benefit from Structure)	0.169, 0.234 (16.9, 23.4)	0.494, 0.285††† (49.4, 28.5)
Boston Naming Test (BNT) (30 item version)	22.4, 5.7 (74.7, 19.0)	18.6, 6.07 (62.0, 20.2)
Hamilton Depression Rating (HDRS)	8.39, 4.9 (11.3, 6.6)	14.1, 7.6† (19.1, 10.3)
Parkinson Disease Motor Performance Scale (PDS)	4.76, 3.5 (14.87, 10.9)	9.82, 6.5 (30.7, 20.2)

Values are given as: mean, standard deviation (scores corrected for diagnostic group effects) and in brackets (percent of total possible score).

*VIST score is the number of correct trials (presented with successively decreasing interstimulus interval) (Maximum possible score equals 14).

**FAS Benefit from semantic structure was computed as (number correct using semantic categories minus number correct using phonemic categories)/(total correct responses). (Maximum possible score = 1.0).

†Student t test for significance of difference between low and high CSF HVA: † p (one-tailed) < 0.05 , †† p (one-tailed) < 0.025 , ††† p (one-tailed) < 0.01 .

manipulation of acquired knowledge, and impaired memory, without aphasia. Studies measuring cognitive speed in Parkinson's disease and multiple sclerosis, and Huntington's disease often use the common term bradyphrenia, but methods to measure cognitive speed vary considerably. For example, cognitive speed has been measured using: speed of scanning elements in short term memory,^{11 12} time to prepare a manual movement,¹¹ difference in time to perform two digit symbol tasks which differed in cognitive complexity,¹⁰ attention and vigilance using a continuous performance task,⁸ reaction time on tasks differing in cognitive complexity¹³ and the Paced Auditory Serial Addition Test.¹⁴ In this pilot study, we used a simpler serial addition task (VIST) to disentangle motor speed and the efficiency of processing speeded information. Because the motor response from the patient was not timed, the score represents an individual's success at processing auditory stimuli at increasingly rapid intervals. However, this efficiency of processing speeded information cannot be equated with cognitive speed. Performance on this task is also dependent on motivation, auditory acuity, short term memory, distractibility, difficulty with calculation, and other factors.

Many investigators have reported decreased verbal fluency in Parkinson's disease^{15 16} (using the FAS test),⁵ but have not specifically examined the benefit provided by semantic categories compared with phonemic categories. In this study, we observe a need for structure from semantic categories on a verbal fluency test. Comparable observations in the literature on Parkinson's disease include the description by Lees and Smith of "mental inflexibility",¹⁵ and observations by Taylor *et al*¹⁷ of impairment in the ability to generate efficient strategies on spontaneously self-directed tasks.

Most reviews of dementia in Parkinson's disease agree that naming is relatively spared¹⁶ and not affected by levodopa treatment.¹⁸ Our findings that naming is relatively spared supports the hypothesis that only a specific set of cognitive functions is impaired and that we are not simply reporting a global cognitive decline.

The results of our study, as well as those from other laboratories,^{10 19} seem to support the earlier theory on the association between dopamine and cognitive impairment.¹ Although there may be a role for mesolimbocortical dopamine neurons to account for this behaviour, other neurotransmitters have also been implicated, for example, in cognitive impairment in Parkinsonism.²⁰ We have des-

cribed a potential neurobehavioural "signature" associated with relatively low dopamine, but only the HVA level in CSF has been examined to date. It is likely that other neurotransmitter systems contribute to the neurobehavioural profile we have identified.

We thank Edith Kaplan for advice on the design of the neuropsychological evaluations, Errol Baker for statistical advice and Guila Glosser for comments on an earlier draft of this paper.
