20 Abstract

Objective Few studies have examined the causal relationships between lifestyle habits and obesity. With a focus on eating speed, this study aimed to analyze the effects of changes in lifestyle habits on changes in obesity utilizing panel data. Methods Patient-level panel data from 2008 to 2013 were generated using commercially available insurance claims data and health checkup data. The study subjects comprised Japanese men and women (n=59,717) enrolled in health insurance societies who had been diagnosed with type 2 diabetes during the study period. Body mass index (BMI) was measured, and obesity was defined as a BMI of 25 or more. Information on lifestyle habits were obtained from the subjects' responses to questions asked during health checkups. The main exposure of interest was eating speed ("fast", "normal", and "slow"). Other lifestyle habits included eating dinner within 2 hours of sleeping, after-dinner snacking, skipping breakfast, alcohol consumption frequency, sleep adequacy, and tobacco consumption. A generalized estimating equation model and fixed-effects model were used to examine the effects of these habits on obesity and BMI, respectively. **Results** The generalized estimating equation model showed that eating slower inhibited the development of obesity. The odds ratios for slow (0.56) and normal-speed eaters (0.70) indicated that these groups were less likely to be obese than fast eaters (P < 0.001). Similarly, the fixed-effects model showed that eating slower reduced BMIs. Relative to fast eaters, the coefficients for slow and normal-speed eaters were -0.11 and -0.07, respectively (P < 0.001). **Discussion** Changes in eating speed can affect changes in obesity and BMI. Interventions aimed at reducing eating speed may be effective in preventing obesity and lowering the associated health risks. **Keywords:** Body mass index, obesity, eating habits, health checkups

74 Introduction

Excess body weight and obesity can lead to an increased risk of developing noncommunicable diseases such as cardiovascular disease, diabetes, and various forms of cancer.¹⁻⁴ Studies have reported that the regulation of body weight can be effective in lowering these health risks.¹⁻⁴ However, a 10-year longitudinal study of Japanese men aged 40 to 69 years found that the proportion of overweight and obese individuals had increased over the study period.⁵ In addition, the Japanese government's Annual Health, Labour and Welfare Report 2014 noted that the prevalence of obesity continues to rise, with a substantially higher prevalence among men in 2012 than in 1982.⁶ The report also revealed that obesity prevalence exceeded 30% in men in their 40s and 50s. These figures suggest that current obesity prevention efforts in Japan may be inadequate.

The fundamental cause of excess weight gain is the failure to ensure a balance between energy intake and energy expenditure.¹ However, recent studies have reported that excess weight gain and metabolic syndrome are affected not only by energy intake, but are also influenced by other factors such as eating speed, eating frequency, and other lifestyle habits.⁷⁻¹⁰ In addition to emphasizing the importance of balancing energy intake and expenditure, these other factors represent possible targets for obesity prevention measures.

In response to the rising prevalence of obesity, Japan's Ministry of Health,
Labour and Welfare introduced a nationwide health screening program (Standard
Health Checkup and Counseling Guidance Program) to detect risk factors for obesity
and metabolic syndrome.^{11,12} Under this program, insurers conduct "specific health
checkups" aimed at insurance enrollees aged 40 years or older. However, participation
in these checkups is not mandatory.

Although many studies have addressed the associations between lifestyle habits
and obesity, few have examined the causal effects of changes in lifestyle habits on
obesity. The main objective of this study was to utilize panel data to analyze the

BMJ Open

- 3 4	102	effects of changes in eating speed and other lifestyle habits on obesity.		
5	103			
6 7	104	Methods		
8 9	105	Data source		
10 11	106	This study used a commercial database obtained from the Japan Medical Data Center		
12 13	107	(JMDC), a for-profit organization that collects, curates, and distributes health-related		
14 15	108	data. The database comprised insurance claims data and health checkup data for		
16 17	109	insurance enrollees and their dependents that were collected through JMDC's		
18 19	110	contracts with several health insurance societies. The claims data included		
20 21	111	information on the dates of consultations and treatments, sex, age, diagnoses, specific		
22 23	112	treatments, and healthcare expenditure. The health checkup data included the dates of		
24 25 26	113	checkups, body mass index (BMI), blood pressure, and the results of blood chemical		
20 27 28	114	analysis, liver function test, blood glucose test, and urinalysis. The health checkup		
20 29 30	115	data also included the subjects' responses to several questions regarding lifestyle		
31 32	116	factors, such as eating habits, alcohol consumption, tobacco use, and sleeping		
33 34	117	habits. ¹² The claims data and health checkup data were linked at the individual		
35 36	118	subject level for analysis.		
37 38	119	subject level for analysis.		
39 40	120	Study design		
41 42	121	We first identified subjects with at least one recorded diagnosis of type 2 diabetes in		
43 44	122	their claims data from January 2005 to June 2013. Both the claims data and health		
45 46	123	checkup data from this study period were used in the analysis. From the claims data,		
47 48	124	we obtained information on subject sex, age, and the starting date of anti-diabetic		
49 50	125	medication. The claims data were linked with the health checkup data at the patient-		
50 51 52	126	month level to generate panel data. We excluded subjects with missing data for BMI		

and lifestyle habits. The results from each subject's first specific health checkup

- during the study period were used as the baseline values.

130 Outcomes

The primary outcome of this study was obesity status. According to the World Health Organization's criteria, a BMI of 25 or more indicates that a person is overweight, and a BMI of 30 or more indicates obesity. However, it has been proposed that these BMI cut-off points should be lower for Asian populations.¹³ The Japan Society for the Study of Obesity has recommended that obesity be defined by a BMI of 25 or more for the Japanese population.¹⁴ In accordance with this recommendation, our study uses a BMI cut-off point of 25 to identify obese individuals. The secondary outcome of this study was BMI, which was analyzed as a continuous variable.

Exposure variables

The exposure variables consisted of the 7 question items regarding lifestyle habits. The main exposure of interest was eating speed. The other items were eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or more per week, skipping breakfast 3 times or more per week, alcohol consumption frequency, sleep adequacy, and habitual smoking. These variables were analyzed as categorical variables based on the response options. Eating speed was analyzed as 3 categories ("fast", "normal", and "slow"). Eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or more per week, skipping breakfast 3 times or more per week, adequate sleep, and habitual smoking were analyzed as 2 categories ("yes" and "no"). Alcohol consumption frequency was analyzed as 3 categories ("every day", "occasionally", and "rarely or never").

154 Covariates

155The covariates were selected from factors thought to influence lifestyle habits and156weight management. These included the use of anti-diabetic medication (as an

157 indicator of diabetes that requires pharmacologic treatment), age, as well as obesity

Page 7 of 19

BMJ Open

status and BMI in the previous checkup. The use or non-use of anti-diabetic medication was determined based on whether the patient had been administered anti-diabetic medication at the time of each health checkup. This variable was analyzed as 2 categories ("yes" and "no"). In addition to human insulin preparations and insulin analogs, anti-diabetic medications also included sulfonylureas, biguanide derivatives, glitazones, α-glucosidase inhibitors, glinides, DPP-4 inhibitors, and GLP-1 receptor agonists. Age and BMI in the previous checkup were analyzed as continuous variables. Obesity status in the previous checkup was analyzed as 2 categories ("yes" for BMI \geq 25 and "no" for BMI <25).

168 Statistical analysis

The subject baseline characteristics of sex, age, BMI, obesity status, and lifestyle habits were compared among the 3 eating speed categories using the χ^2 test or one-way analysis of variance. Patient-level panel data were generated using repeated estimates from multiple health checkups. We constructed a generalized estimating equation model to elucidate the effects of changes in eating speed on obesity. The dependent variable was obesity status. The exposure variables were the 7 lifestyle habit items, and the covariates were the use of anti-diabetic medication, age, and obesity status in the previous checkup.

In order to estimate the influence of changes in eating speed on BMI, we utilized a fixed-effects model where the dependent variable was BMI. The exposure variables were the 7 lifestyle habit items, and the covariates were the use of antidiabetic medication, age, and BMI in the previous checkup. The Hausman test was employed for model selection.

182 All statistical analyses were conducted using Stata 13.1 (Stata Corp., College
183 Station, TX, USA). Statistical significance was set at *P* < 0.05.

185 Results

We identified 92,363 individuals from 303,361 person-months who had been
diagnosed with type 2 diabetes and had health checkup data for the period between
January 2005 and June 2013. After excluding cases with missing data in BMI and the
lifestyle habit items, the sample for analysis comprised 59,717 individuals from
129,978 person-months. The claims data and health checkup data that could be linked
for analysis covered the period from February 2008 to June 2013.

The distribution of baseline characteristics according to eating speed is 192193presented in Table 1. The slow-eating group had a significantly higher proportion of 194women (44.4%), lower mean BMI (22.3 ± 4.0) , lower proportion of obese individuals 195(21.5%), lower alcohol consumption frequency (every day: 22.8%; occasionally: 19627.5%; rarely or never: 49.7%), and lower proportion of habitual smokers (27.3%) when compared with the other 2 groups (all: P < 0.001). In contrast, the fast-eating 197group had a significantly lower proportion of women (27.3%, P < 0.001), but a 198significantly higher mean BMI (25.0 \pm 4.4, P < 0.001) and higher proportion of obese 199200individuals (44.8%, *P* < 0.001).

201Table 2 shows the estimated odds ratios (ORs) of the various determinants of 202obesity derived from the generalized estimating equation model. All eating habit 203items, alcohol consumption frequency, sleep adequacy, and obesity status in the 204previous checkup were significantly associated with obesity. When compared with the 205fast-eating group, the slower eating speeds were significantly associated with reduced 206 ORs for obesity (normal: 0.70; slow: 0.56; P < 0.001). This indicated that slower 207eating speeds may lead to the alleviation of obesity. The results also showed that 208reduced alcohol consumption frequency was significantly associated with higher ORs for obesity (occasionally: 1.13, P < 0.001; rarely or never: 1.09, P = 0.002). In 209210addition, inadequate sleep was significantly associated with a higher OR for obesity 211(1.05, P = 0.023). Habitual smoking and use of anti-diabetic medication were not 212significantly associated with the outcome.

8

Page 9 of 19

BMJ Open

213	The estimated coefficients of the various determinants of changes in BMI are
214	presented in Table 3. Eating speed (normal: $P < 0.001$; slow: $P < 0.001$), eating
215	dinner within 2 hours before sleeping for 3 times or more per week ($P < 0.001$),
216	snacking after dinner for 3 times or more per week ($P < 0.001$), BMI in the previous
217	checkup ($P < 0.001$), alcohol consumption frequency (occasionally: $P < 0.001$; rarely
218	or never: $P = 0.002$), sleep adequacy ($P < 0.001$), and age ($P = 0.008$) were
219	significantly associated with changes in BMI. With the exception of age and BMI in
220	the previous checkup, the coefficients of all the other factors were negative. This
221	indicated that eating slower, not eating dinner within 2 hours before sleeping, not
222	snacking after dinner, drinking infrequently, and not obtaining adequate sleep were
223	associated with reductions in BMI. Skipping breakfast 3 times or more per week,
224	habitual smoking, and the use of anti-diabetic medication were not significantly
225	associated with BMI.

227 Discussion

This study analyzed Japanese men and women who had undergone specific health checkups regardless of obesity status. Possible lifestyle-related determinants of obesity were identified using questionnaire items from the Standard Health Checkup and Counseling Guidance Program.¹² We examined 6-year panel data to determine how changes in eating speed and other lifestyle habits affect obesity and BMI. The main results indicated that decreases in eating speeds can lead to reductions in obesity and BMI after controlling for the covariates. In addition, the study found that the cessation of eating after dinner or within 2 hours before sleeping would also have a similar effect on reducing excess body weight.

The use of panel data increases the accuracy of estimates with substantial
increases in the variable of interest when compared with conventional cross-sectional
and time series data.¹⁵ Panel data also enable adjustments of the unobservable
differences between study subpopulations, thereby facilitating analyses of the effects

241 of behavioral changes in subjects.

The major finding of this study is that changes in eating speed affect obesity and BMI. The control of eating speed may therefore be a possible means of regulating body weight and preventing obesity, which in turn reduces the risk of developing noncommunicable diseases. Eating quickly is associated with impaired glucose tolerance and insulin resistance,^{16,17} and is a known risk factor for diabetes through increases in body weight.¹⁸ Other studies have also reported associations between eating quickly and increased BMI, indicating that eating speed is a contributing factor for obesity.^{7,8,19-24} A possible reason for this association is that fast eaters may continue to eat until they feel full despite having already consumed an adequate amount of calories, and the combined effect of eating quickly and overeating may contribute to weight gain.²⁵ In contrast, eating slowly may help to increase feelings of satiety before an excessive amount of food is ingested.²⁶⁻²⁸ A prospective study of schoolgirls found that the reduction of eating speed was able to suppress weight gain and prevent obesity.²⁹ The findings of these studies are consistent with those of our analysis.

Our results also indicated that frequently eating dinner within 2 hours before sleeping, snacking after dinner, and skipping breakfast contribute to the development of obesity. Previous studies have identified eating after dinner and within 2 hours before sleeping as risk factors of metabolic syndrome.⁷ This supports our findings that the cessation of these habits can help to reduce obesity and BMI. Skipping breakfast has also been shown to be associated with excess weight and obesity, and is a risk factor of metabolic syndrome.^{7,9,30} Our generalized estimating equation model revealed that consistently eating breakfast can reduce obesity, which also corroborates the findings of previous studies. However, our fixed-effects model showed that consistently eating breakfast did not affect changes in BMI. It has been reported that skipping breakfast over a long-period is associated with high BMI and elevated cardiometabolic risks.³¹ Consistently eating breakfast may therefore help to

BMJ Open

control obesity and BMI. Daily alcohol consumption has been reported to be positively associated with obesity, and is another risk factor of metabolic syndrome.^{7,32} However, our findings indicated that alcohol consumption frequency was not significantly associated with obesity. Previous studies have reported that the frequency of alcohol consumption (given the same quantities of alcohol) was inversely associated with obesity.^{33,34} It is possible that the subjects in this study who drank with higher frequency were consuming moderate quantities of alcohol, whereas the subjects who drank infrequently consumed larger quantities during each session. Studies have also found associations between short sleep durations and BMI increases, and that poor-quality sleep is associated with metabolic syndrome.³⁵⁻³⁷ Our analysis produced contradictory results in that a change from adequate sleep to inadequate sleep would reduce BMI but increase obesity progression. A recent study has shown that unstable sleep patterns may increase the quantity of food intake,³⁸ and our findings therefore require further investigation. The lack of association between habitual smoking and BMI or metabolic syndrome has been reported in previous studies,^{7,39} which corroborates our findings. This study has several limitations that should be considered. First, this study utilized health checkup data from health insurance societies. As a result, the data may not have included a large proportion of the insurance enrollees' dependents. In particular, there was a relatively small proportion of older adults in our study population. The results may therefore lack generalizability to other subpopulations. Second, eating speed and the other lifestyle habits were self-assessed, and may therefore be vulnerable to reporting bias. However, while the differences in perceptions of eating and sleeping habits in standardized questionnaires have been described.⁴¹ Sasaki *et al.* reported that there was no difference between the eating speeds assessed by study subjects or by friends of the subjects.²³ In addition, our findings are consistent with those of a previous study that used objective measures of

eating speed and found that slower eating speeds were associated with greater weight 297loss.²⁸ Thirdly, we did not include an analysis of physical exercise. Nevertheless, a 298299previous analysis has reported that eating speed was associated with obesity regardless of the level of physical activity.²⁴ In addition, other studies have reported 300 similar associations between eating speed and BMI given similar overall food intake, 301which corroborates our findings.^{22,23} Finally, the sample comprised relatively health-302conscious individuals who voluntarily participated in health checkups. The findings 303 304 may therefore have limited applicability to less health-conscious people.

Many studies have shown that eating habits are associated with BMI and weight gain.^{7,8,16-29} However, this study utilized panel data to show that changes in eating habits have a causal relationship with obesity and BMI. These findings indicate that weight loss can be supported through the reduction of eating speed, the cessation of eating dinner within 2 hours before sleeping, the cessation of snacking after dinner, and consistently having breakfast.

311

312 Conclusions

Changes in eating habits can affect obesity and BMI. Interventions aimed at altering
eating habits, such as education initiatives and programs to reduce eating speed, may
be useful in preventing obesity and reducing the risk of noncommunicable diseases.

22	Abstract
23	Objective Few studies have examined the causal relationships between lifestyle
24	habits and obesity. With a focus on eating speed, this study aimed to analyze the
25	effects of changes in lifestyle habits on changes in obesity utilizing panel data.
26	Methods Patient-level panel data from 2008 to 2013 were generated using
27	commercially available insurance claims data and health checkup data. The study
28	subjects comprised Japanese men and women (n=59,717) enrolled in health insurance
29	societies who had been diagnosed with type 2 diabetes during the study period. Body
30	mass index (BMI) was measured, and obesity was defined as a BMI of 25 or more.
31	Information on lifestyle habits were obtained from the subjects' responses to
32	questions asked during health checkups. The main exposure of interest was eating
33	speed ("fast", "normal", and "slow"). Other lifestyle habits included eating dinner
34	within 2 hours of sleeping, after-dinner snacking, skipping breakfast, alcohol
35	consumption frequency, sleep adequacy, and tobacco consumption. A generalized
36	estimating equation model and fixed-effects model were used to examine the effects
37	of these habits on obesity and BMI, respectively.
38	Results The generalized estimating equation model showed that eating slower
39	inhibited the development of obesity. The odds ratios for slow (0.58) and normal-
40	speed eaters (0.71) indicated that these groups were less likely to be obese than fast
41	eaters ($P < 0.001$). Similarly, the fixed-effects model showed that eating slower
42	reduced BMIs. Relative to fast eaters, the coefficients for slow and normal-speed
43	eaters were -0.11 and -0.07, respectively ($P < 0.001$).
44	Discussion Changes in eating speed can affect changes in obesity and BMI.
45	Interventions aimed at reducing eating speed may be effective in preventing obesity
46	and lowering the associated health risks.

Strengths and limitations of this study

- 1. This is the first panel data analysis to verify the effects of changes in eating habits on obesity.
- 2. Long-term large-scale longitudinal data were used.
- 3. Lifestyle habits were self-assessed and may be vulnerable to reporting bias.
 - 4. The sample comprised relatively health-conscious individuals who voluntarily
- relar .h.checkups. participated in health checkups, and the findings may therefore have limited
- applicability to less health-conscious people.

59 Introduction

Excess body weight and obesity can lead to an increased risk of developing noncommunicable diseases such as diabetes, cardiovascular disease, and various forms of cancer.¹⁻⁴ Studies have reported that the regulation of body weight can be effective in lowering these health risks.¹⁻⁴ However, a 10-year longitudinal study of Japanese men aged 40 to 69 years found that the proportion of overweight and obese individuals had increased over the study period.⁵ In addition, the Japanese government's Annual Health, Labour and Welfare Report 2014 noted that the prevalence of obesity continues to rise, with a substantially higher prevalence among men in 2012 than in 1982.⁶ The report also revealed that obesity prevalence exceeded 30% in men in their 40s and 50s. These figures suggest that current obesity prevention efforts in Japan may be inadequate.

The fundamental cause of excess weight gain is the failure to ensure a balance between energy intake and energy expenditure.¹ However, recent studies have reported that excess weight gain and metabolic syndrome are affected not only by energy intake, but are also influenced by other factors such as eating speed, eating frequency, and other lifestyle habits.⁷⁻¹⁰ In addition to emphasizing the importance of balancing energy intake and expenditure, these other factors represent possible targets for obesity prevention measures.

In response to the rising prevalence of obesity, Japan's Ministry of Health,
Labour and Welfare introduced a nationwide health screening program (Standard
Health Checkup and Counseling Guidance Program) to detect risk factors for obesity
and metabolic syndrome.^{11,12} Under this program, insurers conduct "specific health
checkups" aimed at insurance enrollees aged 40 years or older. However, participation
in these checkups is not mandatory.

Although many studies have addressed the associations between lifestyle habits and obesity, few have examined the causal effects of changes in lifestyle habits on obesity. In addition, studies from Japan have shown that the number of persons with

BMJ Open

type 2 diabetes has increased with increasing BMI¹³, and that BMI is an independent
risk factor for this condition¹⁴. This study focuses on persons with type 2 diabetes as
they are likely to benefit directly from health improvements arising from the
alleviation of obesity. The main objective of this study was to utilize panel data to
analyze the effects of changes in eating speed and other lifestyle habits on obesity.
For this analysis, we hypothesized that slower eating speeds would reduce obesity.

94 Methods

95 Data source

This study used a commercial database obtained from the Japan Medical Data Center (JMDC), a for-profit organization that collects, curates, and distributes health-related data. The database comprised insurance claims data and health checkup data for insurance enrollees and their dependents that were collected through JMDC's contracts with several health insurance societies in Japan. The claims data included information on the dates of consultations and treatments, sex, age, diagnoses, specific treatments, and healthcare expenditure. The health checkup data included the dates of checkups, body mass index (BMI), waist circumference, blood pressure, and the results of blood chemical analysis, liver function test, blood glucose test, and urinalysis. The health checkup data also included the subjects' responses to several questions regarding lifestyle factors, such as eating habits, alcohol consumption, tobacco use, and sleeping habits.¹² The claims data and health checkup data were linked at the individual subject level for analysis. Approval for this study was obtained from the ethics committee of the JMDC.

111 Study design

112 We first identified subjects with at least one recorded diagnosis of type 2 diabetes in

- their claims data from January 2005 to June 2013 using the corresponding
- 114 International Classification of Diseases, 10th revision codes (E10–E14). Both the

claims data and health checkup data from this study period were used in the analysis.
From the claims data, we obtained information on subject sex, age, and the starting
date of anti-diabetic medication. The claims data were linked with the health checkup
data at the patient-month level to generate panel data. We excluded subjects with
missing data for BMI and lifestyle habits. The results from each subject's first
specific health checkup during the study period were used as the baseline values.

122 Outcomes

The primary outcome of this study was obesity status. According to the World Health Organization's criteria, a BMI of 25 or more indicates that a person is overweight, and a BMI of 30 or more indicates obesity. However, it has been proposed that these BMI cut-off points should be lower for Asian populations.¹⁵ The Japan Society for the Study of Obesity has recommended that obesity be defined by a BMI of 25 or more for the Japanese population.¹⁶ In accordance with this recommendation, our study uses a BMI cut-off point of 25 to identify obese individuals. The secondary outcome of this study was BMI, which was analyzed as a continuous variable.

Exposure variables

The exposure variables consisted of the 7 question items regarding lifestyle habits. The main exposure of interest was eating speed. The other items were eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or more per week, skipping breakfast 3 times or more per week, alcohol consumption frequency, sleep adequacy, and habitual smoking. These variables were analyzed as categorical variables based on the response options. Eating speed was analyzed as 3 categories ("fast", "normal", and "slow"). Eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or more per week, skipping breakfast 3 times or more per week, adequate sleep, and habitual smoking were analyzed as 2 categories ("yes" and "no"). Alcohol

BMJ Open

143 consumption frequency was analyzed as 3 categories ("every day", "occasionally",
144 and "rarely or never").

Covariates

The covariates were selected from factors thought to influence lifestyle habits and weight management. These included the use of anti-diabetic medication (as an indicator of diabetes that requires pharmacologic treatment), age, as well as obesity status and BMI in the previous checkup. The use or non-use of anti-diabetic medication was determined based on whether the patient had been administered anti-diabetic medication at the time of each health checkup. This variable was analyzed as 2 categories ("ves" and "no"). In addition to human insulin preparations and insulin analogs, anti-diabetic medications also included sulfonylureas, biguanide derivatives, glitazones, α-glucosidase inhibitors, glinides, DPP-4 inhibitors, and GLP-1 receptor agonists. Age and BMI in the previous checkup were analyzed as continuous variables. Obesity status in the previous checkup was analyzed as 2 categories ("yes" for BMI \geq 25 and "no" for BMI <25).

160 Statistical analysis

The subject baseline characteristics of sex, age, BMI, obesity status, and lifestyle habits were compared among the 3 eating speed categories using the γ^2 test or one-way analysis of variance. Patient-level panel data were generated using repeated estimates from multiple health checkups. This study used longitudinal data from annual health checkups collected over approximately 6 years. The application of panel data enables the estimation of changes in the dependent variables that result from changes in eating speed (e.g., fast to fast, fast to normal, fast to slow, and so on) in individual subjects.

169 We first constructed a generalized estimating equation model to elucidate the 170 effects of changes in eating speed on obesity. The exposure variables were the 7

lifestyle habit items, and the covariates were the use of anti-diabetic medication, age, 171172sex, and obesity status in the previous checkup. 173In order to estimate the influence of changes in eating speed on BMI, we 174utilized a fixed-effects model where the dependent variable was BMI. The exposure 175variables were the 7 lifestyle habit items, and the covariates were the use of anti-176diabetic medication, age, and BMI in the previous checkup. Sex and other covariates 177that remained unchanged throughout the observation period were adjusted as fixed 178effects. The Hausman test was employed for model selection; the *P*-value was below 1790.001, which confirmed that the use of the fixed-effects model was appropriate.

180 All statistical analyses were conducted using Stata 13.1 (Stata Corp., College
181 Station, TX, USA). Statistical significance was set at P < 0.05.

182

183 Results

We identified 92,363 individuals from 303,361 person-months who had been
diagnosed with type 2 diabetes and had health checkup data for the period between
January 2005 and June 2013. After excluding cases with missing data in BMI and the
lifestyle habit items, the sample for analysis comprised 59,717 individuals from
129,978 person-months. The claims data and health checkup data that could be linked
for analysis covered the period from February 2008 to June 2013.

190 The distribution of baseline characteristics according to eating speed is 191presented in Table 1. The slow-eating group had a significantly higher proportion of 192women (44.4%), lower mean BMI (22.3 ± 4.0) , lower proportion of obese individuals 193(21.5%), lower alcohol consumption frequency (every day: 22.8%; occasionally: 19427.5%; rarely or never: 49.7%), and lower proportion of habitual smokers (27.3%) when compared with the other 2 groups (all: P < 0.001). In contrast, the fast-eating 195group had a significantly lower proportion of women (27.3%, P < 0.001), but a 196 significantly higher mean BMI (25.0 ± 4.4 , P < 0.001) and higher proportion of obese 197 198 individuals (44.8%, P < 0.001).

BMJ Open

2 3	199	Table 2 shows the estimated odds ratios (ORs) of the various determinants of
4 5	200	obesity derived from the generalized estimating equation model. All eating habit
6 7	201	items, alcohol consumption frequency, sleep adequacy, and obesity status in the
8 9	202	previous checkup were significantly associated with obesity. When compared with the
10 11	203	fast-eating group, the slower eating speeds were significantly associated with reduced
12 13	204	ORs for obesity (normal: 0.71; slow: 0.58; $P < 0.001$). The results also showed that
14 15	205	reduced alcohol consumption frequency was significantly associated with higher ORs
16 17	206	for obesity (occasionally: 1.18; rarely or never: 1.22; $P < 0.001$). In addition,
18 19	207	inadequate sleep was significantly associated with a higher OR for obesity $(1.06, P =$
20 21	208	0.007). Habitual smoking was also significantly associated with the outcome.
22 23	209	The estimated coefficients of the various determinants of changes in BMI are
24 25	210	presented in Table 3. Eating speed (normal: $P < 0.001$; slow: $P < 0.001$), eating
26 27	211	dinner within 2 hours before sleeping for 3 times or more per week ($P < 0.001$),
28 29	212	snacking after dinner for 3 times or more per week ($P < 0.001$), BMI in the previous
30 31	213	checkup ($P < 0.001$), alcohol consumption frequency (occasionally: $P < 0.001$; rarely
32 33	214	or never: $P = 0.002$), sleep adequacy ($P < 0.001$), and age ($P = 0.008$) were
34 35	215	significantly associated with changes in BMI. With the exception of age and BMI in
36 37	216	the previous checkup, the coefficients of all the other factors were negative. This
38 39	217	indicated that eating slower, not eating dinner within 2 hours before sleeping, not
40 41	218	snacking after dinner, drinking infrequently, and not obtaining adequate sleep were
42 43	219	associated with reductions in BMI. Skipping breakfast 3 times or more per week,
44 45	220	habitual smoking, and the use of anti-diabetic medication were not significantly
46 47	221	associated with BMI.
48 49	222	
50 51	223	Discussion
52 53	224	This study analyzed Japanese men and women who had undergone specific health
54 55	225	checkups regardless of obesity status. Possible lifestyle-related determinants of
56 57	226	obesity were identified using questionnaire items from the Standard Health Checkup

and Counseling Guidance Program.¹² We examined 6-year panel data to determine how changes in eating speed and other lifestyle habits affect obesity and BMI. The main results indicated that decreases in eating speeds can lead to reductions in obesity and BMI after controlling for the covariates. In addition, the study found that the cessation of eating after dinner or within 2 hours before sleeping would also have a similar effect on reducing excess body weight.

A strength of this study is the utilization of large-scale panel data from approximately 60,000 diabetes patients spanning a 6-year observation period. The use of panel data increases the accuracy of estimates when compared with conventional cross-sectional and time series data.¹⁷ Panel data also enable adjustments of the unobservable differences between study subpopulations, thereby facilitating analyses of the effects of behavioral changes in subjects. Another strength of this study is the incorporation of data on lifestyle habits, such as eating, sleeping, and smoking. By analyzing the associations between these habits and obesity, our study was able to quantify the possible effects of changes in these habits on obesity.

The major finding of this study is that changes in eating speed can affect obesity and BMI. The control of eating speed may therefore be a possible means of regulating body weight and preventing obesity, which in turn reduces the risk of developing noncommunicable diseases. Eating quickly is associated with impaired glucose tolerance and insulin resistance,^{18,19} and is a known risk factor for diabetes through increases in body weight.²⁰ Other studies have also reported associations between eating quickly and increased BMI, indicating that eating speed is a contributing factor for obesity.^{7,8,21-26} A possible reason for this association is that fast eaters may continue to eat until they feel full despite having already consumed an adequate amount of calories, and the combined effect of eating quickly and overeating may contribute to weight gain.²⁷ In contrast, eating slowly may help to increase feelings of satiety before an excessive amount of food is ingested.²⁸⁻³⁰ A prospective study of schoolgirls found that the reduction of eating speed was able to

suppress weight gain and prevent obesity.³¹ The findings of these studies are
consistent with those of our analysis.

257In addition to BMI-based definitions of obesity, waist circumference-based 258definitions of abdominal obesity have also become increasingly important in recent 259years. Cerhan et al. proposed that assessments of waist circumference should accompany assessments of BMI.³² As a supplementary analysis, we employed a fixed-260261effects model to examine the effects of changes in eating speed on waist 262circumference in our subjects. The results showed that when compared with fast 263eaters, normal-speed eaters and slow eaters had reductions in waist circumference of 2640.21 cm and 0.41 cm, respectively (P < 0.001). These results support our findings of 265the effects of changes in eating speed on obesity.

266Our results also indicated that frequently eating dinner within 2 hours before sleeping, snacking after dinner, and skipping breakfast contribute to the development 267268of obesity. Previous studies have identified eating after dinner and within 2 hours 269before sleeping as risk factors of metabolic syndrome.⁷ This supports our findings 270that the cessation of these habits can help to reduce obesity and BMI. Skipping 271breakfast has also been shown to be associated with excess weight and obesity, and is a risk factor of metabolic syndrome.^{7,9,33} Our generalized estimating equation model 272273revealed that consistently eating breakfast can reduce obesity, which also 274corroborates the findings of previous studies. However, our fixed-effects model 275showed that consistently eating breakfast did not affect changes in BMI. It has been 276reported that skipping breakfast over a long-period is associated with high BMI and elevated cardiometabolic risks.³⁴ Consistently eating breakfast may therefore help to 277278control obesity and BMI.

Daily alcohol consumption has been reported to be positively associated with obesity, and is another risk factor of metabolic syndrome.^{7,35} However, our findings indicated that alcohol consumption frequency was not significantly associated with obesity. Previous studies have reported that the frequency of alcohol consumption

(given the same quantities of alcohol) was inversely associated with obesity.^{36,37} It is
possible that the subjects in this study who drank with higher frequency were
consuming moderate quantities of alcohol, whereas the subjects who drank
infrequently consumed larger quantities during each session.

Studies have also found associations between short sleep durations and BMI increases, and that poor-quality sleep is associated with metabolic syndrome.³⁸⁻⁴⁰ Our analysis produced contradictory results in that a change from adequate sleep to inadequate sleep would reduce BMI but increase obesity progression. A recent study has shown that unstable sleep patterns may increase the quantity of food intake,⁴¹ and our findings therefore require further investigation. The lack of association between habitual smoking and BMI or metabolic syndrome has been reported in previous studies,^{7,42} which corroborates our findings.

This study has several limitations that should be considered. First, this study utilized health checkup data from health insurance societies. As a result, the data may not have included a large proportion of the insurance enrollees' dependents. In particular, there was a relatively small proportion of older adults in our study population. The results may therefore lack generalizability to other subpopulations. Second, eating speed and the other lifestyle habits were self-assessed, and may therefore be vulnerable to reporting bias. However, while the differences in perceptions of eating and sleeping habits in standardized questionnaires have been described,⁴³ Sasaki *et al.* reported that there was no difference between the eating speeds assessed by study subjects or by friends of the subjects.²⁵ In addition, our findings are consistent with those of a previous study that used objective measures of eating speed and found that slower eating speeds were associated with greater weight loss.³⁰ Thirdly, we did not include an analysis of physical exercise and energy intake, which may be potential confounders. Nevertheless, a previous analysis has reported that eating speed was associated with obesity regardless of the level of physical activity.²⁶ Other studies have also reported similar associations between eating speed

BMJ Open

and BMI given similar overall food intake, which corroborates our findings.^{24,25} Therefore, these 2 factors are unlikely to be confounders in this study despite their association with BMI. Finally, the sample comprised relatively health-conscious individuals who voluntarily participated in health checkups. The findings may therefore have limited applicability to less health-conscious people. Many studies have shown that eating habits are associated with BMI and weight gain.^{7,8,18-31} However, this study utilized panel data to show that changes in eating habits have a strong relationship with obesity and BMI. These findings indicate that weight loss can be supported through the reduction of eating speed, the cessation of eating dinner within 2 hours before sleeping, the cessation of snacking after dinner, and consistently having breakfast. Conclusions Changes in eating habits can affect obesity and BMI. Interventions aimed at altering eating habits, such as education initiatives and programs to reduce eating speed, may be useful in preventing obesity and reducing the risk of noncommunicable diseases. 12°2

22 Abstract

Objective Few studies have examined the causal relationships between lifestyle
habits and obesity. With a focus on eating speed in patients with type 2 diabetes, this
study aimed to analyze the effects of changes in lifestyle habits on changes in obesity
utilizing panel data.

 $\mathbf{27}$ Methods Patient-level panel data from 2008 to 2013 were generated using commercially available insurance claims data and health checkup data. The study subjects comprised Japanese men and women (n=59,717) enrolled in health insurance societies who had been diagnosed with type 2 diabetes during the study period. Body mass index (BMI) was measured, and obesity was defined as a BMI of 25 or more. Information on lifestyle habits were obtained from the subjects' responses to questions asked during health checkups. The main exposure of interest was eating speed ("fast", "normal", and "slow"). Other lifestyle habits included eating dinner within 2 hours of sleeping, after-dinner snacking, skipping breakfast, alcohol consumption frequency, sleep adequacy, and tobacco consumption. A generalized estimating equation model was used to examine the effects of these habits on obesity. In addition, fixed-effects models were used to assess these effects on BMI and waist circumference.

Results The generalized estimating equation model showed that eating slower 41 inhibited the development of obesity. The odds ratios for slow (0.58) and normal-42 speed eaters (0.71) indicated that these groups were less likely to be obese than fast 43 eaters (P < 0.001). Similarly, the fixed-effects models showed that eating slower 44 reduced BMI and waist circumference. Relative to fast eaters, the coefficients of the 45 BMI model for slow and normal-speed eaters were -0.11 and -0.07, respectively (P <46 0.001).

47 Discussion Changes in eating speed can affect changes in obesity, BMI, and waist
48 circumference. Interventions aimed at reducing eating speed may be effective in
49 preventing obesity and lowering the associated health risks.

Strengths and limitations of this study

- This is the first panel data analysis to verify the effects of changes in eating 1. habits on obesity.
- Long-term large-scale longitudinal data were used. 2.
- Lifestyle habits were self-assessed and may be vulnerable to reporting bias. 3.
- $\mathbf{58}$ The sample comprised relatively health-conscious individuals who voluntarily 4.
- $\mathbf{59}$ participated in health checkups, and the findings may therefore have limited
- lity to less heatm-.. applicability to less health-conscious people.

62 Introduction

63 Excess body weight and obesity can lead to an increased risk of developing 64noncommunicable diseases such as diabetes, cardiovascular disease, and various forms of cancer.¹⁻⁴ Studies have reported that the regulation of body weight can be 65effective in lowering these health risks.¹⁻⁴ However, a 10-year longitudinal study of 66 $\mathbf{67}$ Japanese men aged 40 to 69 years found that the proportion of overweight and obese individuals had increased over the study period.⁵ In addition, the Japanese 68 69 government's Annual Health, Labour and Welfare Report 2014 noted that the 70 prevalence of obesity continues to rise, with a substantially higher prevalence among men in 2012 than in 1982.⁶ The report also revealed that obesity prevalence exceeded 717230% in men in their 40s and 50s. These figures suggest that current obesity 73prevention efforts in Japan may be inadequate.

The fundamental cause of excess weight gain is the failure to ensure a balance between energy intake and energy expenditure.¹ However, recent studies have reported that excess weight gain and metabolic syndrome are affected not only by energy intake, but are also influenced by other factors such as eating speed, eating frequency, and other lifestyle habits.⁷⁻¹⁰ In addition to emphasizing the importance of balancing energy intake and expenditure, these other factors represent possible targets for obesity prevention measures.

In response to the rising prevalence of obesity, Japan's Ministry of Health, Labour and Welfare introduced a nationwide health screening program (Standard Health Checkup and Counseling Guidance Program) to detect risk factors for obesity and metabolic syndrome.^{11,12} Under this program, insurers conduct "specific health checkups" aimed at insurance enrollees aged 40 years or older. However, participation in these checkups is not mandatory.

Although many studies have addressed the associations between lifestyle habits
and obesity, few have examined the causal effects of changes in lifestyle habits on
obesity. In addition, studies from Japan have shown that the number of persons with

5

For peer review only - http://bmjopen.bmj.com/site/about/guidelines.xhtml

90 type 2 diabetes has increased with increasing BMI¹³, and that BMI is an independent 91 risk factor for this condition¹⁴. This study focuses on persons with type 2 diabetes as 92 they are likely to benefit directly from health improvements arising from the 93 alleviation of obesity. The main objective of this study was to utilize panel data to 94 analyze the effects of changes in eating speed and other lifestyle habits on obesity in 95 patients with type 2 diabetes. For this analysis, we hypothesized that slower eating 96 speeds would reduce obesity.

98 Methods

99 Data source

This study used a commercial database obtained from the Japan Medical Data Center (JMDC), a for-profit organization that collects, curates, and distributes health-related data. The database comprised insurance claims data and health checkup data for insurance enrollees and their dependents that were collected through JMDC's contracts with several health insurance societies in Japan. The claims data included information on the dates of consultations and treatments, sex, age, diagnoses, specific treatments, and healthcare expenditure. The health checkup data included the dates of checkups, body mass index (BMI), waist circumference, blood pressure, and the results of blood chemical analysis, liver function test, blood glucose test, and urinalysis. The health checkup data also included the subjects' responses to several questions regarding lifestyle factors, such as eating habits, alcohol consumption, tobacco use, and sleeping habits.¹² The claims data and health checkup data were linked at the individual subject level for analysis. Approval for this study (No. 18-09-2014) was obtained from the ethics committee of the JMDC.

115 Study design

- 116 We first identified subjects with at least one recorded diagnosis of type 2 diabetes in
- 117 their claims data from January 2005 to June 2013 using the corresponding

BMJ Open

International Classification of Diseases, 10th revision codes (E10–E14). Both the claims data and health checkup data from this study period were used in the analysis. From the claims data, we obtained information on subject sex, age, and the starting date of anti-diabetic medication. The claims data were linked with the health checkup data at the patient-month level to generate panel data. We excluded subjects with missing data for BMI and lifestyle habits. The results from each subject's first specific health checkup during the study period were used as the baseline values.

- - 126 Outcomes

The primary outcome of this study was obesity status. According to the World Health Organization's criteria, a BMI of 25 or more indicates that a person is overweight, and a BMI of 30 or more indicates obesity. However, it has been proposed that these BMI cut-off points should be lower for Asian populations.¹⁵ The Japan Society for the Study of Obesity has recommended that obesity be defined by a BMI of 25 or more for the Japanese population.¹⁶ In accordance with this recommendation, our study uses a BMI cut-off point of 25 to identify obese individuals. The secondary outcomes of this study were BMI and waist circumference, which were analyzed as continuous variables.

Exposure variables

The exposure variables consisted of the 7 question items regarding lifestyle habits. The main exposure of interest was eating speed. The other items were eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or more per week, skipping breakfast 3 times or more per week, alcohol consumption frequency, sleep adequacy, and habitual smoking. These variables were analyzed as categorical variables based on the response options. Eating speed was analyzed as 3 categories ("fast", "normal", and "slow"). Eating dinner within 2 hours before sleeping for 3 times or more per week, snacking after dinner for 3 times or

more per week, skipping breakfast 3 times or more per week, adequate sleep, and habitual smoking were analyzed as 2 categories ("yes" and "no"). Alcohol consumption frequency was analyzed as 3 categories ("every day", "occasionally", and "rarely or never"). Covariates The covariates were selected from factors thought to influence lifestyle habits and weight management. These included the use of anti-diabetic medication (as an indicator of diabetes that requires pharmacologic treatment), age, as well as obesity status and BMI in the previous checkup. The use or non-use of anti-diabetic medication was determined based on whether the patient had been administered anti-diabetic medication at the time of each health checkup. This variable was analyzed as 2 categories ("yes" and "no"). In addition to human insulin preparations and insulin analogs, anti-diabetic medications also included sulfonylureas, biguanide derivatives, glitazones, α-glucosidase inhibitors, glinides, DPP-4 inhibitors, and GLP-1 receptor agonists. Age and BMI in the previous checkup were analyzed as continuous variables. Obesity status in the previous checkup was analyzed as 2 categories ("yes" for BMI \geq 25 and "no" for BMI <25). Statistical analysis The subject baseline characteristics of sex, age, BMI, obesity status, waist circumference, and lifestyle habits were compared among the 3 eating speed categories using the γ^2 test or one-way analysis of variance. Patient-level panel data were generated using repeated estimates from multiple health checkups. This study used longitudinal data from annual health checkups collected over approximately 6 years. The application of panel data enables the estimation of changes in the dependent variables that result from changes in eating speed (e.g., fast to fast, fast to normal, fast to slow, and so on) in individual subjects.

1		
2 3	174	We first constructed a generalized estimating equation model to elucidate the
4 5	175	effects of changes in eating speed on obesity. The exposure variables were the 7
6 7	176	lifestyle habit items, and the covariates were the use of anti-diabetic medication, age,
8 9	177	sex, and obesity status in the previous checkup.
10 11	178	In order to estimate the influence of changes in eating speed on BMI and waist
12 13	179	circumference, we utilized fixed-effects models with these factors as the dependent
14 15	180	variables. The exposure variables were the 7 lifestyle habit items, and the covariates
16 17	181	were the use of anti-diabetic medication, age, and BMI or waist circumference in the
18 19	182	previous checkup. Sex and other covariates that remained unchanged throughout the
20 21	183	observation period were adjusted as fixed effects. The Hausman test was employed
22 23	184	for model selection; the P -value was below 0.001, which confirmed that the use of the
24 25	185	fixed-effects model was appropriate.
26 27	186	All statistical analyses were conducted using Stata 13.1 (Stata Corp., College
28 29	187	Station, TX, USA). Statistical significance was set at $P < 0.05$.
30 31	188	
32 33	189	Results
34 35	190	We identified 92,363 individuals from 303,361 person-months who had been
36 37	191	diagnosed with type 2 diabetes and had health checkup data for the period between
38 39	192	January 2005 and June 2013. After excluding cases with missing data in BMI and the
40 41	193	lifestyle habit items, the sample for analysis comprised 59,717 individuals from
42		
43	194	129,978 person-months. The claims data and health checkup data that could be linked

44 45 46 47 48 49 50 51 52 53 54	195 196 197 198	129,978 person-months. The claims data and health checkup data that could be linked for analysis covered the period from February 2008 to June 2013. The distribution of baseline characteristics according to eating speed is presented in Table 1. The slow-eating group had a significantly higher proportion of women (44.4%), lower mean BMI (22.3±4.0), lower proportion of obese individuals
44 45 46 47 48 49 50 51 52 53 54 55 56	195 196 197 198 199	129,978 person-months. The claims data and health checkup data that could be linked for analysis covered the period from February 2008 to June 2013. The distribution of baseline characteristics according to eating speed is presented in Table 1. The slow-eating group had a significantly higher proportion of women (44.4%), lower mean BMI (22.3±4.0), lower proportion of obese individuals (21.5%), smaller mean waist circumference (80.1±10.6 cm), lower alcohol
44 45 46 47 48 49 50 51 52 53 54 55	195 196 197 198 199 200	129,978 person-months. The claims data and health checkup data that could be linked for analysis covered the period from February 2008 to June 2013. The distribution of baseline characteristics according to eating speed is presented in Table 1. The slow-eating group had a significantly higher proportion of women (44.4%), lower mean BMI (22.3±4.0), lower proportion of obese individuals (21.5%), smaller mean waist circumference (80.1±10.6 cm), lower alcohol consumption frequency (every day: 22.8%; occasionally: 27.5%; rarely or never:

2 3	202	other 2 groups (all: $P < 0.001$). In contrast, the fast-eating group had a significantly
4 5	203	lower proportion of women (27.3%, $P < 0.001$), but a significantly higher mean BMI
6 7	204	$(25.0\pm4.4, P < 0.001)$, higher proportion of obese individuals (44.8%, $P < 0.001$), and
8 9	205	larger mean waist circumference (86.8±11.1 cm, $P < 0.001$).
10 11	206	The mean number (and standard deviation) of health checkups among the 59,171
12 13	207	subjects used in the panel data analysis was 1.9 (1.1). The distribution of subjects
14 15	208	(and percentage of all subjects) according to the number of health checkups
16 17	209	undergone during the study period was as follows: 21,805 subjects (36.5%) with 1
18 19	210	checkup, 17,694 (29.6%) subjects with 2 checkups, 12,075 (20.2%) subjects with 3
20 21	211	checkups, 4,524 (7.6%) subjects with 4 checkups, 3,248 (5.4%) subjects with 5
22 23	212	checkups, and 371 (0.6%) subjects with 6 checkups. Table 2 shows the changes in
24 25	213	eating speed across these checkups according to the different baseline eating speeds.
26 27	214	Approximately half (51.9%) of the subjects exhibited changes in eating speed from
28 29	215	baseline during the study period. The results showed that 171 subjects (0.29%)
30 31	216	changed from being fast eaters to slow eaters, whereas 92 subjects (0.15%) changed
32 33	217	from being slow eaters to fast eaters.
34 35 36 37	218	Table 3 shows the estimated odds ratios (ORs) of the various determinants of
	219	obesity derived from the generalized estimating equation model. All eating habit
38 39	220	items, alcohol consumption frequency, sleep adequacy, and obesity status in the
40 41	221	previous checkup were significantly associated with obesity. When compared with the
42 43	222	fast-eating group, the slower eating speeds were significantly associated with reduced
44 45	223	ORs for obesity (normal: 0.71; slow: 0.58; $P < 0.001$). The results also showed that
46 47	224	reduced alcohol consumption frequency was significantly associated with higher ORs
48 49	225	for obesity (occasionally: 1.18; rarely or never: 1.22; $P < 0.001$). In addition,
50 51	226	adequate sleep was significantly associated with a lower OR for obesity (0.94, $P =$
52 53	227	0.007). Habitual smoking was also significantly associated with the outcome.
54 55	228	The estimated coefficients of the various determinants of changes in BMI are
56 57	229	presented in Table 4. Eating speed (normal: $P < 0.001$; slow: $P < 0.001$), eating

230dinner within 2 hours before sleeping for 3 times or more per week (P < 0.001), 231snacking after dinner for 3 times or more per week (P < 0.001), BMI in the previous 232checkup (P < 0.001), alcohol consumption frequency (occasionally: P < 0.001; rarely 233or never: P = 0.002), and age (P = 0.008) were significantly associated with changes 234in BMI. With the exception of inadequate sleep, habitual smoking, age, and BMI in 235the previous checkup, the coefficients of all the other factors were negative. This 236indicated that eating slower, not eating dinner within 2 hours before sleeping, not 237snacking after dinner, and drinking infrequently were associated with reductions in 238BMI. Skipping breakfast 3 times or more per week, habitual smoking, and the use of 239anti-diabetic medication were not significantly associated with BMI. 240Table 5 presents the results of eating speed on waist circumference from the 241fixed-effects model analysis. When compared with fast eaters, normal-speed eaters 242and slow eaters had reductions in waist circumference of 0.21 cm and 0.41 cm, 243CZ: respectively (P < 0.001). 244245Discussion 246This study analyzed Japanese men and women who had undergone specific health 247checkups regardless of obesity status. Possible lifestyle-related determinants of 248obesity were identified using questionnaire items from the Standard Health Checkup and Counseling Guidance Program.¹² We examined 6-year panel data to determine 249250how changes in eating speed and other lifestyle habits affect obesity and BMI. The 251main results indicated that decreases in eating speeds can lead to reductions in 252obesity and BMI after controlling for the covariates. In addition, the study found that 253the cessation of eating after dinner or within 2 hours before sleeping would also have 254a similar effect on reducing excess body weight. 255A strength of this study is the utilization of large-scale panel data from

approximately 60,000 diabetes patients spanning a 6-year observation period. The useof panel data increases the accuracy of estimates when compared with conventional

11

Page 12 of 29

cross-sectional and time series data.¹⁷ Panel data also enable adjustments of the
unobservable differences between study subpopulations, thereby facilitating analyses
of the effects of behavioral changes in subjects. Another strength of this study is the
incorporation of data on lifestyle habits, such as eating, sleeping, and smoking. By
analyzing the associations between these habits and obesity, our study was able to
quantify the possible effects of changes in these habits on obesity.

The major finding of this study is that changes in eating speed can affect obesity, BMI, and waist circumference. The control of eating speed may therefore be a possible means of regulating body weight and preventing obesity, which in turn reduces the risk of developing noncommunicable diseases. Eating quickly is associated with impaired glucose tolerance and insulin resistance,^{18,19} and is a known risk factor for diabetes through increases in body weight.²⁰ Other studies have also reported associations between eating quickly and increased BMI, indicating that eating speed is a contributing factor for obesity.^{7,8,21-26} A possible reason for this association is that fast eaters may continue to eat until they feel full despite having already consumed an adequate amount of calories, and the combined effect of eating quickly and overeating may contribute to weight gain.²⁷ In contrast, eating slowly may help to increase feelings of satiety before an excessive amount of food is ingested.²⁸⁻³⁰ A prospective study of schoolgirls found that the reduction of eating speed was able to suppress weight gain and prevent obesity.³¹ The findings of these studies are consistent with those of our analysis.

In addition to BMI-based definitions of obesity, waist circumference-based definitions of abdominal obesity have also become increasingly important in recent years. Cerhan *et al.* proposed that assessments of waist circumference should accompany assessments of BMI.³² As a supplementary analysis, we employed a fixedeffects model to examine the effects of changes in eating speed on waist circumference in our subjects. The results showed that when compared with fast eaters, normal-speed eaters and slow eaters had reductions in waist circumference of

286 0.21 cm and 0.41 cm, respectively (P < 0.001). These results support our findings of 287 the effects of changes in eating speed on obesity.

288Our results also indicated that frequently eating dinner within 2 hours before 289sleeping, snacking after dinner, and skipping breakfast contribute to the development 290of obesity. Previous studies have identified eating after dinner and within 2 hours 291before sleeping as risk factors of metabolic syndrome.⁷ This supports our findings 292that the cessation of these habits can help to reduce obesity and BMI. Skipping 293breakfast has also been shown to be associated with excess weight and obesity, and is a risk factor of metabolic syndrome.^{7,9,33} Our generalized estimating equation model 294295revealed that consistently eating breakfast can reduce obesity, which also 296corroborates the findings of previous studies. However, our fixed-effects model 297showed that consistently eating breakfast did not affect changes in BMI. It has been reported that skipping breakfast over a long-period is associated with high BMI and 298elevated cardiometabolic risks.³⁴ Consistently eating breakfast may therefore help to 299300 control obesity and BMI.

301The association between daily alcohol consumption and obesity remains 302controversial. While several studies have identified this lifestyle habit as a risk factor of metabolic syndrome,^{7,35} others have reported an inverse association between the 303 304frequency of alcohol consumption (given the same quantities of alcohol) and obesity.^{36,37} In our study, the frequency of alcohol consumption was found to be 305 inversely associated with obesity, but positively associated with BMI and waist 306 307 circumference. In order to clarify this apparent disparity, further analyses of alcohol 308 consumption should be conducted with consideration to the overall quantities of 309 alcohol consumed.

Studies have also found associations between short sleep durations and BMI
 increases, and that poor-quality sleep is associated with metabolic syndrome.³⁸⁻⁴⁰ Our
 analysis produced contradictory results in that a change from adequate sleep to
 inadequate sleep would reduce BMI but increase obesity progression. Moreover, we

13

For peer review only - http://bmjopen.bmj.com/site/about/guidelines.xhtml

1 2		
3	314	did not detect any significant association between sleep and waist circumference. A
4 5	315	recent study has shown that unstable sleep patterns may increase the quantity of food
6 7	316	intake, ⁴¹ and our findings therefore require further investigation. The lack of
8 9	317	association between habitual smoking and BMI or metabolic syndrome has been
10 11	318	reported in previous studies, ^{7,42} which corroborates our findings.
12 13	319	This study has several limitations that should be considered. First, this study
14 15	320	utilized health checkup data from health insurance societies. As a result, the data may
16 17	321	not have included a large proportion of the insurance enrollees' dependents. In
18 19	322	particular, there was a relatively small proportion of older adults in our study
20 21	323	population. The results may therefore lack generalizability to other subpopulations.
22 23	324	Second, eating speed and the other lifestyle habits were self-assessed, and may
24 25	325	therefore be vulnerable to reporting bias. However, while the differences in
26 27	326	perceptions of eating and sleeping habits in standardized questionnaires have been
28 29	327	described, ⁴³ Sasaki <i>et al.</i> reported that there was no difference between the eating
30 31	328	speeds assessed by study subjects or by friends of the subjects. ²⁵ In addition, our
32 33	329	findings are consistent with those of a previous study that used objective measures of
34 35	330	eating speed and found that slower eating speeds were associated with greater weight
36 37	331	loss. ³⁰ Thirdly, we did not include an analysis of physical exercise and energy intake,
38 39	332	which may be potential confounders. Nevertheless, a previous analysis has reported
40 41	333	that eating speed was associated with obesity regardless of the level of physical
42 43	334	activity. ²⁶ Other studies have also reported similar associations between eating speed
44 45	335	and BMI given similar overall food intake, which corroborates our findings. ^{24,25}
46 47	336	Therefore, these 2 factors are unlikely to be confounders in this study despite their
48 49	337	association with BMI. Finally, the sample comprised relatively health-conscious
50 51	338	individuals who voluntarily participated in health checkups. The findings may
52 53	339	therefore have limited applicability to less health-conscious people.
54 55	340	Many studies have shown that eating habits are associated with BMI and weight
56 57	341	gain. ^{7,8,18-31} However, this study utilized panel data to show that changes in eating
58 59		14
60		For peer review only - http://bmjopen.bmj.com/site/about/guidelines.xhtml

BMJ Open

2		
2 3	342	habits have a strong relationship with obesity, BMI, and waist circumference. These
4 5	343	findings indicate that weight loss can be supported through the reduction of eating
6 7	344	speed, the cessation of eating dinner within 2 hours before sleeping, the cessation of
8 9	345	snacking after dinner, and consistently having breakfast.
10 11	346	
12 13	347	Conclusions
14 15	348	Changes in eating habits can affect obesity, BMI, and waist circumference.
16 17	349	Interventions aimed at altering eating habits, such as education initiatives and
18 19	350	programs to reduce eating speed, may be useful in preventing obesity and reducing
20 21	351	the risk of noncommunicable diseases.
22 23	352	programs to reduce eating speed, may be useful in preventing obesity and reducing the risk of noncommunicable diseases.

	Item No.	Recommendation	Page No.	Relevant text fron manuscri
Title and abstract	1	(a) Indicate the study's design with a commonly used term in the title or the abstract	Page 1: Title	
		(b) Provide in the abstract an informative and balanced summary of what was done and what was found \wedge	Page 2: Abstract	
Introduction				
Background/rationale	2	Explain the scientific background and rationale for the investigation being reported	Page 4: Lines 72-77&Lines 84-86	
Objectives	3	State specific objectives, including any prespecified hypotheses	Page 4: Lines 90-92	
Methods				
Study design	4	Present key elements of study design early in the paper	Page 5: Lines 111-120	
Setting	5	Describe the setting, locations, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection	Page 4-5: Lines 95-109	
Participants	6	 (a) Cohort study—Give the eligibility criteria, and the sources and methods of selection of participants. Describe methods of follow-up Case-control study—Give the eligibility criteria, and the sources and methods of case ascertainment and control selection. Give the rationale for the choice of cases and controls Cross-sectional study—Give the eligibility criteria, and the sources and methods of selection of participants 	Page 5: Lines 112-114	
		(b) Cohort study—For matched studies, give matching criteria and number of exposed and unexposed Case-control study—For matched studies, give matching criteria and the number of controls per case	Not Applicable	
Variables	7	Clearly define all outcomes, exposures, predictors, potential confounders, and effect modifiers. Give diagnostic criteria, if applicable	Page 5-6: Lines 122-157	
Data sources/ measurement	8*	For each variable of interest, give sources of data and details of methods of assessment (measurement). Describe comparability of assessment methods if there is more than one group	Page 4-5: Lines 95-109	
Bias	9	Describe any efforts to address potential sources of bias	Not Applicable	
Study size	10	Explain how the study size was arrived at	Not Applicable	
Continued on next page		1		

Quantitative	11	Explain how quantitative variables were handled in the analyses. If applicable, describe which	Page 5-6: Lines 122-157
variables		groupings were chosen and why	
Statistical	12	(a) Describe all statistical methods, including those used to control for confounding	Page 7-8: Lines 159-179
methods		(b) Describe any methods used to examine subgroups and interactions	Not Applicable
		(c) Explain how missing data were addressed	Page 6: Lines 118-119
		(d) Cohort study—If applicable, explain how loss to follow-up was addressed	Not Applicable
		Case-control study-If applicable, explain how matching of cases and controls was addressed	
		Cross-sectional study—If applicable, describe analytical methods taking account of sampling	
		strategy	
		(<u>e</u>) Describe any sensitivity analyses	Not Applicable
Results			
Participants	13*	(a) Report numbers of individuals at each stage of study—eg numbers potentially eligible, examined	Page 6: Lines 181-187
		for eligibility, confirmed eligible, included in the study, completing follow-up, and analysed	
		(b) Give reasons for non-participation at each stage	Not Applicable
		(c) Consider use of a flow diagram	Not Applicable
Descriptive data	14*	(a) Give characteristics of study participants (eg demographic, clinical, social) and information on	Page 20: Table 1
_		exposures and potential confounders	-
		(b) Indicate number of participants with missing data for each variable of interest	Page 20: Lines 181-187
		(c) <i>Cohort study</i> —Summarise follow-up time (eg, average and total amount)	Page 20: Line 183-184
Outcome data	15*	Cohort study—Report numbers of outcome events or summary measures over time	Page 20: Table 1
		<i>Case-control study</i> —Report numbers in each exposure category, or summary measures of exposure	Page 20: Table 1
		Cross-sectional study—Report numbers of outcome events or summary measures	Page 20: Table 1
Main results	16	(a) Give unadjusted estimates and, if applicable, confounder-adjusted estimates and their precision	Page 21-22: Table 2 & Table 3
		(eg, 95% confidence interval). Make clear which confounders were adjusted for and why they were	C
		included	
		(b) Report category boundaries when continuous variables were categorized	Page 7: Lines 145-157
		(c) If relevant, consider translating estimates of relative risk into absolute risk for a meaningful time	Not Applicable
		period	Not Applicable

Other analyses	17	Report other analyses done-eg analyses of subgroups and interactions, and sensitivity analyses	Not Applicable
Discussion			
Key results	18	Summarise key results with reference to study objectives	Page 9-10: Lines 221-229
Limitations	19	Discuss limitations of the study, taking into account sources of potential bias or imprecision. Discuss	Page 12-13: Lines 291-311
		both direction and magnitude of any potential bias	
Interpretation	20	Give a cautious overall interpretation of results considering objectives, limitations, multiplicity of	Page 10: Lines 239-252
		analyses, results from similar studies, and other relevant evidence	
Generalisability	21	Discuss the generalisability (external validity) of the study results	Page 12: Lines 291-295
Other informat	ion		
Funding	22	Give the source of funding and the role of the funders for the present study and, if applicable, for the	Page 14: Lines 324-326
