Fig. S1. Conduit diameter-stem length scaling and the WBE model. (A) The model of West, Brown and Enquist (1999) (1) depicts plants as made up of cylindrical segments. The rules at left specify the dimensions of stem segments (white cylinders), which contain conduits (black cylinders, shown outside the stem for clarity). γ specifies the length l of a segment k relative to the length of the segment subtending it, $k+1$. n is the number of branches at each branching node (for simplicity and to highlight the stem tip-to-base length of the conductive path, in the drawing at right we only show a single branch at each node). r_k is the branch segment radius, and d_k the conduit radius. In a way analogous to γ , β specifies the relative diameters of the stem segments, and $\bar{\beta}$ specifies conduit diameter. a and \bar{a} relate branch and conduit transectional area between segments. (B) In the idealized WBE plant, $a=1$, implying area-preserving branching, $\bar{a}=1/6$, minimizing the accumulation of hydraulic resistance with increasing total plant height (1), and $n=2$, implying bifurcation at each node (again, we show only one branch at each node because branching does not affect the longest base-to-tip conductive distance). Given these values, assuming a tree with a terminal twig diameter of 5.5 mm and 20 branching generations results in a range of conduit diameters very similar to those observed in nature. Plotting these conduit diameters against the accumulated distance to the stem tip (i.e. summing l_k from the stem tip) results in a power-law like function with a scaling exponent of approximately 0.2. Poiseuille's law shows that conduit diameter-stem length exponents of 0.25 or slightly above should minimize the accumulation of hydraulic resistance with height growth while minimizing embolism risk and conduit construction costs (1–10). Our empirical results across angiosperm climates, habits, and lineages fall strikingly within this range.

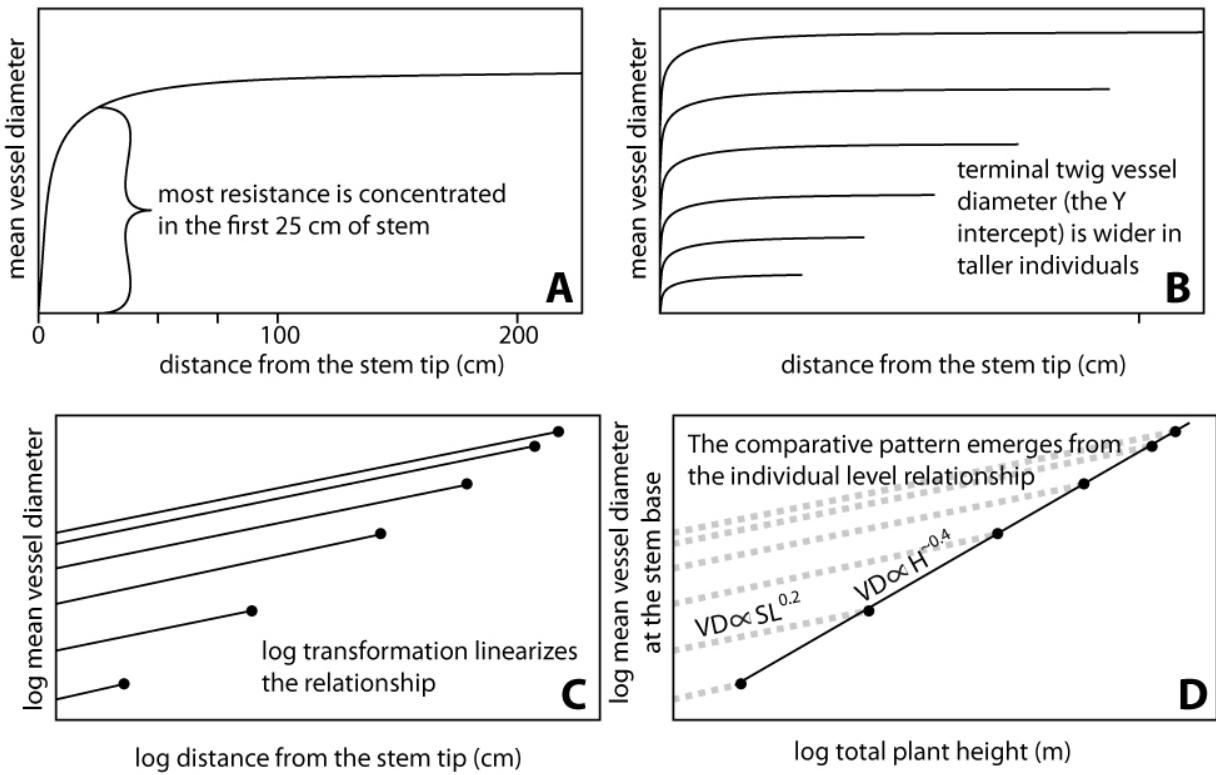

Fig. S2. Schematics illustrating the relationship between within-individual patterns of longitudinal vessel widening from the stem tip to the base, and across-species studies of vessel diameter at the stem base. (A) The relationship between vessel diameter and distance from the stem tip within a single individual approximates a power law of the form $VD \propto SL^a$, where a is usually about 0.2-0.26 (10). Most of the change in vessel diameter occurs within the first 25 cm or so of twig. This means that most of the resistance in the stem is concentrated in the terminal portions of branches, and that vessel diameter increase is relatively slow in large branches and along the bole. It also means that vessel diameter, and functional properties that depend on it such as embolism vulnerability, change more rapidly in small plants than in large plants for a given unit of height increase. (B) Our data indicate that in angiosperms terminal twig vessel diameter increases with height growth (Fig. 2). This implies that, if the tip-to-base vessel diameter profile were traced for the same individual as it grows in height, the Y-intercept would increase as its maximum height increases (the right end of each curve indicates the total height of the plant). (C) Because the vessel diameter-distance from the stem tip relationship approximates a power law, log transformation linearizes it effectively. The black dots represent the vessel diameter found at the stem base, to show how the within-individual slope is related to the across-species slope. (D) Plotting mean vessel diameter at the stem base against plant height, which we did here (Fig. 2), results in a relationship of similar form as the within-individual relationship (which usually has a slope of 0.2 or slightly above, log transformed shown here), but of steeper slope (usually of about 0.4 or slightly above, as recovered in the present study). We standardized by tip vessel diameter, and the resulting interspecific slope fell within the usual intra-individual range. In this way, the cross species patterns we studied here (D) are related straightforwardly to the intraspecific ontogenetic pattern described by each individual (A-C).

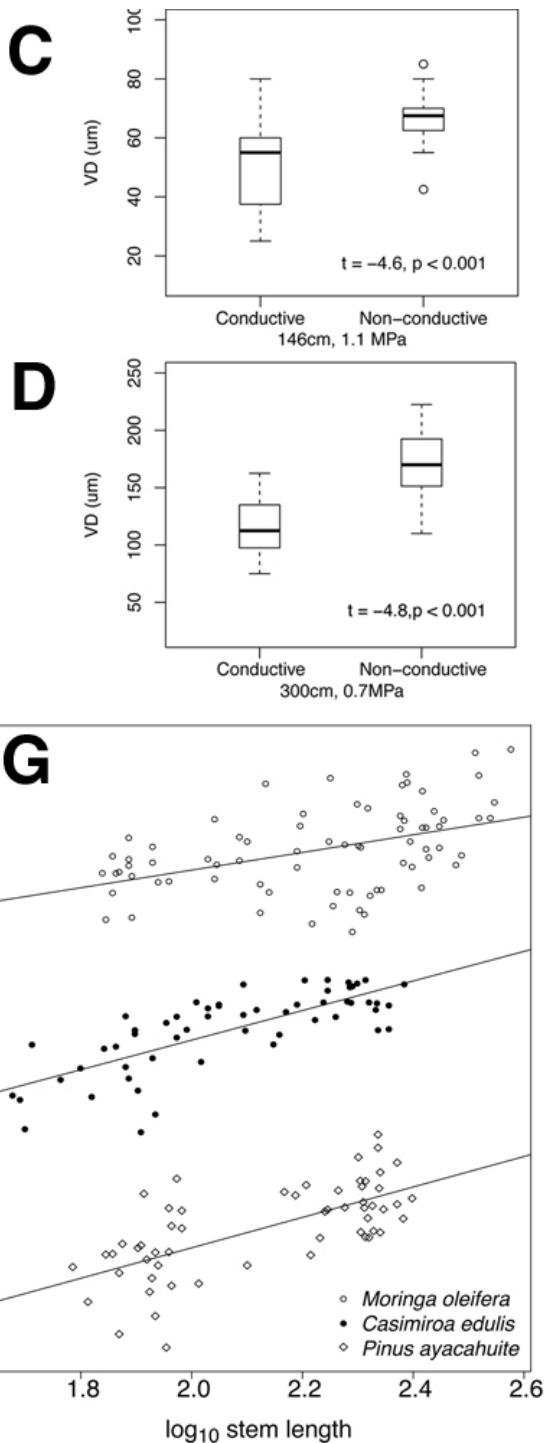

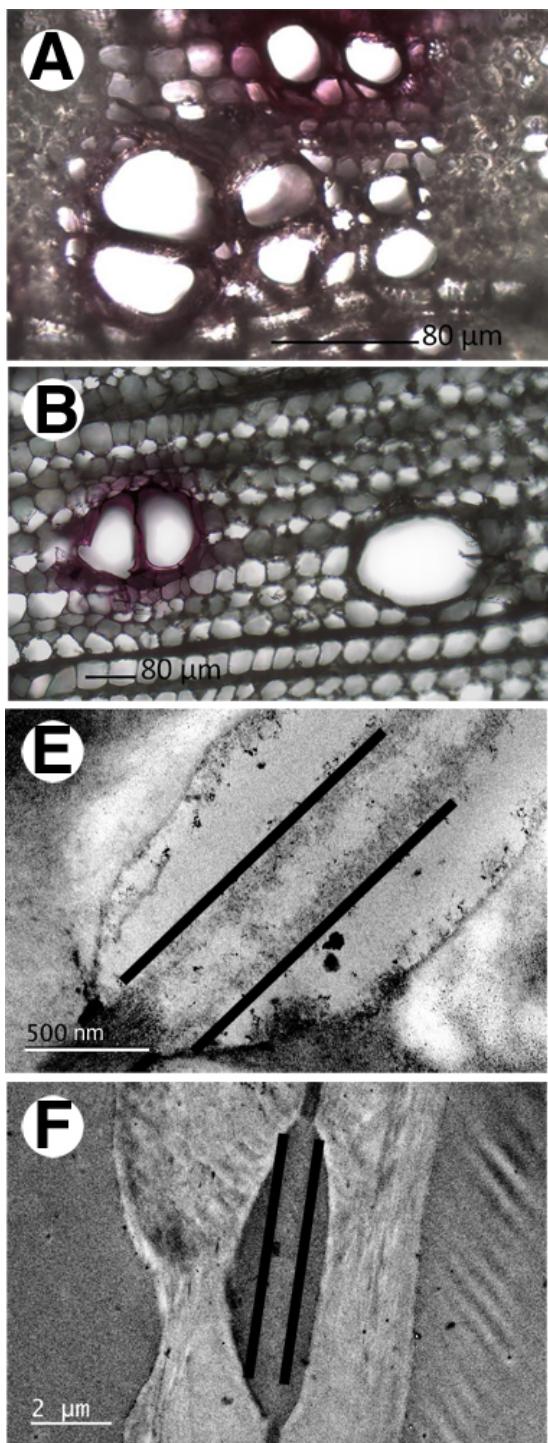

Fig. S3. Vessel diameter-stem length relations in *Moringa oleifera*, *Casimiroa edulis*, and *Pinus ayacahuite*, perfusion experiments, and intervessel pit membrane thickness. (A,B) Xylem transections following perfusion experiments showing that wider vessels on average embolize before narrow ones. We exposed different stems to different xylem tensions, provoking differing levels of embolism, and then perfused stem segments with acid fuchsin. Stain surrounding vessels indicates that they were conductive, unstained

embolized ones. Taller plants have wider vessels, and are thus more vulnerable than shorter conspecifics, and wider vessels within size classes embolize first. (A) *Casimiroa edulis*, functional vessels at top, (B) *Moringa oleifera*, functional vessels at left. (C, D) Graphs showing that after exposing stems to a given tension, embolized vessels are significantly wider than the functional vessels. (C) *Casimiroa edulis*, (D) *Moringa oleifera*. (E, F) Transmission electron micrographs of intervessel pit membranes in xylem transverse sections, showing that *Casimiroa edulis* (E), which for a given height is more resistant to embolism than *Moringa oleifera* (F), has thicker intervessel pit membranes. (G) While conduit diameter scaled broadly similarly across the three species in our plantation experiment, *Moringa oleifera*, with its very low wood density, had the widest vessels for a given height, and *Casimiroa edulis*, with its higher wood density, had narrower vessels for a given height. *Pinus ayacahuite* conducts water in tracheids, rather than vessels, and tracheids are much narrower for a given height than vessels.

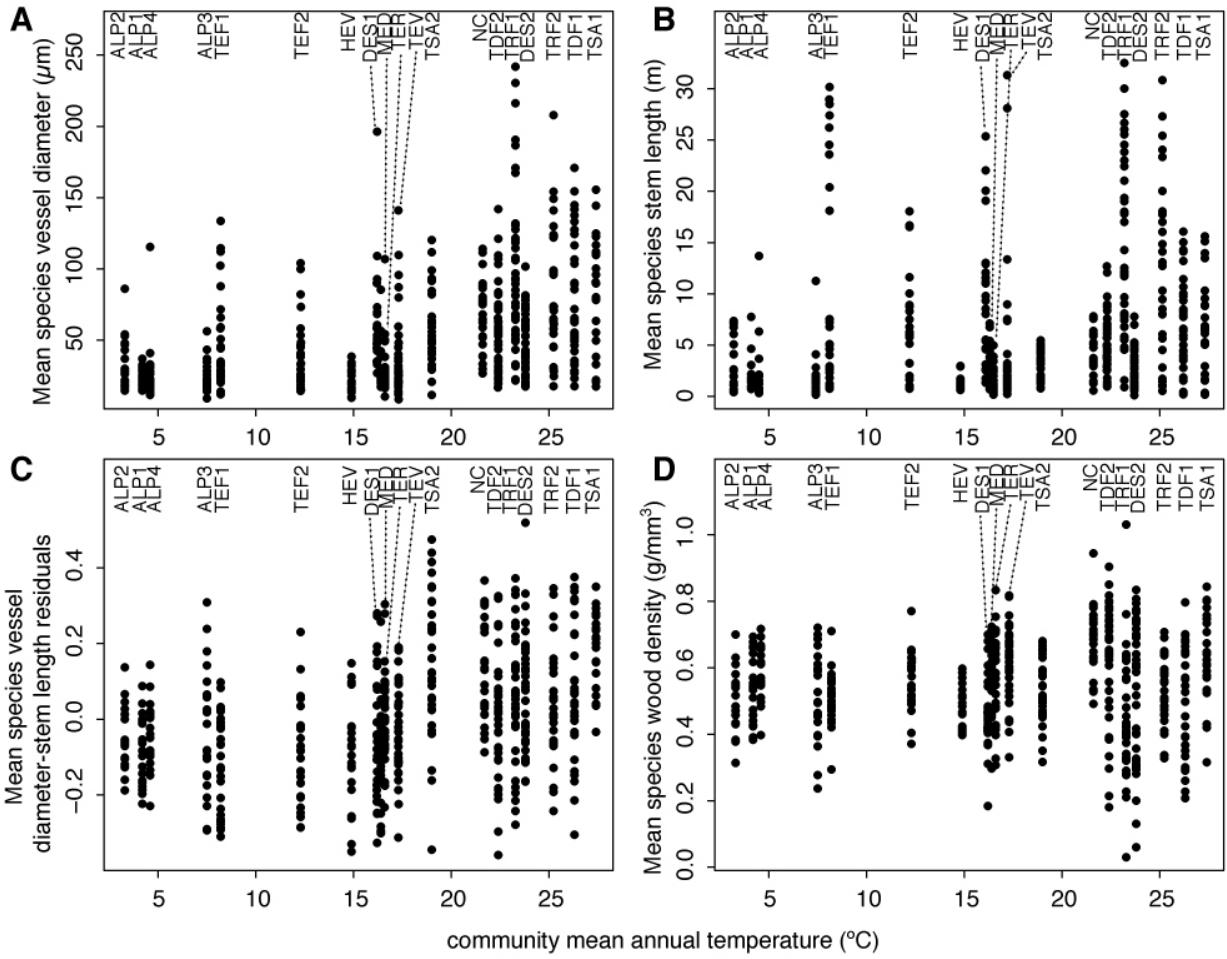

Fig. S4. Variance in vessel diameter, plant size, and wood density with temperature across communities. (A,B) The distribution of raw vessel diameter across communities closely paralleled that of plant height. (C) Correcting for stem size reveals that the relatively narrowest vessels are found not in cold but in warmer communities, where the relatively widest vessels were also found. A very slight tendency for wider vessel diameter in warmer climates can be seen. (D) Warmer communities not only had wider ranges of size-corrected vessel diameter but also of wood density. Because species with lower density have wider vessels, the patterns in wood density variance and size-corrected vessel diameter parallel one another. Community codes are from Extended Data Table 1.

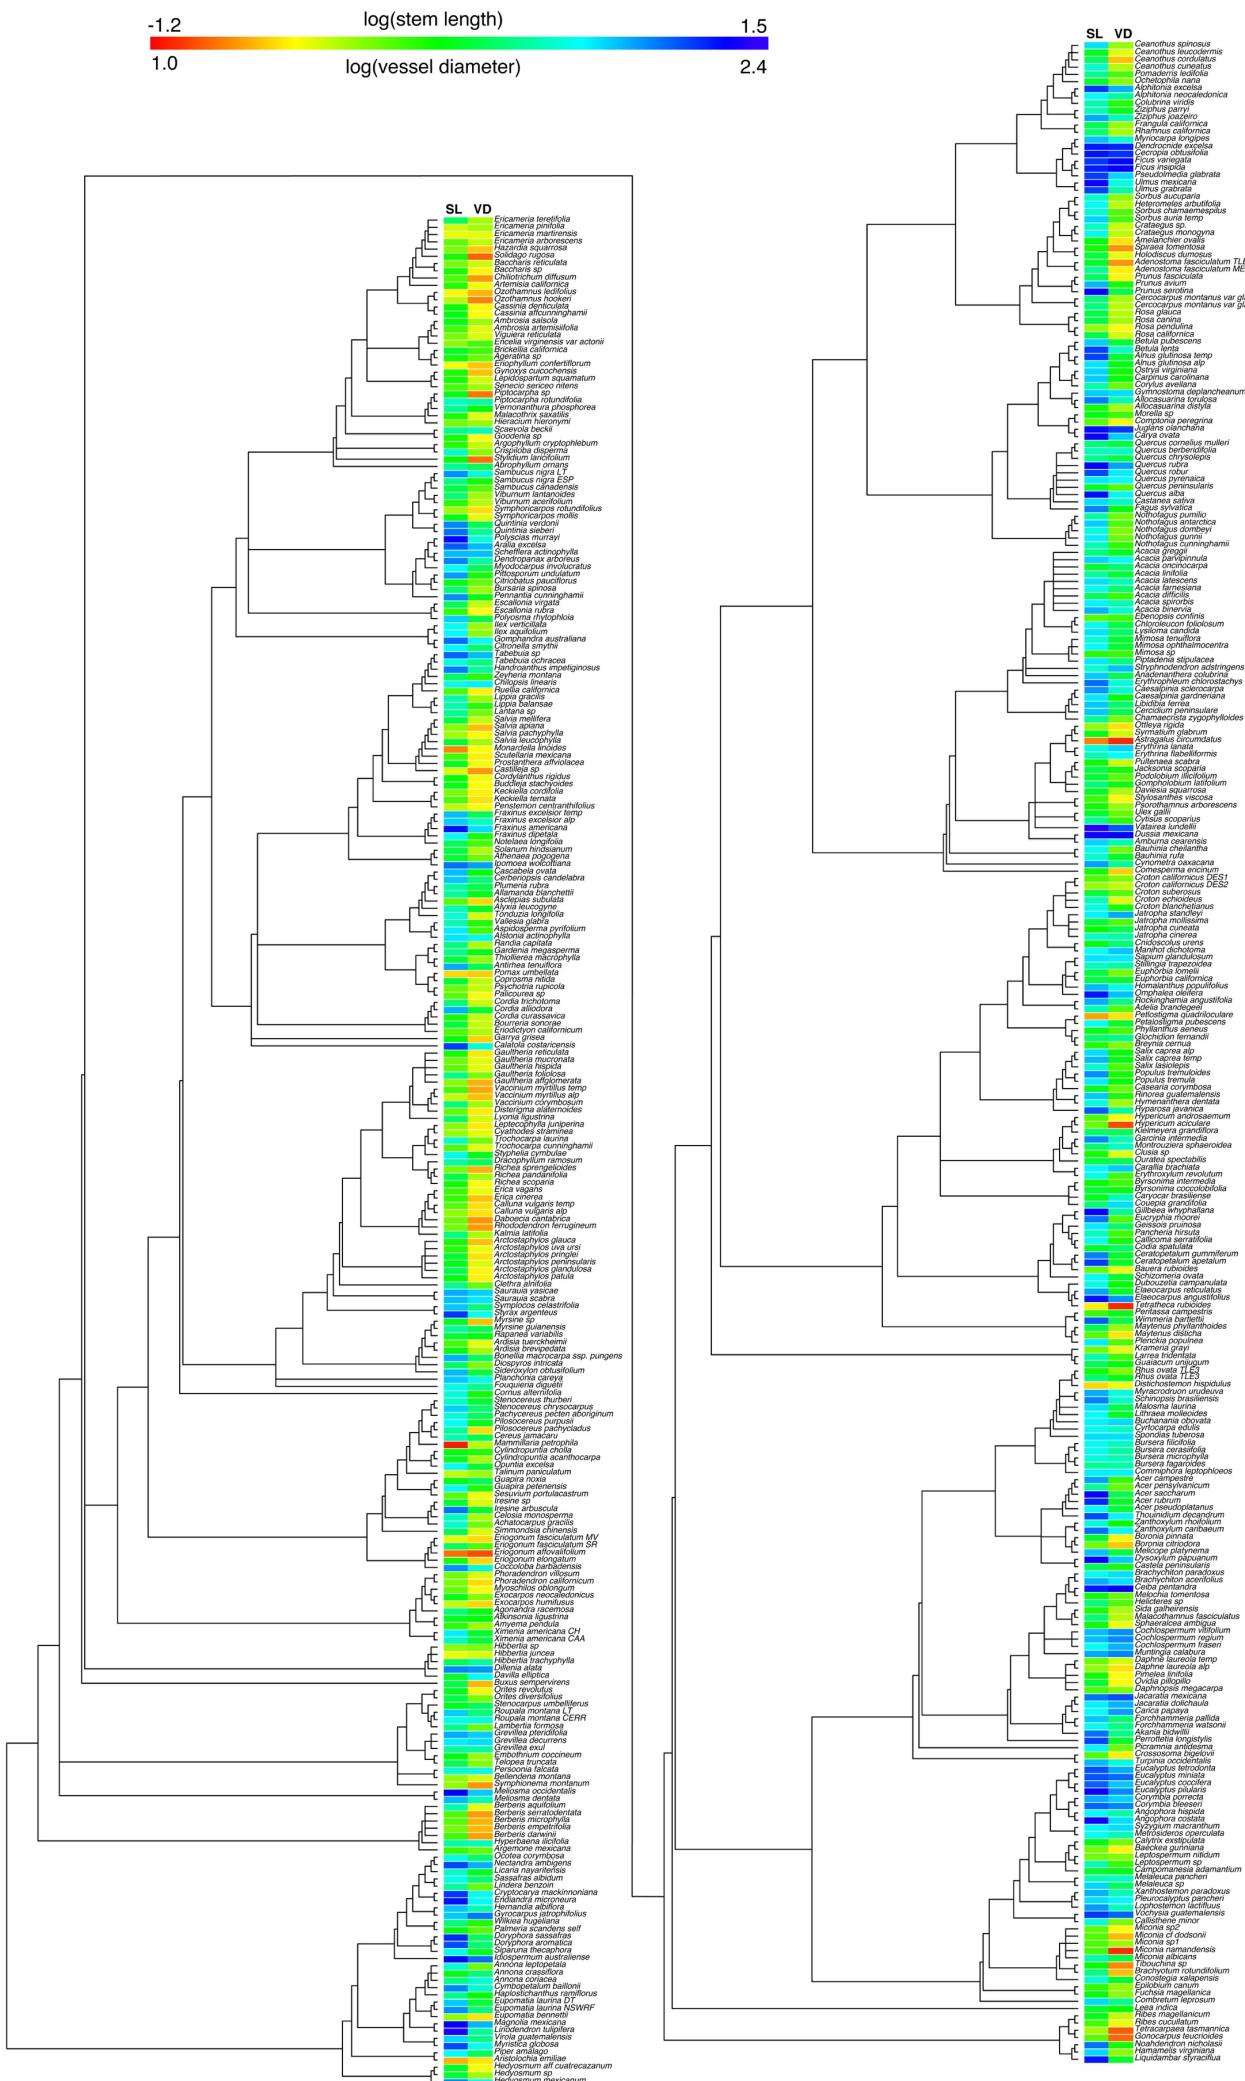

Fig. S5. Phylogenetic relationships of the studied species and phylogenetic distribution of vessel diameter and stem length. Colors represent the values of \log_{10} vessel diameter (VD) and plant height (SL), to show that colors usually covary independently of the values of the phylogenetic neighbors of a given species.

Table S1. Communities studied, ordered from low to high mean annual precipitation (MAP), with coordinates, mean annual temperature (MAT), mean basal vessel diameter (VD_{base}), and mean stem length (SL), with ranges in parentheses
