### SUPPLEMENTARY REFERENCES

## SUPPLEMENTARY METHODS

### *Data Source*

Data were acquired from the National Cancer Data Base (NCDB), a tumor registry maintained by the American Cancer Society and the Commission on Cancer of the American College of Surgeons. The NCDB records data from more than 1500 hospitals, capturing roughly 70% of all cancer cases treated in the United States. All current NCDB head and neck participant user files were evaluated, covering from 2004 to 2013. This study was deemed exempt by the Cedars-Sinai institutional review board.

### *Statistical analysis*

Data patterns for the variables with missing values were examined using the method proposed by Little.<sup>1</sup> Missing rates were 31.6% for extranodal extension (ENE), 12.7% for LN size, 7.4% for lower neck LN involvement, and 0.1%-3.6% for other covariates. The data was found to be not missing completely at random (MCAR). To mitigate the possibility of bias related to missing data, missing values were imputed using fully conditional specification using the multivariate imputation by chained equations (MICE) algorithm under the missing at random (MAR) assumption.<sup>2,3</sup> Thirty complete data sets were generated and analyzed separately. Results were combined using the formula given in Rubin.<sup>4</sup>

The study's primary endpoint was overall survival (OS), defined as the time from diagnosis to death. Patients not experiencing an event were censored at the time of last follow-up. Baseline patient characteristics were compared between nodal status (N0 vs. N+) with Wilcoxon rank-sum test or chi-squared test, where appropriate. Median follow-up was calculated via the reverse Kaplan-Meier method.<sup>5</sup> Survival curves were calculated using the Kaplan-Meier method and compared with a log-rank test.<sup>6</sup> Univariate and multivariable survival analyses were performed with Cox proportional hazards models.<sup>7</sup> Multivariable models were constructed using a stepwise variable selection procedure based on Akaike Information Criterion (AIC).<sup>8</sup> Final multivariable models were chosen based on the lowest AIC value. In multivariable analyses, the possibility of multicollinearity was assessed by examining tolerance and the variance inflation factor (VIF). Two-way interaction effects between variables in relation to OS were examined. The proportional hazards assumption was assessed with scaled Schoenfeld residuals.<sup>9</sup> Stratified Cox regression models were used to account for covariates violating the proportional hazards assumption. The set S of covariates included in the multivariable model in **eTable 2** were common to all models fitted to the 30 imputed data sets. Each multivariable model from the 30 imputed data sets had between 0 and 3 additional covariates to the list in the set S. Likelihood ratio tests were carried out to compare each full model to the reduced model that has the set S of covariates and the results were not statistically significant.

Given the non-linear relationship between number of positive LNs and OS, a restricted cubic spline function was employed to model this relationship. The optimal number of knots was chosen based on the lowest AIC.<sup>10</sup> Three knots were placed at 1, 3, and 9 positive metastatic LN corresponding to 55<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles, respectively, due to their right-skewed distribution. Hazard ratios were estimated with Cox proportional hazards models stratified on postoperative radiation and adjusted for age, gender, tumor site, insurance status, income, Charlson/Deyo comorbidity index, T-

classification, number of positive metastatic LN with three knots, number of LN examined, extranodal extension (ENE), margins, and postoperative chemotherapy. A change point in the number of positive metastatic LN was estimated with a piecewise linear regression model.<sup>25</sup>

Recursive partitioning analysis (RPA)<sup>11,12</sup> with independent nodal predictors of mortality (i.e., number of positive LN and ENE) was used to create a novel nodal classification system in patients with a determinable AJCC 8E stage. A conditional inference tree was estimated by the optimized binary recursive partitioning based on a permutation test with a quadratic form of the standardized log-rank statistic with Bonferroni-adjusted p-values for multiple comparisons. The performance of the multivariable models with the proposed N-classification system derived from RPA and AJCC 8E N-classification were assessed with c-indices.<sup>10</sup> Internal validation was performed by estimating and correcting possible optimism in c-indices using the bootstrap method with 1000 replicates.<sup>13,14</sup>

Statistical analyses were performed using SAS 9.3 (SAS Institute, Inc., Cary, North Carolina) and R package version 3.3.2 (*mice*, *rms*, *survival*, *SiZer*, *party* libraries)<sup>15</sup>, with two-sided tests and a significance level of 0.05.

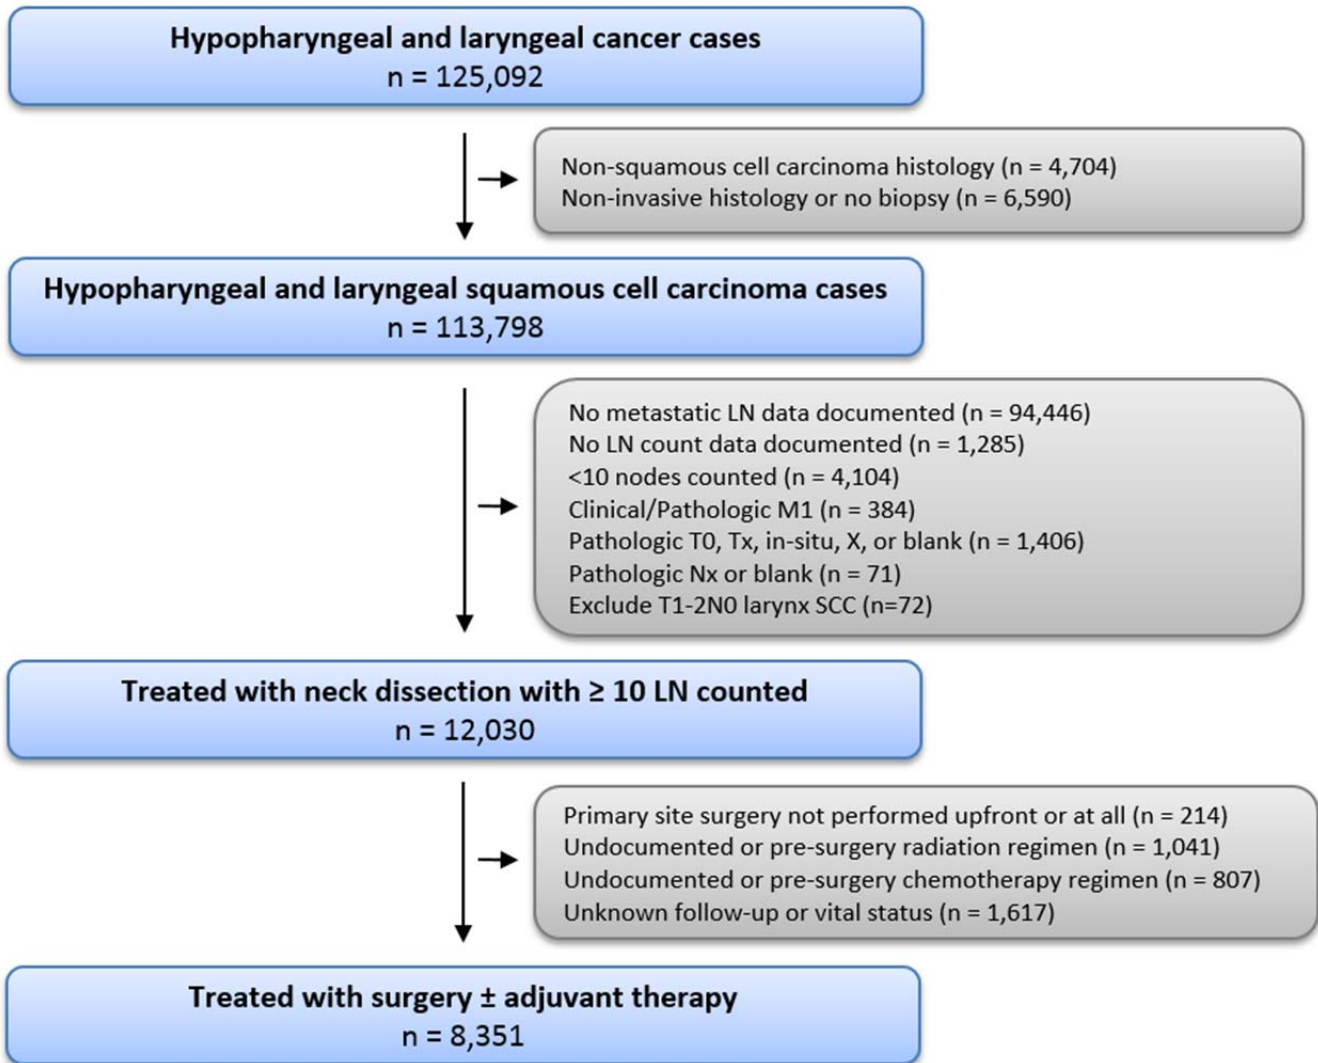

## SUPPLEMENTARY RESULTS

In multivariable analyses, no evidence of multicollinearity was found. We also examined all possible two-way interaction effects between covariates included in the multivariable model (total 66 interaction terms). Three of these interaction terms were found to be statistically significant, including the interaction between (1) number of positive metastatic LN and tumor site, (2) number of LN examined and margins, and (3) gender and tumor site.

Because of the significant interaction between anatomic site and number of positive LN, we analyzed the larynx and hypopharynx subgroups separately. Although both sites had a change point identified at 5 LN, the impact of number of positive LN was stronger for larynx cancer (HR 1.21, 95% CI 1.17-1.25,  $p < 0.001$ ) than for hypopharynx cancers (HR 1.10, 95% CI 1.17-1.25,  $p < 0.001$ ) for each LN  $\leq 5$  (**eTable 4**). The reverse pattern was seen for each positive LN  $> 5$  when comparing larynx (HR 1.01, 95% CI 1.00-1.02,  $p = 0.046$ ) and hypopharynx cancer (HR 1.03, 95% CI 1.01-1.05,  $p < 0.001$ ).

Similarly, we analyzed the impact of number of LN examined separately for subgroups of patients with negative versus positive margins. Although there was a significant benefit from increased number of LN examined without evidence of change point in both groups of patients, the impact was greater in patients with positive margins (HR 0.92 per 10 LN, 95% CI 0.88-0.95,  $p < 0.001$ ) than in those with negative margins (HR 0.98 per 10 LN, 95% CI 0.97-1.00,  $p = 0.023$ ). Gender was also associated with an improved OS in larynx cancer female patients (HR 0.75, 95% CI 0.69-0.82;  $p < 0.001$ ) while there was no difference in OS between male and female in hypopharynx cancer patients (**eTable 5**).

Number of LN examined (per 10 LN) <sup>b</sup>	0.98 (0.97-0.98)	0.001	0.97 (0.96-0.98)	<.001
Missing data were imputed by multiple imputation.				
<sup>a</sup> Multivariable models were stratified on postoperative radiation and adjusted for age, gender, tumor site, insurance status, income, Charlson/Deyo comorbidity index, AJCC T-Classification, number of LN examined, extranodal extension, margins, and postoperative chemotherapy.				
<sup>b</sup> Multivariable model was stratified on postoperative radiation and adjusted for age, gender, tumor site, insurance status, income, Charlson/Deyo comorbidity index, AJCC T-Classification, number of positive LN with three knots at 1, 3, and 9 LN corresponding to 55 <sup>th</sup> , 75 <sup>th</sup> and 95 <sup>th</sup> percentiles, respectively, extranodal extension, margins, and postoperative chemotherapy.				

**eTable 4.** Summary of hazard ratios for positive metastatic lymph nodes, stratified by hypopharyngeal or laryngeal cancer site and change point. LN, lymph nodes

Variable	Univariate		Multivariable	
	Hazard Ratio (95% CI)	p-value	Hazard Ratio (95% CI)	p-value
Number of positive metastatic LN (per 1 LN) In larynx patients (N=7,019)				
> 5 LN+	1.01 (1.00-1.02)	0.011	1.01 (1.00-1.02)	0.046
≤ 5 LN+	1.22 (1.19-1.25)	<.001	1.21 (1.17-1.25)	<.001
In hypopharynx patients (N=1,332)				
> 5 LN+	1.03 (1.01-1.04)	<.001	1.03 (1.01-1.05)	<.001
≤ 5 LN+	1.11 (1.05-1.16)	<.001	1.10 (1.03-1.18)	0.005
Missing data were imputed by multiple imputation. Multivariable models were stratified on postoperative radiation and adjusted for age, gender, insurance status, income, Charlson/Deyo comorbidity index, AJCC T-Classification, number of LN examined, extranodal extension, margins, postoperative chemotherapy, and interaction term between number of LN examined and margins.				

**eTable 5.** Summary of hazard ratios for number of lymph nodes examined stratified by margin status, and for gender stratified by hypopharynx or larynx cancer site. LN, lymph nodes

Variable	Multivariable	
	Hazard Ratio (95% CI)	P-value
Interaction between number of LN examined and margins		
Number of LN examined (10 units) in negative margins	0.98 (0.97-1.00)	0.023
Number of LN examined (10 units) in positive margins	0.92 (0.88-0.95)	<.001
Interaction between gender and cancer site		
Female vs. male in larynx	0.75 (0.69-0.82)	<.001
Female vs. male in hypopharynx	1.07 (0.89-1.28)	0.502
Missing data were imputed by multiple imputation. Multivariable models were stratified on postoperative radiation and adjusted for age, gender, insurance status, income, Charlson/Deyo comorbidity index, AJCC T-Classification, number of LN examined, extranodal extension, margins, postoperative chemotherapy, and three interaction terms between number of positive metastatic LN and tumor site, gender and tumor site, and number of LN examined and margins.		

**eTable 6.** Multivariable analyses with proposed N-Classification system and AJCC 8<sup>th</sup> Edition N-Classification system in hypopharyngeal and laryngeal cancer.
