

# BMJ Open

BMJ Open is committed to open peer review. As part of this commitment we make the peer review history of every article we publish publicly available.

When an article is published we post the peer reviewers' comments and the authors' responses online. We also post the versions of the paper that were used during peer review. These are the versions that the peer review comments apply to.

The versions of the paper that follow are the versions that were submitted during the peer review process. They are not the versions of record or the final published versions. They should not be cited or distributed as the published version of this manuscript.

BMJ Open is an open access journal and the full, final, typeset and author-corrected version of record of the manuscript is available on our site with no access controls, subscription charges or pay-per-view fees (<http://bmjopen.bmj.com>).

If you have any questions on BMJ Open's open peer review process please email [info.bmjopen@bmj.com](mailto:info.bmjopen@bmj.com)

## ABSTRACT

**Objectives:** Development of digital biomarkers to predict treatment response to a digital behavioral intervention.

**Design:** Machine learning using random forest classifiers on data generated through the use of a digital therapeutic which delivers behavioral therapy to treat cardiometabolic disease. Data from 13 explanatory variables (biometric and engagement in nature) generated in the first 28 days of a 12-week intervention were used to train models. Two levels of response to treatment were predicted: 1) systolic change  $\geq 10$  mmHg (SC model), and 2) shift down to a blood pressure category of elevated or better (ER model). Models were validated using leave-one-out cross-validation and evaluated using area under the curve receiver operating characteristics (AUROC) and specificity-sensitivity. Ability to predict treatment response with a subset of 9 variables, including app use and baseline blood pressure was also tested (models SC-APP and ER-APP).

**Setting:** Data generated through ad libitum use of a digital therapeutic in the United States.

**Participants:** De-identified data from 135 adults with a starting blood pressure  $\geq 130 / 80$ , who tracked blood pressure for at least 7 weeks using the digital therapeutic.

**Results:** The SC model had an AUROC of .82 and a sensitivity of 58% at a specificity of 90%. The ER model had an AUROC of .69 and a sensitivity of 32% at a specificity at 91%. Dropping explanatory variables related to blood pressure resulted in an AUROC of .72 with a sensitivity of 42% at a specificity of 90% for the SC-APP model and an AUROC of .53 for the ER-APP model.

**Conclusions:** Machine learning was used to transform data from a digital therapeutic into digital biomarkers that predicted treatment response in individual participants. Digital biomarkers have potential to improve treatment outcomes in a digital behavioral intervention.

## ARTICLE SUMMARY

### Key messages

- Digital biomarkers can be created using machine learning to predict therapeutic response and dynamically adjust treatment parameters.
- Predictive models can be used to generate and communicate clinically actionable insights.
- Digital biomarkers have potential to improve treatment outcomes in digitally delivered behavioral interventions.

### Strengths and limitations of this study

- Practical applications of digital biomarkers in the treatment of cardiometabolic diseases are presented.
- Proof of concept biomarkers demonstrated predictive power despite the small size of the training dataset.

## INTRODUCTION

Modifiable behaviors are responsible for 70% or more of all cardiometabolic diseases.[1–3] Health systems are ill equipped to address the current epidemic of cardiometabolic diseases and, in particular, lack widely available behavioral therapies to address the common root causes of these conditions. Digital therapeutics, software designed to encourage changes in behaviors which treat disease, offer a means to deliver behavioral therapy to large populations and preliminary studies demonstrate their potential as a cost-effective treatment for cardiometabolic disease.[4–6]

Compared to pharmacotherapy, digital therapeutics offer potential advantages such as ease of access, ease of use, fewer side-effects and cost-effectiveness.[4, 7–9] Digital therapeutics also generate readily accessible patient data without requiring an office or lab visit. The data generated are voluminous and vary in both type and quality. These can include remotely sensed measures of physiology (e.g., blood pressure, blood glucose, heart rate variability), behavioral data (e.g., about eating, moving, thinking), medication adherence, as well as engagement parameters of unknown significance (e.g., app use, geographic location, circadian patterns of use).

The best use of these data remains an open question. Feeding data directly into EMRs is of limited utility to providers or patients. Whereas, transforming the data into markers of disease status, termed digital biomarkers[10] could provide clinically actionable insights with or without conventional biometric data.[11–13] Digital biomarkers afford a pragmatic approach to remotely monitor patients and intervene on a continuous rather than episodic basis. Greatly expanding opportunities to intervene means that patients have greater access to personalized care, which could improve treatment outcomes.[14, 15]

Machine learning, a type of artificial intelligence (AI) used to make predictions with large and complex datasets, offers a novel approach for creating digital biomarkers. The exponential growth of smartphone use in the United States and advancing interoperability standards allow for digital biomarkers to be compiled across diverse populations and data sources. As a result, the opportunity to advance digital biomarker methodologies has never been greater.[16, 17]

Machine learning is particularly valuable when there is ambiguity about what variables, or to what extent a set of variables predict an outcome of interest. Such ambiguity is inherent to behavioral interventions, like those used in the treatment of cardiometabolic disease. Human behavior results from a complex interaction between the anthropogenic features of our living environment, genetic and epigenetic determinants of behavior, neurobiology, social influences and to some degree chance events.[18–21] While clinical experience and the scientific literature can identify many variables that influence behavior, the interplay of these variables in a given individual and their environment is difficult for a clinician or patient to discern. This ambiguity

1  
2  
3 limits enthusiasm for behavioral interventions because it makes it difficult for clinicians and  
4 patients to rely on behavioral therapy to achieve a predictable level of therapeutic response.  
5  
6

7 Digital biomarkers can reduce ambiguity by predicting current and forecasting future disease  
8 status during the course of treatment.[22–24] Digital biomarkers that serve as markers of current  
9 disease status allow for tailoring or adjusting treatment between clinic visits (e.g., when a patient  
10 is not doing as well as expected). Similarly, markers of future disease status enable preemptive  
11 action, such as adding or subtracting additional treatments, or taking preventive steps to avoid  
12 complications of the disease.[13, 24]  
13  
14  
15

16 In this paper, we present our ongoing work to develop digital biomarkers and aim to illustrate  
17 their utility in digitally-delivered behavioral interventions to both the patient and prescribing  
18 clinician. We describe the analytic process to show that the development of digital biomarkers  
19 requires a hypothesis-driven approach, particularly when datasets are small. Finally, using actual  
20 examples of digital biomarkers intended to predict blood pressure status, we discuss the practical  
21 and ethical considerations involved in both developing and applying digital biomarkers using  
22 machine learning.

25  
26

## 27 **METHODS**

### 28 **Digital Therapeutic**

29 The digital biomarkers discussed in this paper were generated using data from a digital  
30 therapeutic created by Better Therapeutics LLC (San Francisco, CA), a developer of prescription  
31 digital therapeutics for the treatment of cardiometabolic diseases.  
32  
33  
34

35 The digital therapeutic integrates a mobile medical application (“app”) that delivers behavioral  
36 therapy with the support of a remote multidisciplinary care team. The app delivers a personalized  
37 behavior change intervention, including tools for goal setting, skill building, self-monitoring,  
38 biometric tracking and behavioral feedback designed to provide cognitive training and support  
39 the participant’s daily efforts to improve overall cardiometabolic disease status. The app  
40 facilitates the adoption of evidenced-based behavioral strategies, such as planning and self-  
41 monitoring, to increase physical activity and consumption of vegetables, whole grains, fruits,  
42 nuts, seeds, beans and other legumes.[25, 26]  
43  
44  
45  
46

47 Participants were over 18 years of age who self-identified with a diagnosis of hypertension, type  
48 2 diabetes and/or hyperlipidemia. Those reporting to have hypertension at enrollment were  
49 offered a free Omron 7 Series Upper Arm Blood Pressure Monitor (Omron Healthcare Inc,  
50 Kyoto, Japan) to use during the intervention and to keep at its conclusion. This 12-week  
51 intervention was available to all participants at no cost.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 This analysis of existing data from the digital therapeutic was approved and overseen by Quorum  
4 Review Institutional Review Board[27] and a waiver of informed consent was granted for this  
5 retrospective analysis.  
6  
7

### 8 **Constraining the Training Dataset**

9  
10 The clinical intent of this biomarker exploration was to generate digital biomarkers that could  
11 improve treatment outcomes in future participants with hypertension for whom blood pressure  
12 was not optimally controlled despite the use of pharmacological treatment. We first identified  
13 prior participants that met the following criteria: baseline blood pressure was 1) at or above the  
14 cutoff for stage I hypertension (systolic  $\geq 130$  or diastolic  $\geq 80$ )[25] and, 2) recorded no more  
15 than 2 weeks prior to or 2 weeks after the start of the intervention.  
16  
17  
18

19 The development of a predictive model using a training dataset requires all participants to have  
20 known outcomes. This is referred to as the “ground truth” in machine learning. In this case, the  
21 ground truth was change in blood pressure from baseline. Of the participants identified, we only  
22 included those with a follow-up blood pressure value in weeks 7 to 14 of the intervention.  
23  
24  
25

26 The training set also needs to be a valid representation of future experience to make sure the data  
27 sources present are sufficiently representative of those that will be collected in future  
28 participants. This is an important consideration because of the evolving nature of digital  
29 therapeutics. As the therapeutic is modified over time, the data types collected in earlier versions  
30 of the app could be different from those collected in later versions. Therefore, for the purpose of  
31 developing biomarkers that predict blood pressure status, we further constrained the training  
32 dataset to include participants who used versions of the app which enabled automatic blood  
33 pressure tracking.  
34  
35  
36  
37

### 38 **Choosing Response Variables and Training Window**

39 The intent of machine learning is to train an algorithm that can predict a specific outcome,  
40 termed the “response variable.” The response variable must be both clinically relevant and  
41 sufficiently, but not universally, prevalent in the population of interest. For example, if the  
42 outcome is “any degree of improvement”, but “any degree of improvement” occurs in  $> 95\%$  of  
43 participants in the training dataset, then a predictive model may appear to work well, but could  
44 actually be invalid.[28] Furthermore, “any improvement” is arguably less clinically meaningful  
45 than “a specific degree of improvement”.  
46  
47  
48  
49

50 To address these concerns, we chose response variables that were well distributed in the training  
51 dataset, as detailed in the results section, and were also clinically meaningful in the management  
52 of hypertension. Specifically, we chose to predict: 1) a systolic blood pressure improvement of  
53 10 mmHg or higher near the end of a 12-week intervention period (defined as 7 to 14 weeks after  
54 start), because 10 mmHg has been well demonstrated to be clinically meaningful[29, 30] and that  
55  
56  
57  
58  
59  
60

1  
2  
3 degree of change is near the mean for participants in the training dataset (66/135 participants);  
4 and 2) a reduction in blood pressure to the elevated range or below (systolic  $\leq 130$ ), because this  
5 level of blood pressure control would signal a clinician to stop adding additional pharmaceuticals  
6 or consider reducing or deprescribing pharmaceuticals (48/135 participants).[25]  
7  
8  
9

10 For a digital biomarker that predicts blood pressure status to be clinically useful, it needs to  
11 compute with data collected in a short period of time, and in less time than typically occurs  
12 between clinic visits. This means the biomarker could be used to intervene between office visits  
13 and could play a role in addressing clinical inertia that limits primary care providers ability to  
14 optimize blood pressure control in their patients.[31, 32] To demonstrate proof of concept, we  
15 chose a 28-day training interval, meaning that we trained machine learning models on the first 28  
16 days of patient data to evaluate whether it could predict blood pressure change in weeks 7 to 14.  
17 We hypothesized that data collected within this short training window could sufficiently  
18 represent changing behavioral patterns and treatment response, so as to predict future blood  
19 pressure status.  
20  
21  
22  
23

### 24 **Choosing Modeling Techniques and Explanatory Variables**

25 There are many valid methodologies for machine learning. These methods can be categorized by  
26 the type of learning involved - supervised or unsupervised. While a discussion on the merits and  
27 nature of each type is beyond the scope of this paper, it is important to select modeling  
28 techniques appropriate for the size of the dataset and nature of response variables chosen. For the  
29 biomarkers presented herein, we utilized random forest models, which is a form of supervised  
30 classification learning known to reduce overfitting in small datasets.[33] The models are  
31 supervised because the ground truth (i.e., actual blood pressure change) for each participant in  
32 the training dataset is labeled. The models are attempting to learn whether the classification was  
33 or was not achieved; for example, will a participant achieve a  $> 10$  mmHg blood pressure  
34 reduction, or not?  
35  
36  
37  
38  
39

40 In addition to classification labels, random forest models must be trained on a set of explanatory  
41 variables. For a small training dataset, each model must have a limited number of variables so as  
42 to avoid excess noise and overfitting that can lead to reduced generalizability. These explanatory  
43 variables must be selected by hypothesis. For example, we hypothesized that baseline blood  
44 pressure and achievement of behavioral goals would influence the degree of blood pressure  
45 change observed and used these as explanatory variables. In a large dataset, feature engineering  
46 can be used to identify the most predictive explanatory variables.  
47  
48  
49

50 For each biomarker model, denoted SC (systolic change of 10 mmHg or more) or ER (elevated  
51 range achieved), we used 13 explanatory variables, which can be categorized as engagement or  
52 biometric variables. Engagement variables are counts of actions related to the use of the digital  
53 therapeutic, including count of all meals reported, plant-based meals reported, physical activity  
54  
55  
56  
57  
58  
59

1  
2  
3 reported and length of exposure to the intervention. Biometric variables included baseline  
4 systolic, baseline diastolic, mean systolic and diastolic at training window end, initial systolic  
5 and diastolic change (end training mean - baseline), minutes of physical activity, and baseline  
6 Body Mass Index (BMI).  
7  
8

9  
10 We trained each biomarker model on data generated during a 28-day training window, starting  
11 with participant day 0 (sign up) up to day 28 (a third of the way through the studied 12-week  
12 intervention period). We utilized hyperparameter optimization to minimize overfitting and to  
13 achieve the maximal leave-one-out cross-validated area under the receiver operating  
14 characteristic curve for both models.  
15  
16

### 17 **Model Validation**

18  
19 Performance of each biomarker model was assessed using leave-one-out cross-validation, which  
20 is a common and valid technique for use in samples of this size.[34–36] This was done by  
21 training each model on N-1 samples of the data and then making a prediction on that one sample  
22 that was left out, producing an “out of sample” prediction for all N samples. The N predictions  
23 were pooled to generate the classification variables of the receiver operator characteristic curve  
24 (ROC), the area under the curve of the ROC (AUROC) and a confusion matrix of true versus  
25 predicted values.[37]  
26  
27  
28  
29

30 For each biomarker model, the ROC curve illustrates predictive ability of the response variable  
31 (in this case systolic change of 10 mmHg or move to a range of elevated BP) at different  
32 thresholds of discrimination. At each prediction discrimination threshold, the ROC displays the  
33 false positive rate (FPR) against the true positive rate (TPR). The FPR is the ratio of truly  
34 negative events categorized as positive (FP) to the total number of actual negative events (N).  
35 Specificity or true negative rate of a model is calculated as  $1 - \text{FPR}$  and is an indication of how  
36 well a model does in correctly identifying those who do not achieve a successful outcome, as  
37 defined by the response variable.  
38  
39  
40

41  
42 Since the intended application of these biomarkers is analogous to a diagnostic test, which are  
43 traditionally evaluated based on their specificity, we evaluated model performance at a  
44 specificity of 90% ( $\text{FPR} = .10$ ). A low FPR minimizes the number of participants who the model  
45 would predict to achieve a healthier state who actually will not. In turn, this minimizes the  
46 number of participants who might be erroneously taken off blood pressure medicine as a result of  
47 an erroneous prediction. It is less critical to avoid labeling participants who had achieved a  
48 healthier state as though they had not. This is why we choose a discrimination threshold with a  
49 low FPR, and then evaluate the TPR at that point.  
50  
51  
52

53  
54 As a further validation step, we examined the performance of each biomarker by excluding the  
55 four explanatory variables that capture blood pressure change in the training window. While we  
56  
57  
58  
59  
60

1  
2  
3 hypothesized that these models would perform less well, they serve to test the concept that a  
4 digital biomarker that predicts blood pressure status can be generated without using ongoing  
5 blood pressure data. These validation models using only app engagement and other biometric  
6 variables, are denoted SC-APP and ER-APP.  
7  
8

### 9 **Making Use of Explainable Artificial Intelligence (AI)**

10 Digital biomarkers that are generated using machine learning do not need to be viewed as a black  
11 box. Instead, explainable AI techniques are available that can provide more granular details  
12 about the explanatory variables that influenced the prediction made. Explainable AI can afford  
13 both individual participant and population level insights.  
14  
15

16  
17 We used the Tree Shapley Additive Explanation (SHAP) algorithm on the random forest  
18 models[38] to generate more interpretable predictions at the participant level. The SHAP  
19 algorithm assigns each explanatory variable an importance value for each prediction. Using  
20 SHAP on a machine learning model is analogous to coefficient analysis in classical regression.  
21 Similar to coefficient analysis, it can be used to determine the relative importance of explanatory  
22 variables in addition to determining which explanatory variables drove a particular prediction.  
23 Predictions start at a base value that is the expectation of the response variable. For binary  
24 classification models, this is defined by the proportion of outcomes by class (e.g., the proportion  
25 of participants who successfully reduced their blood pressure). Then SHAP values attribute to  
26 each explanatory variable the change in expected model prediction given the addition of that  
27 explanatory variable. This provides insight into how much each explanatory variable positively  
28 or negatively impacts the prediction made for each participant. The final prediction probability of  
29 whether the participant will achieve the response variable is the sum of the base value and all of  
30 the explanatory variable attributions.  
31  
32  
33  
34  
35  
36

37 Individual SHAP values can be used to provide specific behavioral feedback to participants, with  
38 the intent of motivating a change in behavioral pattern that may improve treatment outcomes.  
39 SHAP values for all participants can also be plotted to reveal the overall ranking of variables in  
40 the population studied. These variable rank lists can then inform hypotheses about how to further  
41 improve the design of the digital therapeutic to optimize clinical outcomes.  
42  
43  
44

45 All machine learning model development was done using open-source packages in Python. The  
46 packages include but are not limited to Scikit-Learn, SHAP, Pandas, and Numpy.  
47  
48

### 49 **Patient and Public Involvement**

50 We did not directly involve patients or public (PPI) in the current study. However, the digital  
51 therapeutic that is the source of the database used in this study was developed with PPI input  
52 over the product development lifecycle.  
53  
54

## 55 **RESULTS**

### Dataset

The training dataset contained 135 participants who met the inclusion criteria. The mean age was 54.9 years (95% CI 53.5, 56.3), mean baseline BMI was 34.5 (95% CI 33.1, 35.8) and 83% (112/135) were female. Based on the 2017 ACC/AHA definition,<sup>[25]</sup> half of the participants (68/135) had stage 1 hypertension at baseline, with the other half (67/135) having stage II hypertension at baseline. Of those with stage 1 hypertension at baseline, 51.5% (35/68) had isolated diastolic hypertension (i.e., diastolic BP 80-90 mmHg). Of those with stage II hypertension at baseline, 14.9% (10/67) had isolated diastolic hypertension (i.e., diastolic BP  $\geq$  89 mmHg). Baseline characteristics are listed in Table 1.

Over the intervention period examined, systolic blood pressure changed by -12.7 mmHg (95% CI -14.8, -9.6), diastolic blood pressure changed by -7.1 mmHg (95% CI -9.0, -5.2) and the mean duration of days between baseline and most recent value for blood pressure was 79.3 days (95% CI 76.8, 81.9). Of all participants, 35.6% (48/135) shifted to a blood pressure range below stage I (<130/80). A shift to a normal range was seen in 16.4% (11/67) of those starting with stage II hypertension and 29.4% (20/68) of those starting with stage I hypertension.

**Table 1.** Participant characteristics at baseline

Participant Characteristics	Total (n = 135)	Stage I BP (n = 68)	Stage II BP (n = 67)
Age (years), mean (95% CI)	54.9 (53.5 to 56.3)	55.7 (53.7 to 57.7)	54.2 (52.1 to 56.2)
Body mass index (kg/m <sup>2</sup> ), mean (95% CI)	34.5 (33.1 to 35.8)	33.8 (31.9 to 35.6)	35.2 (33.2 to 37.2)
Female, n (%)	112 (83)	54 (79.4)	58 (86.6)
Systolic BP (mmHg), mean (95% CI)	138.9 (136.2 to 141.6)	127.9 (126.1 to 129.7)	150.0 (146.6 to 153.5)
Diastolic BP (mmHg), mean (95% CI)	87.8 (86.1 to 89.4)	82.3 (81.1 to 83.6)	93.3 (90.7 to 95.8)

Isolated diastolic hypertension, n (%)	45 (33.3)	35 (51.5)	10 (14.9)
BP medications (count), mean (95% CI)	1.3 (1.1 to 1.5)	1.2 (1.0 to 1.4)	1.4 (1.1 to 1.7)

### Predictive Models

The random forest classifier achieved optimal performance with 100 trees and a minimum of 3 samples per leaf node for the SC model. For the ER model optimal performance was achieved with 400 trees and a minimum of 5 samples per leaf nodes.

Biomarker models were assessed at the operating point on each ROC that was as close as possible to a FPR of 10%. The SC model (predicting a systolic change of 10 points) was assessed at a FPR of 10%, which means that 10% of participants who didn't achieve a reduction in systolic blood pressure of 10 mmHg were labeled as though they had. Evaluating the model at 10% FPR, we were able to achieve a TPR of 58%. This means that 58% of participants who achieved a reduction in systolic blood pressure of 10 mmHg were labeled correctly. The AUROC was .82, model specificity (1 - FPR) was 90%, sensitivity (TPR) was 58% and accuracy ((TP+TN)/n) was 74%. In the SC-APP model, where variables related to changes in blood pressure were removed, the AUROC was .72 and at a FPR of 10% (specificity of 90%), the TPR was 42%. The resultant receiver operator curves for these 2 models can be seen in Figure 1.

The biomarker models exploring the ability to predict a shift down to a blood pressure range of elevated or better (ER and ER-APP) also demonstrated predictive capacity, but less so than the SC models. For the ER model, the AUROC was .69 and at a FPR of 9% the TPR was 32%. When the BP change variables were removed, in the ER-APP model, the prediction ability was only slightly above chance (AUC = .53, TPR 26% at FPR of 12%).

Plots of the Tree SHAP algorithm results for the SC and SC-APP models are shown in Figure 2. Explanatory variables on the y-axis are ordered from most to least predictive based on their average absolute contribution to the response variable. Each dot represents the SHAP value of that variable for one participant and the placement of the dots on the x-axis indicate if the contribution was subtractive or additive for a specific participant. The color of the dot is indicative of the value for that variable, with highly positive values displayed as red and low or negative values showing up as light blue. The plot for the SC model reveals that explanatory variables related to blood pressure were top contributors to the prediction. For example, the distribution of dots across the x-axis for the first variable listed shows that improvements in systolic BP early in the intervention, as seen by the blue and purple dots to the right of 0 on the

1  
2  
3 x-axis, contributed positively to the prediction that a participant would succeed. Behavioral  
4 variables also had predictive power. For example, a high count of physical activity minutes and  
5 plant-based meals reported positively contributed to a prediction of success for most participants.  
6  
7

8 Shapley values can be aggregated and illustrated for every participant. A plot of the SHAP  
9 values helps to visualize which variables contributed most to a low or high prediction of success  
10 for an individual participant. In figure 3, we display the SHAP values for two participants, one  
11 with a lower than expected probability of success (example A), and one with a higher than  
12 expected probability of success (example B). In example A, the participant experienced a large  
13 improvement in their systolic blood pressure in weeks 3 and 4 (-14 mmHg), yet is given a low  
14 probability of sustaining this improvement at the end of the intervention period. This surprisingly  
15 low probability is explained by the SHAP values, which reveal low counts for several behavioral  
16 explanatory variables, such as the number of plant-based meals and minutes of physical activity  
17 reported. This data can be automatically translated into a simple explanation to the participant,  
18 that their probability for sustaining meaningful change could be higher if they made incremental  
19 improvements in their meal and activity pattern. Furthermore, the exact number of additional  
20 meals and activity minutes to accrue per week to sufficiently increase the probability of success  
21 could be calculated, to motivate the participant and to give meaning to the additional efforts  
22 prescribed.  
23  
24  
25  
26  
27  
28

29 In example B, the participant has evidenced no improvement in systolic blood pressure at the end  
30 of week 4, yet they are predicted to meaningfully improve blood pressure by the of the treatment  
31 period. This unexpected prediction is explained by the SHAP values, which show that the  
32 combined impact of their baseline blood pressure and behavioral explanatory variables suggests  
33 a high likelihood of success. This data can be automatically translated to provide timely  
34 encouragement to the participant to maintain or advance their behavioral changes even though  
35 their blood pressure has not yet responded.  
36  
37  
38

## 39 **DISCUSSION**

40 In this paper, we present a proof of concept that digital biomarkers can be developed using even  
41 a small training dataset from a digital therapeutic. We demonstrated that 28 days of data can be  
42 transformed, using machine learning, into a digital biomarker that predicts the degree of  
43 treatment response, in this case whether a meaningful drop in blood pressure will occur at the  
44 end of the treatment period.  
45  
46  
47  
48

49 There are many ways to use such a biomarker in practice to tailor behavioral treatment and  
50 improve outcomes. For a patient, these biomarkers can be used as a continuous form of treatment  
51 feedback and behavioral reinforcement. The probability of a significant treatment response can  
52 be translated into a treatment score, much like a credit score. Since this score could be  
53 recalculated with every new engagement recorded in the digital therapeutic, it would serve to  
54  
55  
56  
57  
58  
59

1  
2  
3 motivate app use and reinforce healing behaviors. In addition, the biomarker output can be made  
4 more meaningful using explainable AI techniques. For example, SHAP values can be translated  
5 into a prioritized list of behavioral actions to help a patient focus their attention on efforts that  
6 are most predictive of success.  
7  
8

9  
10 For clinicians and health systems, digital biomarkers can function as a form of automated patient  
11 monitoring. The probability of a positive treatment response can be translated into a clinical alert  
12 by setting an acceptable specificity-sensitivity threshold for each biomarker paired with a  
13 duration of time above this threshold. Like any diagnostic test, the performance characteristics of  
14 the alert should be made known to those acting upon it. Since such an alert would be intended to  
15 influence treatment decisions, for example via a clinical decision support tool, specificity-  
16 sensitivity pairs need to be evaluated from a risk-benefit perspective. For instance, how do the  
17 risks associated with false positives and false negatives compare to the benefits of identifying  
18 true positives and true negatives? To accurately weigh these risks and benefits requires us to  
19 understand the context that the biomarker and therapeutics are used. Current clinical practice, for  
20 example, is plagued by high rates of clinical inertia (i.e., a lack of timely and appropriate  
21 treatment decisions). Therefore, a higher false positive rate may be tolerated as a trade-off for an  
22 easier-to-access biomarker.  
23  
24  
25  
26  
27

28 For a developer of digital therapeutics, digital biomarkers provide not just a way to personalize  
29 treatment and communicate clinical status to providers, but also a way to better understand what  
30 variables within the therapeutic are most predictive of clinical outcomes. These data can be used  
31 to guide the ongoing refinement of a digital therapeutic. When datasets are of sufficient size, the  
32 machine learning techniques used to generate digital biomarkers can also be applied to identify  
33 distinct digital phenotypes, that is, unique patterns of engagement with a behavioral intervention  
34 that represent meaningful subpopulations who share the same diagnosis. Identifying and  
35 targeting treatment to previously unknown subpopulations is thought of as meaningful step  
36 towards more personalized medicine.[15, 39]  
37  
38  
39  
40

#### 41 **Limitations, Practical and Ethical Considerations**

42 The main limitation of the work presented here is the size of the training dataset used. It is likely  
43 that a larger dataset would improve the performance characteristics of biomarkers tested.[14] It is  
44 noteworthy, given this limitation, that one of the biomarkers (SC) had an AUC greater than 0.8.  
45 This suggests the utility of beginning digital biomarker development in early in the  
46 implementation of a digital therapeutic.  
47  
48  
49

50  
51 Other limitations include the omission of known predictors of treatment response (e.g.,  
52 medication adherence or change), the reliance on a small set of explanatory variables and the  
53 inclusion of self-reported variables that may be subject to human error. Addressing these  
54 limitations may enable more accurate biomarkers.  
55  
56  
57  
58  
59

1  
2  
3  
4 The ethical and practical implications of applying complex, ever-changing, predictive models  
5 generated by machine learning are only beginning to be appreciated. To preempt potential  
6 misuse of digital biomarkers, we must understand the true meaning of the data these biomarkers  
7 present. For example, a predictive model can identify variables that are predictive of a given  
8 outcome. This does not mean highly predictive variables caused the outcome, nor does it mean  
9 that poorly predictive variables are not causative. Instead, the predictive strength of each variable  
10 should be treated literally as “markers.” This does not preclude the automated use of explanatory  
11 variables to guide the personalization of behavioral therapy. However, since the individual level  
12 of each variable could be influenced by unknown confounding factors, and since the degree of  
13 modifiability of each variable is not known, the impact of this form of behavioral therapy must  
14 be studied.  
15  
16  
17  
18  
19

20 Finally, like any biomarker, a digital biomarker is only generalizable if the training dataset is  
21 truly representative of future patients. If the training dataset is biased or overly skewed, it may  
22 produce a biomarker that underperforms at best, and is harmful at worst. To guard against this  
23 bias, re-validation of a digital biomarker should be performed if the treatment population or  
24 digital therapeutic change substantially. And when applying these novel biomarkers, we must  
25 appreciate that unknown sources of bias may exist, so that we avoid over-reliance on such  
26 biomarkers.  
27  
28  
29  
30

### 31 **Future Work**

32 There are three areas of work that will extend this initial phase of digital biomarker development.  
33 As research expands into larger clinical trials, it will enable the revalidation and to some degree  
34 reconstruction of these biomarkers using larger training datasets, creating even more robust  
35 biomarkers. A larger dataset enables inclusion of other potentially predictive variables, such as  
36 demographics, sociomarkers, or omics data, and splitting of the dataset into a training and test set  
37 to minimize overfitting.  
38  
39  
40

41 Second, it will be important to study whether the intended effects (e.g., the improvement of  
42 treatment outcomes) are actualized when these biomarkers are put into practice and to observe  
43 whether there are any unintended consequences. Alongside empirical research, software usability  
44 testing must insure that the practical application of biomarkers is interpreted by both patients and  
45 clinicians in the intended manner.  
46  
47  
48

49 Third, similar machine learning methods can be applied to develop digital biomarkers that  
50 predict present physiological status, for instance current blood pressure or fasting blood sugar.  
51 This will require a larger training dataset with frequent (i.e., multiple times per week) measures  
52 of the ground truth (i.e., resting blood pressure, fasting blood sugar). A similar validation  
53 strategy can be used to determine the validity of the biomarkers with and without self-monitoring  
54  
55  
56  
57  
58  
59

1  
2  
3 of the ground truth. Our aim is to develop cuff-less blood pressure and stick-less blood glucose  
4 biomarkers that would allow for more continuous patient care at a lower burden to patients and  
5 the health system. Our hypothesis is that these biomarkers will significantly reduce clinical  
6 inertia, enhance behavioral therapy delivery, and further empower patients and providers,  
7 meaningfully increasing treatment outcomes at both the patient and population level.  
8  
9

## 10 11 **CONCLUSIONS**

12 Machine learning can be used to transform data from a digital therapeutic into actionable digital  
13 biomarkers. In this paper, we present a successful proof of concept for a biomarker that utilizes  
14 28 days of patient-generated data to predict a clinically meaningful response to digitally-  
15 delivered behavioral therapy. Many practical and ethical considerations arise in the development  
16 of digital biomarkers. Applying conventional clinical thinking to these novel computational  
17 processes provides the basis to identify and resolve these considerations. There is great potential  
18 to design digital biomarkers to enhance the delivery of medical care and improve treatment  
19 outcomes.

## 24 25 **ACKNOWLEDGMENTS**

26 The authors would like to thank all of the participants whose use of the Better digital therapeutic  
27 contributed to the data that made this analysis possible. The authors would also like to thank the  
28 employees of Better Therapeutics, LLC (the study sponsor and intervention developer) for their  
29 many contributions and Val de Castro for graphics support.  
30  
31

## 32 33 **AUTHOR CONTRIBUTIONS**

34 NLG, MAB, JC and SD prepared the data and conducted the analysis. All authors contributed to  
35 the conceptualization of the project, the interpretations of results and the writing of all sections of  
36 the paper.  
37  
38

## 39 40 **FUNDING AND DISCLAIMER**

41 This work was supported by Better Therapeutics, LLC.  
42

## 43 44 **COMPETING INTERESTS**

45 All authors have completed the ICMJE uniform disclosure form at  
46 [www.icmje.org/coi\\_disclosure.pdf](http://www.icmje.org/coi_disclosure.pdf) and declare: authors NG, KE, KA, DK, and MB are  
47 employees and equity owners of Better Therapeutics, LLC, authors DE, JC, and SD are  
48 independent paid scientific consultants of Better Therapeutics and JC was provided the raw data  
49 to perform all machine learning methods independently; no other relationships or activities that  
50 could appear to have influenced the submitted work.

Figure 1: Receiver Operator Characteristics (ROC) curves for machine learning model predicting systolic change (SC) and a model predicting systolic change without use of ongoing blood pressure data (SC-APP).

934x608mm (72 x 72 DPI)

43 Figure 2: Shapley values illustrate how explanatory variables contribute to success meeting the response  
 44 variable (improvement in systolic blood pressure  $\geq 10$  mmHg). The feature list down the y-axis is in order of  
 45 contribution to the model (most to least). Each dot represents the value for one participant. SBP change and  
 46 DBP change are the difference in measurements from baseline to the end of the 28-day training period.

47 922x1058mm (72 x 72 DPI)

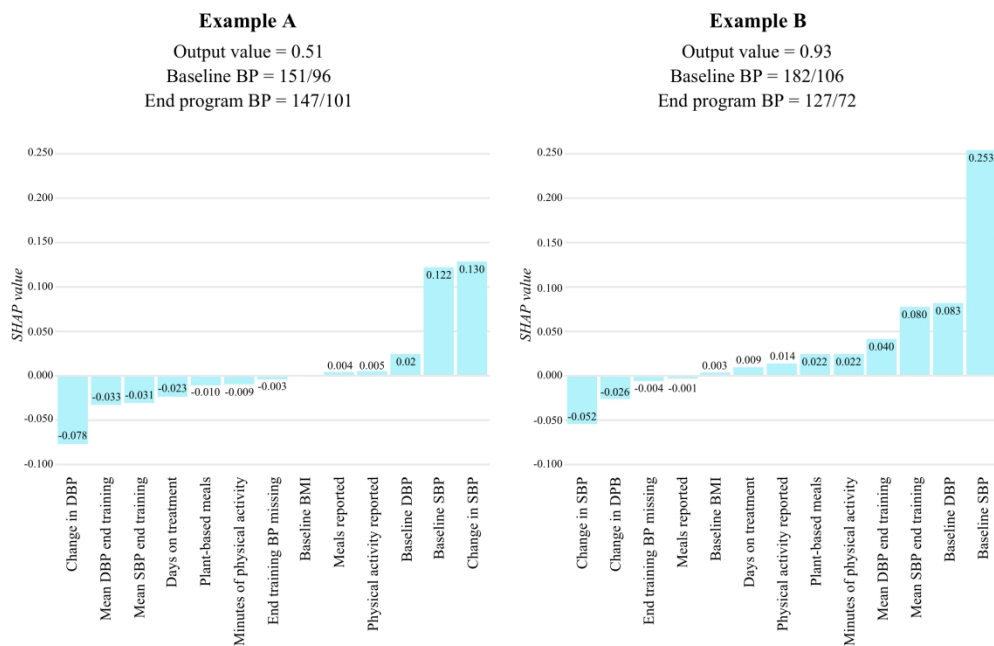

Figure 3: SHAP values for explanatory variables for 2 participants. The SHAP value plotted on the y-axis indicates that amount the variable positively or negatively contributes to the prediction of success (the output value). The probability threshold (output value that assigns a prediction of success) is 0.66.

934x680mm (72 x 72 DPI)

# Reporting checklist for prediction model development and validation study.

Based on the TRIPOD guidelines.

## Instructions to authors

Complete this checklist by entering the page numbers from your manuscript where readers will find each of the items listed below.

Your article may not currently address all the items on the checklist. Please modify your text to include the missing information. If you are certain that an item does not apply, please write "n/a" and provide a short explanation.

Upload your completed checklist as an extra file when you submit to a journal.

In your methods section, say that you used the TRIPOD reporting guidelines, and cite them as:

Collins GS, Reitsma JB, Altman DG, Moons KG. Transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD): The TRIPOD statement.

	Reporting Item	Page Number
	#1 Identify the study as developing and / or validating a multivariable prediction model, the target population, and the outcome to be predicted.	2
	#2 Provide a summary of objectives, study design, setting, participants, sample size, predictors, outcome, statistical analysis, results, and conclusions.	2
	#3a Explain the medical context (including whether diagnostic or prognostic) and rationale for developing or validating the multivariable prediction model, including references to existing models.	3-4
	#3b Specify the objectives, including whether the study describes the development or validation of the model or both.	4
Source of data	#4a Describe the study design or source of data (e.g., randomized trial, cohort, or registry data), separately for the development and validation data sets, if applicable.	4-5

1		#4b	Specify the key study dates, including start of accrual; end of accrual;	n/a
2			and, if applicable, end of follow-up.	
3				
4				
5	Participants	#5a	Specify key elements of the study setting (e.g., primary care,	4
6			secondary care, general population) including number and location of	
7			centres.	
8				
9				
10		#5b	Describe eligibility criteria for participants.	5
11				
12		#5c	Give details of treatments received, if relevant	4
13				
14				
15	Outcome	#6a	Clearly define the outcome that is predicted by the prediction model,	5-6
16			including how and when assessed.	
17				
18		#6b	Report any actions to blind assessment of the outcome to be	n/a
19			predicted.	
20				
21				
22	Predictors	#7a	Clearly define all predictors used in developing or validating the	5-7
23			multivariable prediction model, including how and when they were	
24			measured	
25				
26				
27				
28		#7b	Report any actions to blind assessment of predictors for the outcome	n/a
29			and other predictors.	
30				
31	Sample size	#8	Explain how the study size was arrived at.	5
32				
33				
34	Missing data	#9	Describe how missing data were handled (e.g., complete-case	n/a
35			analysis, single imputation, multiple imputation) with details of any	
36			imputation method.	
37				
38				
39	Statistical analysis	#10a	If you are developing a prediction model describe how predictors	5-7
40	methods		were handled in the analyses.	
41				
42				
43		#10b	If you are developing a prediction model, specify type of model, all	6-8
44			model-building procedures (including any predictor selection), and	
45			method for internal validation.	
46				
47				
48		#10c	If you are validating a prediction model, describe how the predictions	7-8
49			were calculated.	
50				
51				
52		#10d	Specify all measures used to assess model performance and, if	7-8
53			relevant, to compare multiple models.	
54				
55				
56		#10e	If you are validating a prediction model, describe any model updating	7-8
57			(e.g., recalibration) arising from the validation, if done	
58				
59				
60				

1	Risk groups	#11	Provide details on how risk groups were created, if done.	n/a
2				
3	Development vs.	#12	For validation, identify any differences from the development data in	8
4	validation		setting, eligibility criteria, outcome, and predictors.	
5				
6				
7	Participants	#13a	Describe the flow of participants through the study, including the	9
8			number of participants with and without the outcome and, if	
9			applicable, a summary of the follow-up time. A diagram may be	
10			helpful.	
11				
12				
13				
14		#13b	Describe the characteristics of the participants (basic demographics,	9-10
15			clinical features, available predictors), including the number of	
16			participants with missing data for predictors and outcome.	
17				
18				
19		#13c	For validation, show a comparison with the development data of the	9-10
20			distribution of important variables (demographics, predictors and	
21			outcome).	
22				
23				
24	Model	#14a	If developing a model, specify the number of participants and	9-10
25	development		outcome events in each analysis.	
26				
27				
28		#14b	If developing a model, report the unadjusted association, if calculated	10-11
29			between each candidate predictor and outcome.	
30				
31				
32	Model	#15a	If developing a model, present the full prediction model to allow	10-11
33	specification		predictions for individuals (i.e., all regression coefficients, and model	
34			intercept or baseline survival at a given time point).	
35				
36				
37		#15b	If developing a prediction model, explain how to use it.	10-11
38				
39				
40	Model	#16	Report performance measures (with CIs) for the prediction model.	10-11
41	performance			
42				
43				
44	Model-updating	#17	If validating a model, report the results from any model updating, if	n/a
45			done (i.e., model specification, model performance).	
46				
47				
48	Limitations	#18	Discuss any limitations of the study (such as nonrepresentative	12-13
49			sample, few events per predictor, missing data).	
50				
51	Interpretation	#19a	For validation, discuss the results with reference to performance in	11-12
52			the development data, and any other validation data	
53				
54				
55		#19b	Give an overall interpretation of the results, considering objectives,	14
56			limitations, results from similar studies, and other relevant evidence.	
57				
58				
59				
60				

1	Implications	#20	Discuss the potential clinical use of the model and implications for	13-14
2			future research	
3				
4				
5	Supplementary	#21	Provide information about the availability of supplementary	14-15
6	information		resources, such as study protocol, Web calculator, and data sets.	
7				
8				
9	Funding	#22	Give the source of funding and the role of the funders for the present	14
10			study.

## ABSTRACT

**Objectives:** Development of digital biomarkers to predict treatment response to a digital behavioral intervention.

**Design:** Machine learning using random forest classifiers on data generated through the use of a digital therapeutic which delivers behavioral therapy to treat cardiometabolic disease. Data from 13 explanatory variables (biometric and engagement in nature) generated in the first 28 days of a 12-week intervention were used to train models. Two levels of response to treatment were predicted: 1) systolic change  $\geq 10$  mmHg (SC model), and 2) shift down to a blood pressure category of elevated or better (ER model). Models were validated using leave-one-out cross-validation and evaluated using area under the curve receiver operating characteristics (AUROC) and specificity-sensitivity. Ability to predict treatment response with a subset of 9 variables, including app use and baseline blood pressure was also tested (models SC-APP and ER-APP).

**Setting:** Data generated through ad libitum use of a digital therapeutic in the United States.

**Participants:** De-identified data from 135 adults with a starting blood pressure  $\geq 130 / 80$ , who tracked blood pressure for at least 7 weeks using the digital therapeutic.

**Results:** The SC model had an AUROC of .82 and a sensitivity of 58% at a specificity of 90%. The ER model had an AUROC of .69 and a sensitivity of 32% at a specificity at 91%. Dropping explanatory variables related to blood pressure resulted in an AUROC of .72 with a sensitivity of 42% at a specificity of 90% for the SC-APP model and an AUROC of .53 for the ER-APP model.

**Conclusions:** Machine learning was used to transform data from a digital therapeutic into digital biomarkers that predicted treatment response in individual participants. Digital biomarkers have potential to improve treatment outcomes in a digital behavioral intervention.

## ARTICLE SUMMARY

### Strengths and Limitations

- Proof of concept biomarkers demonstrated good power to predict treatment outcomes despite the small size of the training dataset.
- Use of additional explanatory variables to develop the biomarkers may enhance the accuracy of predictions.
- Generalizability of the biomarkers is unknown and may be limited by the demographics of the training dataset.

## INTRODUCTION

Modifiable behaviors are responsible for 70% or more of all cardiometabolic diseases.[1–3] Health systems are ill equipped to address the current epidemic of cardiometabolic diseases and, in particular, lack widely available behavioral therapies to address the common root causes of these conditions. Digital therapeutics, software designed to encourage changes in behaviors which treat disease, offer a means to deliver behavioral therapy to large populations and

1  
2  
3 preliminary studies demonstrate their potential as a cost-effective treatment for cardiometabolic  
4 disease.[4–7]  
5

6  
7 Compared to pharmacotherapy, digital therapeutics offer potential advantages such as ease of  
8 access, ease of use, fewer side-effects and cost-effectiveness.[4, 8–10] Digital therapeutics also  
9 generate readily accessible patient data without requiring an office or lab visit. The data  
10 generated are voluminous and vary in both type and quality. These can include remotely sensed  
11 measures of physiology (e.g., blood pressure, blood glucose, heart rate variability), behavioral  
12 data (e.g., about eating, moving, thinking), medication adherence, as well as engagement  
13 parameters of unknown significance (e.g., app use, geographic location, circadian patterns of  
14 use).  
15  
16  
17  
18

19 The best use of these data remains an open question. Feeding data directly into EMRs is of  
20 limited utility to providers or patients. Whereas, transforming the data into markers of disease  
21 status, termed digital biomarkers[11] could provide clinically actionable insights with or without  
22 conventional biometric data.[12–14] Digital biomarkers afford a pragmatic approach to remotely  
23 monitor patients and intervene on a continuous rather than episodic basis. Greatly expanding  
24 opportunities to intervene means that patients have greater access to personalized care, which  
25 could improve treatment outcomes.[15, 16]  
26  
27  
28

29 Machine learning, a type of artificial intelligence (AI) used to make predictions with large and  
30 complex datasets, offers a novel approach for creating digital biomarkers. The exponential  
31 growth of smartphone use in the United States and advancing interoperability standards allow for  
32 digital biomarkers to be compiled across diverse populations and data sources. As a result, the  
33 opportunity to advance digital biomarker methodologies has never been greater.[17, 18]  
34  
35  
36

37 Machine learning is particularly valuable when there is ambiguity about what variables, or to  
38 what extent a set of variables predict an outcome of interest. Such ambiguity is inherent to  
39 behavioral interventions, like those used in the treatment of cardiometabolic disease. Human  
40 behavior results from a complex interaction between the anthropogenic features of our living  
41 environment, genetic and epigenetic determinants of behavior, neurobiology, social influences  
42 and to some degree chance events.[19–22] While clinical experience and the scientific literature  
43 can identify many variables that influence behavior, the interplay of these variables in a given  
44 individual and their environment is difficult for a clinician or patient to discern. This ambiguity  
45 limits enthusiasm for behavioral interventions because it makes it difficult for clinicians and  
46 patients to rely on behavioral therapy to achieve a predictable level of therapeutic response.  
47  
48  
49  
50

51 Digital biomarkers can reduce ambiguity by predicting current and forecasting future disease  
52 status during the course of treatment.[23–25] Digital biomarkers that serve as markers of current  
53 disease status allow for tailoring or adjusting treatment between clinic visits (e.g., when a patient  
54  
55  
56  
57  
58  
59

1  
2  
3 is not doing as well as expected). Similarly, markers of future disease status enable preemptive  
4 action, such as adding or subtracting additional treatments, or taking preventive steps to avoid  
5 complications of the disease.[14, 25]  
6  
7

8  
9 In this paper, we present our ongoing work to develop digital biomarkers and aim to illustrate  
10 their utility in digitally-delivered behavioral interventions to both the patient and prescribing  
11 clinician. We describe the analytic process to show that the development of digital biomarkers  
12 requires a hypothesis-driven approach, particularly when datasets are small. Finally, using actual  
13 examples of digital biomarkers intended to predict blood pressure status, we discuss the practical  
14 and ethical considerations involved in both developing and applying digital biomarkers using  
15 machine learning.  
16  
17

## 18 19 **METHODS**

### 20 **Digital Therapeutic**

21 The digital biomarkers discussed in this paper were generated using data from a digital  
22 therapeutic created by Better Therapeutics LLC (San Francisco, CA), a developer of prescription  
23 digital therapeutics for the treatment of cardiometabolic diseases.  
24  
25  
26

27 The digital therapeutic integrates a mobile medical application (“app”) that delivers behavioral  
28 therapy with the support of a remote multidisciplinary care team. The app delivers a personalized  
29 behavior change intervention, including tools for goal setting, skill building, self-monitoring,  
30 biometric tracking and behavioral feedback designed to provide cognitive training and support  
31 the participant’s daily efforts to improve overall cardiometabolic disease status. The app  
32 facilitates the adoption of evidenced-based behavioral strategies, such as planning and self-  
33 monitoring, to increase physical activity and consumption of vegetables, whole grains, fruits,  
34 nuts, seeds, beans and other legumes.[26, 27]  
35  
36  
37  
38

### 39 **Participants**

40 Participants were over 18 years of age who self-identified with a diagnosis of hypertension, type  
41 2 diabetes and/or hyperlipidemia. Those reporting to have hypertension at enrollment were  
42 offered a free Omron 7 Series Upper Arm Blood Pressure Monitor (Omron Healthcare Inc,  
43 Kyoto, Japan) to use during the intervention and to keep at its conclusion. This 12-week  
44 intervention was available to all participants at no cost.  
45  
46  
47

48 This analysis of existing data from participants using the digital therapeutic was approved and  
49 overseen by Quorum Review Institutional Review Board[28] and a waiver of informed consent  
50 was granted for this retrospective analysis.  
51  
52  
53

### 54 **Constraining the Training Dataset**

55  
56  
57  
58  
59  
60

1  
2  
3 The clinical intent of this biomarker exploration was to generate digital biomarkers that could  
4 improve treatment outcomes in future participants with hypertension for whom blood pressure  
5 was not optimally controlled despite the use of pharmacological treatment. We first identified  
6 prior participants that met the following criteria: baseline blood pressure was 1) at or above the  
7 cutoff for stage I hypertension (systolic  $\geq 130$  or diastolic  $\geq 80$ )[26] and, 2) recorded no more  
8 than 2 weeks prior to or 2 weeks after the start of the intervention. The baseline value was  
9 calculated by taking an average of all values reported in a 6-day interval defined as starting with  
10 the date of the first blood pressure value reported and all values reported in the following 5 days.  
11  
12  
13  
14

15 The development of a predictive model using a training dataset requires all participants to have  
16 known outcomes. This is referred to as the “ground truth” in machine learning. In this case, the  
17 ground truth was change in blood pressure from baseline. The follow-up blood pressure values  
18 were calculated by taking an average over a 6-day interval ending with the last blood pressure  
19 reported and all values in the previous 5 days. Of the participants identified, we only included  
20 those with a follow-up blood pressure value in weeks 7 to 14 of the intervention.  
21  
22  
23

24 The training set also needs to be a valid representation of future experience to make sure the data  
25 sources present are sufficiently representative of those that will be collected in future  
26 participants. This is an important consideration because of the evolving nature of digital  
27 therapeutics. As the therapeutic is modified over time, the data types collected in earlier versions  
28 of the app could be different from those collected in later versions. Therefore, for the purpose of  
29 developing biomarkers that predict blood pressure status, we further constrained the training  
30 dataset to include participants who used versions of the app which enabled automatic blood  
31 pressure tracking.  
32  
33  
34  
35

### 36 **Choosing Response Variables and Training Window**

37 The intent of machine learning is to train an algorithm that can predict a specific outcome,  
38 termed the “response variable.” The response variable must be both clinically relevant and  
39 sufficiently, but not universally, prevalent in the population of interest. For example, if the  
40 outcome is “any degree of improvement”, but “any degree of improvement” occurs in  $> 95\%$  of  
41 participants in the training dataset, then a predictive model may appear to work well, but could  
42 actually be invalid.[29] Furthermore, “any improvement” is arguably less clinically meaningful  
43 than “a specific degree of improvement”.  
44  
45  
46  
47

48 To address these concerns, we chose response variables that were well distributed in the training  
49 dataset, as detailed in the results section, and were also clinically meaningful in the management  
50 of hypertension. Specifically, we chose to predict: 1) a systolic blood pressure improvement of  
51 10 mmHg or higher near the end of a 12-week intervention period (defined as 7 to 14 weeks after  
52 start), because 10 mmHg has been well demonstrated to be clinically meaningful[30, 31] and that  
53 degree of change is near the mean for participants in the training dataset (66/135 participants);  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 and 2) a reduction in blood pressure to the elevated range or below (systolic  $\leq 130$ ), because this  
4 level of blood pressure control would signal a clinician to stop adding additional pharmaceuticals  
5 or consider reducing or deprescribing pharmaceuticals (48/135 participants).[26]  
6  
7

8 For a digital biomarker that predicts blood pressure status to be clinically useful, it needs to  
9 compute with data collected in a short period of time, and in less time than typically occurs  
10 between clinic visits. This means the biomarker could be used to intervene between office visits  
11 and could play a role in addressing clinical inertia that limits primary care providers ability to  
12 optimize blood pressure control in their patients.[32, 33] To demonstrate proof of concept, we  
13 chose a 28-day training interval, meaning that we trained machine learning models on the first 28  
14 days of patient data to evaluate whether it could predict blood pressure change in weeks 7 to 14.  
15 We hypothesized that data collected within this short training window could sufficiently  
16 represent changing behavioral patterns and treatment response, so as to predict future blood  
17 pressure status.  
18  
19  
20  
21  
22

### 23 **Choosing Modeling Techniques and Explanatory Variables**

24 There are many valid methodologies for machine learning. These methods can be categorized by  
25 the type of learning involved - supervised or unsupervised. While a discussion on the merits and  
26 nature of each type is beyond the scope of this paper, it is important to select modeling  
27 techniques appropriate for the size of the dataset and nature of response variables chosen. For the  
28 biomarkers presented herein, we utilized random forest models, which is a form of supervised  
29 classification learning known to reduce overfitting in small datasets.[34] The models are  
30 supervised because the ground truth (i.e., actual blood pressure change) for each participant in  
31 the training dataset is labeled. The models are attempting to learn whether the classification was  
32 or was not achieved; for example, will a participant achieve a  $> 10$  mmHg blood pressure  
33 reduction, or not?  
34  
35  
36  
37  
38

39 In addition to classification labels, random forest models must be trained on a set of explanatory  
40 variables. For a small training dataset, each model must have a limited number of variables so as  
41 to avoid excess noise and overfitting that can lead to reduced generalizability. These explanatory  
42 variables must be selected by hypothesis. For example, we hypothesized that baseline blood  
43 pressure and achievement of behavioral goals would influence the degree of blood pressure  
44 change observed and used these as explanatory variables. In a large dataset, feature engineering  
45 can be used to identify the most predictive explanatory variables.  
46  
47  
48

49 For each biomarker model, denoted SC (systolic change of 10 mmHg or more) or ER (elevated  
50 range achieved), we used 13 explanatory variables, which can be categorized as engagement or  
51 biometric variables. Engagement variables are counts of actions related to the use of the digital  
52 therapeutic, including count of all meals reported, plant-based meals reported, physical activity  
53 reported and length of exposure to the intervention. Biometric variables included baseline  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 systolic, baseline diastolic, mean systolic and diastolic at training window end, initial systolic  
4 and diastolic change (end training mean - baseline), minutes of physical activity, and baseline  
5 Body Mass Index (BMI).  
6  
7

8 We trained each biomarker model on data generated during a 28-day training window, starting  
9 with participant day 0 (sign up) up to day 28 (a third of the way through the studied 12-week  
10 intervention period). We utilized hyperparameter optimization [35] to minimize overfitting and  
11 to achieve the maximal leave-one-out cross-validated area under the receiver operating  
12 characteristic curve for both models.  
13  
14  
15

### 16 **Model Validation**

17 Performance of each biomarker model was assessed using leave-one-out cross-validation, which  
18 is a common and valid technique for use in samples of this size.[36–38] This was done by  
19 training each model on N-1 samples of the data and then making a prediction on that one sample  
20 that was left out, producing an “out of sample” prediction for all N samples. The N predictions  
21 were pooled to generate the classification variables of the receiver operator characteristic curve  
22 (ROC), the area under the curve of the ROC (AUROC) and a confusion matrix of true versus  
23 predicted values.[39]  
24  
25  
26  
27

28 For each biomarker model, the ROC curve illustrates predictive ability of the response variable  
29 (in this case systolic change of 10 mmHg or more to a range of elevated BP) at different  
30 thresholds of discrimination. At each prediction discrimination threshold, the ROC displays the  
31 false positive rate (FPR) against the true positive rate (TPR). The FPR is the ratio of truly  
32 negative events categorized as positive (FP) to the total number of actual negative events (N).  
33 Specificity or true negative rate of a model is calculated as  $1 - \text{FPR}$  and is an indication of how  
34 well a model does in correctly identifying those who do not achieve a successful outcome, as  
35 defined by the response variable.  
36  
37  
38  
39

40 Since the intended application of these biomarkers is analogous to a diagnostic test, which are  
41 traditionally evaluated based on their specificity, we evaluated model performance at a  
42 specificity of 90% ( $\text{FPR} = .10$ ). A low FPR minimizes the number of participants who the model  
43 would predict to achieve a healthier state who actually will not. In turn, this minimizes the  
44 number of participants who might be erroneously taken off blood pressure medicine as a result of  
45 an erroneous prediction. It is less critical to avoid labeling participants who had achieved a  
46 healthier state as though they had not. This is why we choose a discrimination threshold with a  
47 low FPR, and then evaluate the TPR at that point.  
48  
49  
50  
51

52 As a further validation step, we examined the performance of each biomarker by excluding the  
53 four explanatory variables that capture blood pressure change in the training window. While we  
54 hypothesized that these models would perform less well, they serve to test the concept that a  
55  
56  
57  
58  
59  
60

1  
2  
3 digital biomarker that predicts blood pressure status can be generated without using ongoing  
4 blood pressure data. These validation models using only app engagement and other biometric  
5 variables, are denoted SC-APP and ER-APP.  
6  
7

### 8 **Making Use of Explainable Artificial Intelligence (AI)**

9  
10 Digital biomarkers that are generated using machine learning do not need to be viewed as a black  
11 box. Instead, explainable AI techniques are available that can provide more granular details  
12 about the explanatory variables that influenced the prediction made. Explainable AI can afford  
13 both individual participant and population level insights.  
14  
15

16 We used the Tree Shapley Additive Explanation (SHAP) algorithm on the random forest  
17 models[40] to generate more interpretable predictions at the participant level. The SHAP  
18 algorithm assigns each explanatory variable an importance value for each prediction. Using  
19 SHAP on a machine learning model is analogous to coefficient analysis in classical regression.  
20 Similar to coefficient analysis, it can be used to determine the relative importance of explanatory  
21 variables in addition to determining which explanatory variables drove a particular prediction.  
22 Predictions start at a base value that is the expectation of the response variable. For binary  
23 classification models, this is defined by the proportion of outcomes by class (e.g., the proportion  
24 of participants who successfully reduced their blood pressure). Then SHAP values attribute to  
25 each explanatory variable the change in expected model prediction given the addition of that  
26 explanatory variable. This provides insight into how much each explanatory variable positively  
27 or negatively impacts the prediction made for each participant. The final prediction probability of  
28 whether the participant will achieve the response variable is the sum of the base value and all of  
29 the explanatory variable attributions.  
30  
31  
32  
33  
34  
35

36 Individual SHAP values can be used to provide specific behavioral feedback to participants, with  
37 the intent of motivating a change in behavioral pattern that may improve treatment outcomes. In  
38 particular, explanatory variables that are theoretically modifiable (such as minutes of exercise, or  
39 number of plant-based meals consumed) can be displayed to motivate changes, whereas fixed  
40 explanatory variables (such as baseline values) can be displayed to provide context. SHAP  
41 values for all participants can also be plotted to reveal the overall ranking of variables in the  
42 population studied. These variable rank lists can then inform hypotheses about how to further  
43 improve the design of the digital therapeutic to optimize clinical outcomes.  
44  
45  
46  
47

48 All machine learning model development was done using open-source packages in Python. The  
49 packages include but are not limited to Scikit-Learn, SHAP, Pandas, and Numpy.  
50  
51

### 52 **Patient and Public Involvement**

53 We did not directly involve patients or public (PPI) in the current study. However, the digital  
54 therapeutic that is the source of the database used in this study was developed with PPI input  
55 over the product development lifecycle.  
56  
57  
58  
59

## RESULTS

### Dataset

The training dataset contained 135 participants who met the inclusion criteria. The mean age was 54.9 years (95% CI 53.5, 56.3), mean baseline BMI was 34.5 (95% CI 33.1, 35.8) and 83% (112/135) were female. Based on the 2017 ACC/AHA definition,[26] half of the participants (68/135) had stage 1 hypertension at baseline, with the other half (67/135) having stage II hypertension at baseline. Of those with stage 1 hypertension at baseline, 51.5% (35/68) had isolated diastolic hypertension (i.e., diastolic BP 80-90 mmHg). Of those with stage II hypertension at baseline, 14.9% (10/67) had isolated diastolic hypertension (i.e., diastolic BP  $\geq$  89 mmHg). On average, participants contributed 3 blood pressure readings to the baseline value (95% CI 2.5, 3.4) and 2.5 readings to the end-intervention value (95% CI 2.2, 2.9). Baseline characteristics are listed in Table 1.

Over the intervention period examined, systolic blood pressure changed by -12.7 mmHg (95% CI -14.8, -9.6), diastolic blood pressure changed by -7.1 mmHg (95% CI -9.0, -5.2) and the mean duration of days between baseline and most recent value for blood pressure was 79.3 days (95% CI 76.8, 81.9). Of all participants, 35.6% (48/135) shifted to a blood pressure range below stage I (<130/80). A shift to a normal range was seen in 16.4% (11/67) of those starting with stage II hypertension and 29.4% (20/68) of those starting with stage I hypertension.

**Table 1.** Participant characteristics at baseline

Participant Characteristics	Total (n = 135)	Stage I BP (n = 68)	Stage II BP (n = 67)
Age (years), mean (95% CI)	54.9 (53.5 to 56.3)	55.7 (53.7 to 57.7)	54.2 (52.1 to 56.2)
Body mass index (kg/m <sup>2</sup> ), mean (95% CI)	34.5 (33.1 to 35.8)	33.8 (31.9 to 35.6)	35.2 (33.2 to 37.2)
Female, n (%)	112 (83)	54 (79.4)	58 (86.6)
Systolic BP (mmHg), mean (95% CI)	138.9 (136.2 to 141.6)	127.9 (126.1 to 129.7)	150.0 (146.6 to 153.5)

Diastolic BP (mmHg), mean (95% CI)	87.8 (86.1 to 89.4)	82.3 (81.1 to 83.6)	93.3 (90.7 to 95.8)
Isolated diastolic hypertension, n (%)	45 (33.3)	35 (51.5)	10 (14.9)
BP medications (count), mean (95% CI)	1.3 (1.1 to 1.5)	1.2 (1.0 to 1.4)	1.4 (1.1 to 1.7)

### Predictive Models

The random forest classifier achieved optimal performance with 100 trees and a minimum of 3 samples per leaf node for the SC model. For the ER model optimal performance was achieved with 400 trees and a minimum of 5 samples per leaf nodes.

Biomarker models were assessed at the operating point on each ROC that was as close as possible to a FPR of 10%. The SC model (predicting a systolic change of 10 points) was assessed at a FPR of 10%, which means that 10% of participants who didn't achieve a reduction in systolic blood pressure of 10 mmHg were labeled as though they had. Evaluating the model at 10% FPR, we were able to achieve a TPR of 58%. This means that 58% of participants who achieved a reduction in systolic blood pressure of 10 mmHg were labeled correctly. The AUROC was .82, model specificity (1 - FPR) was 90%, sensitivity (TPR) was 58% and accuracy ((TP+TN)/n) was 74%. In the SC-APP model, where variables related to changes in blood pressure were removed, the AUROC was .72 and at a FPR of 10% (specificity of 90%), the TPR was 42%. The resultant receiver operator curves for these 2 models can be seen in Figure 1.

The biomarker models exploring the ability to predict a shift down to a blood pressure range of elevated or better (ER and ER-APP) also demonstrated predictive capacity, but less so than the SC models. For the ER model, the AUROC was .69 and at a FPR of 9% the TPR was 32%. When the BP change variables were removed, in the ER-APP model, the prediction ability was only slightly above chance (AUC = .53, TPR 26% at FPR of 12%).

Plots of the Tree SHAP algorithm results for the SC and SC-APP models are shown in Figure 2. Explanatory variables on the y-axis are ordered from most to least predictive based on their average absolute contribution to the response variable. Each dot represents the SHAP value of that variable for one participant and the placement of the dots on the x-axis indicate if the contribution was subtractive or additive for a specific participant. The color of the dot is indicative of the value for that variable, with highly positive values displayed as red and low or negative values showing up as light blue. The plot for the SC model reveals that explanatory

1  
2  
3 variables related to blood pressure were top contributors to the prediction. For example, the  
4 distribution of dots across the x-axis for the first variable listed shows that improvements in  
5 systolic BP early in the intervention, as seen by the blue and purple dots to the right of 0 on the  
6 x-axis, contributed positively to the prediction that a participant would succeed. Behavioral  
7 variables also had predictive power. For example, a high count of physical activity minutes and  
8 plant-based meals reported positively contributed to a prediction of success for most participants.  
9

10  
11  
12 Shapley values can be aggregated and illustrated for every participant. A plot of the SHAP  
13 values helps to visualize which variables contributed most to a low or high prediction of success  
14 for an individual participant. In figure 3, we display the SHAP values for two participants, one  
15 with a lower than expected probability of success (example A), and one with a higher than  
16 expected probability of success (example B). In example A, the participant experienced a large  
17 improvement in their systolic blood pressure in weeks 3 and 4 (-14 mmHg), yet is given a low  
18 probability of sustaining this improvement at the end of the intervention period. This surprisingly  
19 low probability is explained by the SHAP values, which reveal low counts for several behavioral  
20 explanatory variables, such as the number of plant-based meals and minutes of physical activity  
21 reported. This data can be automatically translated into a simple explanation to the participant,  
22 that their probability for sustaining meaningful change could be higher if they made incremental  
23 improvements in their meal and activity pattern. Furthermore, the exact number of additional  
24 meals and activity minutes to accrue per week to sufficiently increase the probability of success  
25 could be calculated, to motivate the participant and to give meaning to the additional efforts  
26 prescribed.  
27  
28  
29  
30  
31  
32

33  
34 In example B, the participant has evidenced no improvement in systolic blood pressure at the end  
35 of week 4, yet they are predicted to meaningfully improve blood pressure by the of the treatment  
36 period. This unexpected prediction is explained by the SHAP values, which show that the  
37 combined impact of their baseline blood pressure and behavioral explanatory variables suggests  
38 a high likelihood of success. This data can be automatically translated to provide timely  
39 encouragement to the participant to maintain or advance their behavioral changes even though  
40 their blood pressure has not yet responded.  
41  
42  
43

## 44 **DISCUSSION**

45 In this paper, we present a proof of concept that digital biomarkers can be developed using even  
46 a small training dataset from a digital therapeutic. We demonstrated that 28 days of data can be  
47 transformed, using machine learning, into a digital biomarker that predicts the degree of  
48 treatment response, in this case whether a meaningful drop in blood pressure will occur at the  
49 end of the treatment period.  
50  
51  
52

53 There are many ways to use such a biomarker in practice to tailor behavioral treatment and  
54 improve outcomes. For a patient, these biomarkers can be used as a continuous form of treatment  
55  
56  
57  
58  
59

1  
2  
3 feedback and behavioral reinforcement. The probability of a significant treatment response can  
4 be translated into a treatment score, much like a credit score. Since this score could be  
5 recalculated with every new engagement recorded in the digital therapeutic, it would serve to  
6 motivate app use and reinforce healing behaviors. In addition, the biomarker output can be made  
7 more meaningful using explainable AI techniques. For example, SHAP values can be translated  
8 into a prioritized list of behavioral actions to help a patient focus their attention on efforts that  
9 are most predictive of success.  
10  
11  
12

13  
14 For clinicians and health systems, digital biomarkers can function as a form of automated patient  
15 monitoring. The probability of a positive treatment response can be translated into a clinical alert  
16 by setting an acceptable specificity-sensitivity threshold for each biomarker paired with a  
17 duration of time above this threshold. Like any diagnostic test, the performance characteristics of  
18 the alert should be made known to those acting upon it. Since such an alert would be intended to  
19 influence treatment decisions, for example via a clinical decision support tool, specificity-  
20 sensitivity pairs need to be evaluated from a risk-benefit perspective. For instance, how do the  
21 risks associated with false positives and false negatives compare to the benefits of identifying  
22 true positives and true negatives? To accurately weigh these risks and benefits requires us to  
23 understand the context that the biomarker and therapeutics are used. Current clinical practice, for  
24 example, is plagued by high rates of clinical inertia (i.e., a lack of timely and appropriate  
25 treatment decisions). Therefore, a higher false positive rate may be tolerated as a trade-off for an  
26 easier-to-access biomarker.  
27  
28  
29  
30  
31

32 For a developer of digital therapeutics, digital biomarkers provide not just a way to personalize  
33 treatment and communicate clinical status to providers, but also a way to better understand what  
34 variables within the therapeutic are most predictive of clinical outcomes. These data can be used  
35 to guide the ongoing refinement of a digital therapeutic. When datasets are of sufficient size, the  
36 machine learning techniques used to generate digital biomarkers can also be applied to identify  
37 distinct digital phenotypes, that is, unique patterns of engagement with a behavioral intervention  
38 that represent meaningful subpopulations who share the same diagnosis. Identifying and  
39 targeting treatment to previously unknown subpopulations is thought of as meaningful step  
40 towards more personalized medicine.[16, 41]  
41  
42  
43  
44

### 45 **Limitations, Practical and Ethical Considerations**

46 The main limitation of the work presented here is the size of the training dataset used. It is likely  
47 that a larger dataset would improve the performance characteristics of biomarkers tested.[15] It is  
48 noteworthy, given this limitation, that one of the biomarkers (SC) had an AUC greater than 0.8.  
49 This suggests the utility of beginning digital biomarker development in early in the  
50 implementation of a digital therapeutic.  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 To lower the risk of prematurely taking patients off of medications, the digital biomarkers  
4 presented decreased the false positive rate (i.e., a higher specificity), which resulted in a lower  
5 true positive rate (i.e., a lower sensitivity). In this context, a lower sensitivity means that the  
6 digital biomarker will fail to identify some successful individuals and as a result they may not  
7 have their medications reduced as promptly as possible. This means that the current performance  
8 of the digital biomarker does not fully obviate the need for traditional biomarkers or in-office  
9 visits.  
10  
11  
12

13  
14 Other limitations include the omission of known predictors of treatment response (e.g., time  
15 since diagnosis, medication adherence or change), the reliance on a small set of explanatory  
16 variables and the inclusion of self-reported variables that may be subject to human error.  
17 Addressing these limitations may enable more accurate biomarkers.  
18  
19

20  
21 The ethical and practical implications of applying complex, ever-changing, predictive models  
22 generated by machine learning are only beginning to be appreciated. To preempt potential  
23 misuse of digital biomarkers, we must understand the true meaning of the data these biomarkers  
24 present. For example, a predictive model can identify variables that are predictive of a given  
25 outcome. This does not mean highly predictive variables caused the outcome, nor does it mean  
26 that poorly predictive variables are not causative. Instead, the predictive strength of each variable  
27 should be treated literally as “markers.” This does not preclude the automated use of explanatory  
28 variables to guide the personalization of behavioral therapy. However, since the individual level  
29 of each variable could be influenced by unknown confounding factors, and since the degree of  
30 modifiability of each variable is not known, the impact of this form of behavioral therapy must  
31 be studied.  
32  
33  
34  
35

36  
37 Finally, like any biomarker, a digital biomarker is only generalizable if the training dataset is  
38 truly representative of future patients. If the training dataset is biased or overly skewed, it may  
39 produce a biomarker that underperforms at best, and is harmful at worst. To guard against this  
40 bias, re-validation of a digital biomarker should be performed if the treatment population or  
41 digital therapeutic change substantially. And when applying these novel biomarkers, we must  
42 appreciate that unknown sources of bias may exist, so that we avoid over-reliance on such  
43 biomarkers.  
44  
45  
46

### 47 **Future Work**

48 There are three areas of work that will extend this initial phase of digital biomarker development.  
49 As research expands into larger clinical trials, it will enable the revalidation (often called  
50 external validation) and to some degree reconstruction of these biomarkers using larger training  
51 datasets, creating even more robust biomarkers. A larger dataset enables inclusion of other  
52 potentially predictive variables, such as demographics, sociomarkers, or omics data, and splitting  
53 of the dataset into a training and test set to minimize overfitting. External validation also gives  
54  
55  
56  
57  
58  
59

1  
2  
3 the end-users of the biomarker greater confidence that the biomarker performs well with varied  
4 individuals, settings or time or year.[42–44]  
5  
6

7 Second, it will be important to conduct an impact analysis to study whether the intended effects  
8 (e.g., the improvement of treatment outcomes) are actualized when these biomarkers are put into  
9 practice and to observe whether there are any unintended consequences. Alongside empirical  
10 research, software usability testing must insure that the practical application of biomarkers is  
11 interpreted by both patients and clinicians in the intended manner.  
12  
13

14  
15 Third, similar machine learning methods can be applied to develop digital biomarkers that  
16 predict present physiological status, for instance current blood pressure or fasting blood sugar.  
17 This will require a larger training dataset with frequent (i.e., multiple times per week) measures  
18 of the ground truth (i.e., resting blood pressure, fasting blood sugar). A similar validation  
19 strategy can be used to determine the validity of the biomarkers with and without self-monitoring  
20 of the ground truth. Our aim is to develop cuff-less blood pressure and stick-less blood glucose  
21 biomarkers that would allow for more continuous patient care at a lower burden to patients and  
22 the health system. Our hypothesis is that these biomarkers will significantly reduce clinical  
23 inertia, enhance behavioral therapy delivery, and further empower patients and providers,  
24 meaningfully increasing treatment outcomes at both the patient and population level.  
25  
26  
27  
28  
29

## 30 **CONCLUSIONS**

31 Machine learning can be used to transform data from a digital therapeutic into actionable digital  
32 biomarkers. In this paper, we present a successful proof of concept for a biomarker that utilizes  
33 28 days of patient-generated data to predict a clinically meaningful response to digitally-  
34 delivered behavioral therapy. Many practical and ethical considerations arise in the development  
35 of digital biomarkers. Applying conventional clinical thinking to these novel computational  
36 processes provides the basis to identify and resolve these considerations. There is great potential  
37 to design digital biomarkers to enhance the delivery of medical care and improve treatment  
38 outcomes.

## 22 FIGURE LEGENDS

23  
24 **Figure 1:** Receiver Operator Characteristics (ROC) curves for machine learning model predicting  
25 systolic change (SC) and a model predicting systolic change without use of ongoing blood pressure data  
26 (SC-APP).  
27

28  
29 **Figure 2:** Shapley values illustrate how explanatory variables contribute to success meeting the response  
30 variable (improvement in systolic blood pressure  $\geq 10$  mmHg). The feature list down the y-axis is in  
31 order of contribution to the model (most to least). Each dot represents the value for one participant. SBP  
32 change and DBP change are the difference in measurements from baseline to the end of the 28-day  
33 training period.  
34  
35  
36

37  
38 **Figure 3:** SHAP values for explanatory variables for 2 participants. The SHAP value plotted on the y-  
39 axis indicates that amount the variable positively or negatively contributes to the prediction of success  
40 (the output value). The probability threshold (output value that assigns a prediction of success) is 0.66.

# Reporting checklist for prediction model development and validation study.

Based on the TRIPOD guidelines.

## Instructions to authors

Complete this checklist by entering the page numbers from your manuscript where readers will find each of the items listed below.

Your article may not currently address all the items on the checklist. Please modify your text to include the missing information. If you are certain that an item does not apply, please write "n/a" and provide a short explanation.

Upload your completed checklist as an extra file when you submit to a journal.

In your methods section, say that you used the TRIPOD reporting guidelines, and cite them as:

Collins GS, Reitsma JB, Altman DG, Moons KG. Transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD): The TRIPOD statement.

	Reporting Item	Page Number
	#1 Identify the study as developing and / or validating a multivariable prediction model, the target population, and the outcome to be predicted.	2
	#2 Provide a summary of objectives, study design, setting, participants, sample size, predictors, outcome, statistical analysis, results, and conclusions.	2
	#3a Explain the medical context (including whether diagnostic or prognostic) and rationale for developing or validating the multivariable prediction model, including references to existing models.	3-4
	#3b Specify the objectives, including whether the study describes the development or validation of the model or both.	4
Source of data	#4a Describe the study design or source of data (e.g., randomized trial, cohort, or registry data), separately for the development and validation data sets, if applicable.	4-5

1		#4b	Specify the key study dates, including start of accrual; end of accrual;	n/a
2			and, if applicable, end of follow-up.	
3				
4				
5	Participants	#5a	Specify key elements of the study setting (e.g., primary care,	4
6			secondary care, general population) including number and location of	
7			centres.	
8				
9				
10		#5b	Describe eligibility criteria for participants.	5
11				
12		#5c	Give details of treatments received, if relevant	4
13				
14				
15	Outcome	#6a	Clearly define the outcome that is predicted by the prediction model,	5-6
16			including how and when assessed.	
17				
18		#6b	Report any actions to blind assessment of the outcome to be	n/a
19			predicted.	
20				
21				
22	Predictors	#7a	Clearly define all predictors used in developing or validating the	5-7
23			multivariable prediction model, including how and when they were	
24			measured	
25				
26				
27				
28		#7b	Report any actions to blind assessment of predictors for the outcome	n/a
29			and other predictors.	
30				
31	Sample size	#8	Explain how the study size was arrived at.	5
32				
33				
34	Missing data	#9	Describe how missing data were handled (e.g., complete-case	n/a
35			analysis, single imputation, multiple imputation) with details of any	
36			imputation method.	
37				
38				
39	Statistical analysis	#10a	If you are developing a prediction model describe how predictors	5-7
40	methods		were handled in the analyses.	
41				
42				
43		#10b	If you are developing a prediction model, specify type of model, all	6-8
44			model-building procedures (including any predictor selection), and	
45			method for internal validation.	
46				
47				
48		#10c	If you are validating a prediction model, describe how the predictions	7-8
49			were calculated.	
50				
51				
52		#10d	Specify all measures used to assess model performance and, if	7-8
53			relevant, to compare multiple models.	
54				
55				
56		#10e	If you are validating a prediction model, describe any model updating	7-8
57			(e.g., recalibration) arising from the validation, if done	
58				
59				
60				

1	Risk groups	#11	Provide details on how risk groups were created, if done.	n/a
2				
3	Development vs.	#12	For validation, identify any differences from the development data in	8
4	validation		setting, eligibility criteria, outcome, and predictors.	
5				
6				
7	Participants	#13a	Describe the flow of participants through the study, including the	9
8			number of participants with and without the outcome and, if	
9			applicable, a summary of the follow-up time. A diagram may be	
10			helpful.	
11				
12				
13				
14		#13b	Describe the characteristics of the participants (basic demographics,	9-10
15			clinical features, available predictors), including the number of	
16			participants with missing data for predictors and outcome.	
17				
18				
19		#13c	For validation, show a comparison with the development data of the	9-10
20			distribution of important variables (demographics, predictors and	
21			outcome).	
22				
23				
24	Model	#14a	If developing a model, specify the number of participants and	9-10
25	development		outcome events in each analysis.	
26				
27				
28		#14b	If developing a model, report the unadjusted association, if calculated	10-11
29			between each candidate predictor and outcome.	
30				
31				
32	Model	#15a	If developing a model, present the full prediction model to allow	10-11
33	specification		predictions for individuals (i.e., all regression coefficients, and model	
34			intercept or baseline survival at a given time point).	
35				
36				
37		#15b	If developing a prediction model, explain how to use it.	10-11
38				
39				
40	Model	#16	Report performance measures (with CIs) for the prediction model.	10-11
41	performance			
42				
43				
44	Model-updating	#17	If validating a model, report the results from any model updating, if	n/a
45			done (i.e., model specification, model performance).	
46				
47				
48	Limitations	#18	Discuss any limitations of the study (such as nonrepresentative	12-13
49			sample, few events per predictor, missing data).	
50				
51	Interpretation	#19a	For validation, discuss the results with reference to performance in	11-12
52			the development data, and any other validation data	
53				
54				
55		#19b	Give an overall interpretation of the results, considering objectives,	14
56			limitations, results from similar studies, and other relevant evidence.	
57				
58				
59				
60				

1	Implications	#20	Discuss the potential clinical use of the model and implications for	13-14
2			future research	
3				
4				
5	Supplementary	#21	Provide information about the availability of supplementary	14-15
6	information		resources, such as study protocol, Web calculator, and data sets.	
7				
8				
9	Funding	#22	Give the source of funding and the role of the funders for the present	14
10			study.	
11
