### 3 *Age-specific reproduction*

4 The demographic dataset of Myanmar timber elephants for age-specific analyses includes 2,685 females  
5 with known birth origin (captive-born vs. wild-caught) and survival information, which lived beyond the  
6 earliest age of reproduction, 5 years. Of these females, 1,323 were captive-born between 1942-2011 and  
7 1,362 were wild-caught, captured between 1951-2002 at estimated ages of 0-55 years (mean capture age  
8  $16.13 \pm 10.91$ ). Exact lifespan was known for 1,079 females. Elephants were born (or estimated to be born)  
9 between 1921-2011 and come from 11 out of 14 regional divisions in Myanmar: Ayeyarwaddy (N = 39),  
10 Bago (N = 314), Chin (N = 31), Kachin (N = 266), Magway (N = 104), Mandalay (N = 401), Rakhine (N  
11 = 91), Sagaing (N = 928), Shan (N = 242), Tanintharyi (N = 6), Yangon (N = 8) and unknown (N = 255).  
12 In these analyses, we grouped regions together based on proximity and elevation, where conditions for  
13 elephants were more similar: Ayeyarwaddy, Tanintharyi, Bago, Rakhine and Yangon were grouped  
14 together, Chin and Shan were grouped together, and Magway and Mandalay were grouped together.  
15 Accounting for spatial variation in reproduction in our analyses was important because MTE elephants  
16 from different regions experience differences in forest cover, habitat availability and climatic conditions,  
17 which may influence survival and reproduction. Furthermore, grouping regional divisions based on  
18 elevation and proximity made sample sizes in each region group more comparable for analyses.  
19 Approximately 95% of the original demographic data was retained with reliable birth, capture, departure  
20 and death information.

21

### 22 *Calf survival and mother's birth origin*

23 To investigate whether captive-born and wild-caught females show differences in calf survival before age  
24 5, we analyzed 2423 calves (F = 1,235, M = 1,188; 1,290 born to captive-born females and 1,133 born to  
25 wild-caught females) born between 1960 and 2016 to 1030 mothers (500 captive-born and 530 wild-caught  
26 mothers). Generally, age-specific mortality in this population is greatest within the first 5 years [1], and

27 therefore we concentrated on this age range in the analysis. We excluded stillborn calves, calves born to  
28 mothers captured before 1952, twins, and calves with mistakes or missing information (on sex, maternal  
29 presence, or exact/censored lifespan). These calves come from 11 regions in Myanmar: Ayeyarwaddy (N  
30 = 59), Bago (N = 282), Chin (N = 4) Kachin (N = 130), Magway (N = 344), Mandalay (N = 255), Rakhine  
31 (N = 29), Sagaing (N = 956), Shan (N = 196), Taninthary (N = 7), Yangon (N = 9) and unknown (N = 152).  
32 In the analyses, regions were grouped in the same way as in age-specific reproduction analyses above  
33 resulting in 6 grouped regions.

34  
35 Calf age was included as a linear and quadratic term to control for the quadratic age effect on calf mortality  
36 before age 5 [1]. Birth cohorts and regions were also controlled for in the model (grouped the same way as  
37 in age-specific reproduction analyses, see SI). Maternal death is known to increase calf mortality [2], and  
38 maternal presence was therefore coded as a time-dependent variable in every year from birth to calf age 5  
39 (0 = mother died during the focal year/had died during previous years; 1 = mother was alive during the  
40 focal year). We also included an interaction term between calf age and maternal presence to control for the  
41 changing effect of maternal death on calf mortality at different calf ages [2]. Maternal age at the birth of  
42 the calf was included in the model, which ranged from 7-63 years old in the current sample. Maternal ages  
43 above 60 were grouped together because of small sample sizes (N = 6 calves). Short previous birth intervals  
44 are known to increase calf mortality [1], and we categorized birth intervals as short, medium, long, and  
45 firstborn categories based on the 25% and 75% quartiles of birth-interval length (3.84 and 7.44 years,  
46 respectively; average =  $6.28 \pm 3.75$  years). Birth order was not included because of its collinearity with  
47 maternal age and birth interval. We also controlled for the differences in survival between male and female  
48 calves [1], and an increased effect of maternal death on male calves by including calf sex and an interaction  
49 between maternal presence and calf sex in the model [2]. Finally, the mother's individual identification  
50 number was included as an intercept-only random effect to account for repeated births by the same female  
51 (ranges of 1-8 calves for wild-caught mothers and 1-10 calves for captive-born mothers; average = 2.35  
52 calves).

53

## 54 **S2. Age-specific reproduction model selection – additional details**

55 The model selection was carried out in two phases. First, we explored the full set (21,089 models) of age  
56 term models with generalized linear models (GLMs) with binomial error structures, incorporating all fixed  
57 effects, but excluding the random effects terms. Then, we re-ran the best 100 models using GLMMs, to  
58 incorporate the random effects terms of individual ID number and regional division group. We used this  
59 approach to reduce the computational power needed to assess all models, while maintaining a large enough  
60 subset of models incorporating the random effects. We compared the predictive performance of each model  
61 using the Akaike Information Criterion (AIC) [3]. The use of AIC was appropriate for the current study  
62 because each of the model parameters and interactions were considered *a priori* in the base model, and so  
63 all models contained the same number of parameters and interactions. The best ‘final’ model was the model  
64 with the lowest AIC value (Table S1). We assessed the significance of the terms in the best-fit model using  
65 likelihood ratio tests (LRTs) with the Chi-squared ( $\chi^2$ ) distribution. Where a model term was included as  
66 both a fixed effect and an interaction, all terms with that effect were removed in the LRT calculation.

67

68 The AIC value of the best model was 0.04 lower than the second explanatory model with three thresholds  
69 (different thresholds at 20 and 44, as opposed to 19 and 44 years of age; Table S2; Figure S1). This small  
70 difference is therefore consistent with a peak of reproduction of between 19 and 20. The difference between  
71 the best and twentieth explanatory models was 2.74, indicating clear support for the best model relative to  
72 other competitive models (Figure S1). The best-fit 20 three-threshold models are shown in Table S2. Of the  
73 best 100 models, all were three-threshold models, and we found little support for linear, quadratic or cubic  
74 age terms relative to threshold models.

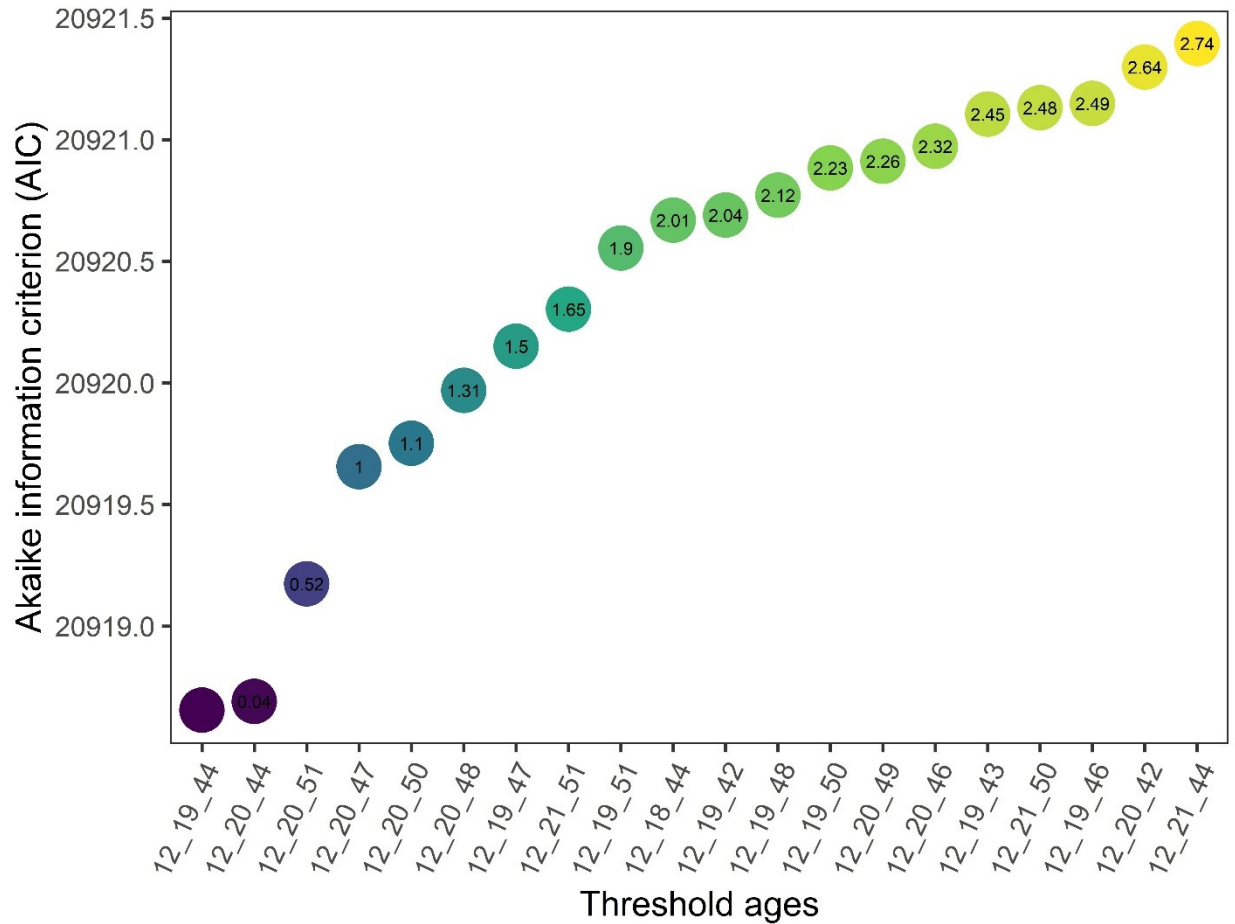

75

92  
 93 Figure S1. The best age-specific model was a three-threshold model with a peak reproductive age of 19.  
 94 Figure shows AIC scores and threshold ages for the best-fit 20 models incorporating age terms. Colour  
 95 denotes the AIC value, and the numbers within the points are the differences with respect to the best-fit  
 96 model. The AIC differences indicate small differences between the first- and second-best models, but clear  
 97 support for peak age of reproduction between 19 and 20.

108 Figure S2. Wild-caught females had a greatly reduced odds of reproduction at peak reproductive ages (20-  
 109 44) and at the onset of reproduction (13-19). Furthermore, the decrease in reproductive rates immediately  
 110 after capture was the most pronounced in wild-caught females that were captured at older ages. Age-specific  
 111 reproduction odds ratios comparing wild-caught to captive-born, for all individuals (1323 captive-born  
 112 females and 1362 wild-caught females). Solid black line is the average age-specific odds ratio of  
 113 reproduction for wild-caught females relative to captive-born females, irrespective of capture age. Points  
 114 are examples of age-specific odds ratios for wild-caught females at different ages, where the colour and  
 115 shape denote predictions for specific capture ages (5,13,20,30). Dashed black line at odds 1 indicates an  
 116 equal odds for wild-caught and captive-born females.

Figure S5. Calves of wild-caught (WB) mothers had increased mortality odds ratios (at each age from birth to age 5) compared to calves of captive-born (CB) mothers, the effect decreasing slowly and lasting ~16 years after mother's capture from wild (n=10,192 observations, 2423 calves, 1030 mothers). Points are yearly odds ratios after the mother's capture for calves born to wild-caught females relative to calves born to captive-born females. Dashed black line at odds 1 indicates an equal odds for calves of wild-caught mothers and calves of captive-born mothers.

187 **Table S1.** Parameter estimates and likelihood ratio tests (LRTs) for the effect of birth origin on lifetime  
 188 reproduction (a- binomial mixed effects model, n = 1678) and log-transformed age at first reproduction (b-  
 189 linear mixed effects model, n = 843) for female timber elephants. Estimates and standard errors presented  
 190 on the logit scale for table a). Colon (:) denotes an interaction terms.
