S2. Correlations between gB2rest and frontoparietal and frontooccipital PLVs in resting-state

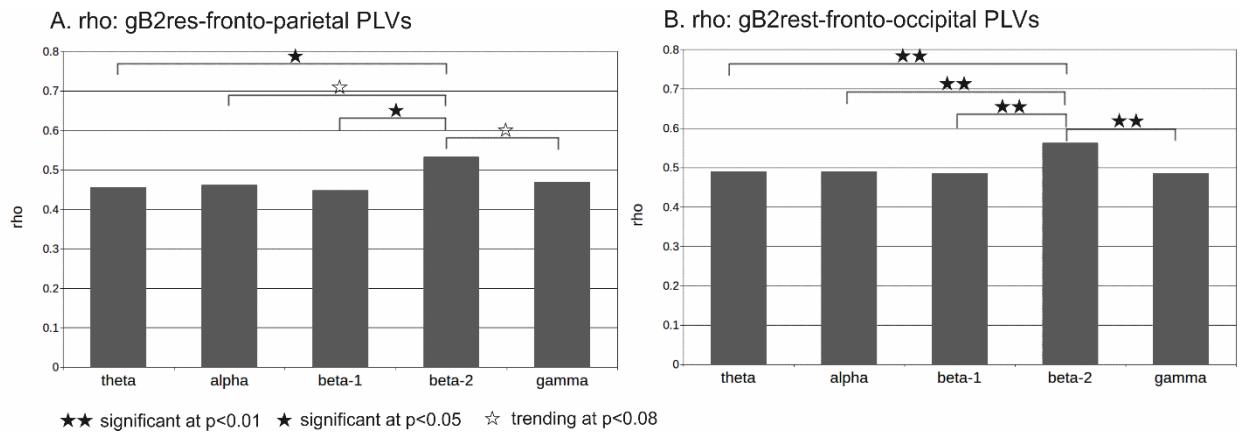

Fig. S2. Averaged correlations between gB2rest and frontoparietal (A) as well as frontooccipital (B) PLVs calculated for all investigated bands. Note that for both connections PLVs in the beta-2 band were significantly higher than PLVs in any other EEG band.

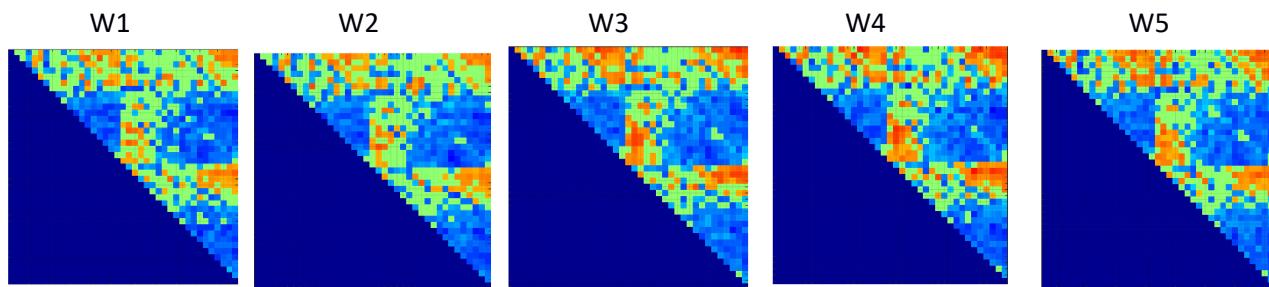

In total, frontoparietal PLVs included 101 pairs of signals spanning frontal (F) and centroparietal (CP) as well as frontal (F) and parietal (P) recordings. Frontooccipital PLVs included 39 pairs of signals spanning frontal (F) parietooccipital (PO) and occipital (O) recordings.

For each of the two groups (frontoparietal and frontooccipital) 2-tailed t-test was calculated to compare average PLV differences between investigated bands.

Significant differences between test and retest are marked with colors (blue for decrease and red increase). T – test,

R – retest.

S11. Behavioral differences between groups with high and low global beta-2 resting state power (gB2rest)

To verify whether detected correlations between gB2rest and behavioral performance yielded significant differences we divided all subjects into two equally numbered groups (HIGH and LOW, each containing 16 participants with highest and lowest beta-2 global values, respectively) and compared their behavioral results in TEST and RETEST.

The ANOVA analysis of the reaction times in the attention task showed significant effect of the group ($F(1,30) = 5.5104$ $p=0.0257$). Subsequent Tukey post-hoc test showed trending shorter reaction times of the LOW beta-2 group in both experiments in TEST (diff: 0.1 s; $p=0.0562$) and RETEST (diff: 0.11 s; $p<0.0508$). Significant effect of interaction between groups and sessions ($F(1,30) = 5.3273$, $p=0.0281$) indicated also better performance improvement of the LOW group. HIGH group shortened average RT by 0.0581 s and LOW group by 0.0629 respectively.

The analysis of the shooting scores showed significant effect of the group ($F(1,30) = 7.3565$, $p=0.011$). Subsequent Tukey post-hoc test confirmed significantly higher average number of precision points in the LOW than HIGH beta-2 group in TEST (diff: 26 points; $p=0.0209$) and RETEST (diff: 22 points; $p=0.0394$). Significant effect of interaction between groups and sessions ($F(1,30) = 6.7990$, $p=0.0141$) indicated larger improvement of performance of the HIGH group. The HIGH group increased their precision results by 36 points while LOW group by 32 points. Both differences between sessions were significant ($p<0.01$, all subjects participated in the shooting lessons).

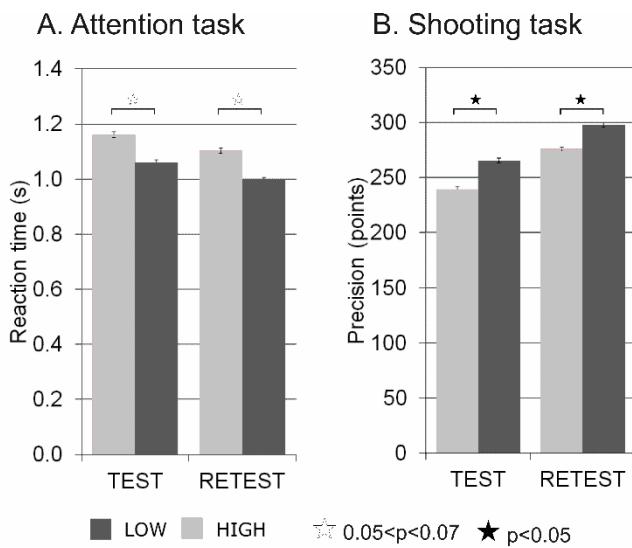

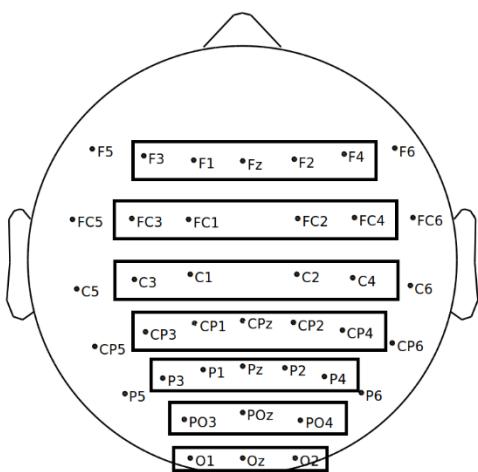

Fig. S11. Reaction times (A) and precision scores (B) measured for HIGH and LOW group in TEST and RETEST. Filled stars indicate differences at $p<0.05$ and empty stars at $p<0.01$.

S12. Exclusion of the possible effects of impedance and volume conduction

While high and low groups were defined on the basis of beta-2 powers it came out that their resting state power spectra differed also in the whole range from 2 to 45 Hz ($p<0.01$, FDR corrected for all electrodes). This result could be attributed to differences in impedance of the electrodes for particular subjects resulting from the differences of conductivity or electrodes impedance. It appeared, however, that the average impedances of the electrodes measured for high and low groups did not differ (two-sample t-test; $p=0.22$). Additionally, we calculated average impedance value from all electrodes of each subject and selected equally numbered (16 subjects each) subgroups with high and low impedance values. Then we calculated correlations and ANOVA analyses for reaction times and corresponding ERP/FFT/PLV data comparing high and low impedance groups. None of these analyses yielded significant results precluding influence of impedance or conductivity on analyzed parameters.

S13. Electrode locations and regions of interest used for defining behaviorally relevant EEG bands

A. Visual search task

B. Shooting task

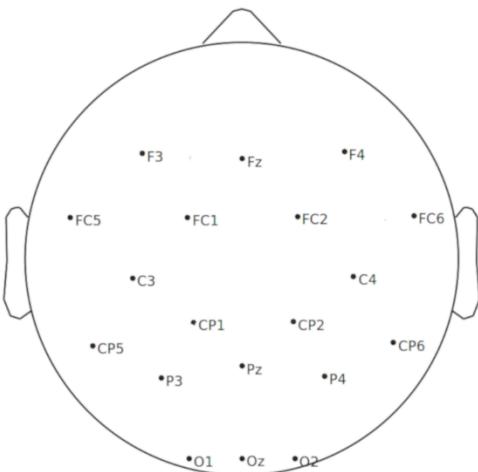

Fig. S13. A. Locations of electrodes and regions of interest used in visual search task data analyses. Each set of outlined electrodes formed separate region of interest (ROI) and their grouped signals were averaged for analyses. The ROIs were labeled (anterior to posterior) as follows: frontal (F). fronto–central (FC). central (C). centro–parietal (CP). parietal (P). parieto–occipital (PO) and occipital (O). (Adopted from Toffanin et al. 2007). B. Locations of electrodes used in shooting task data analyses.

S14. Connectivity analyses with use of phase lag index (PLI)

Comparison of the test-retest connectivity differences with use of the phase lag index showed higher number of significant differences between retest and test in the low gb2rest group than in the high one (except for the alpha band) concordant with results obtained with PLV method. Due to lesser sensitivity of the phase lag index than the phase locking value the number of the pairs of electrodes showing significant (uncorrected) retest to retest differences is much smaller than the results obtained by PLV method.

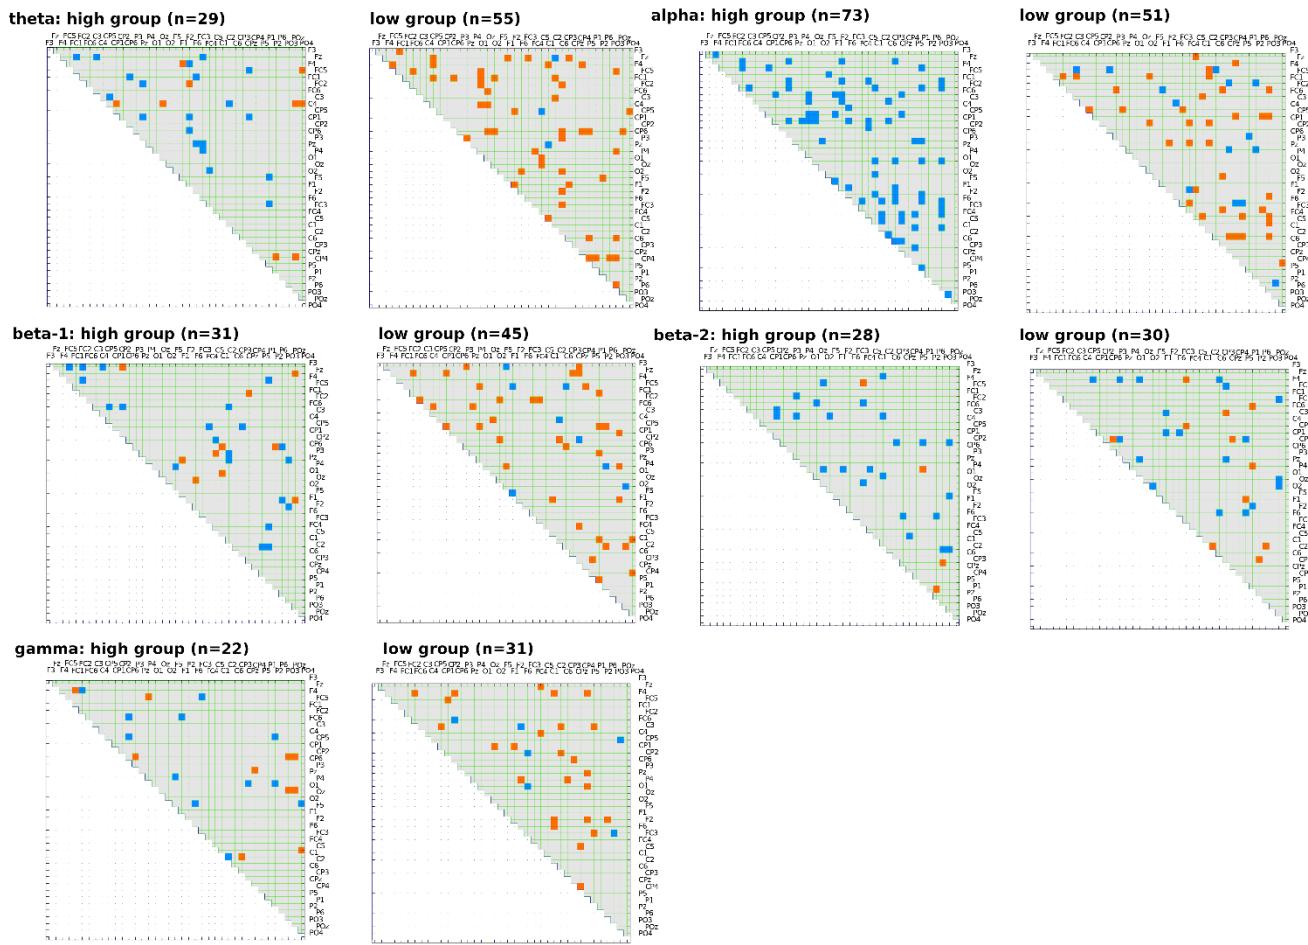

Fig. S14. Significant ($p < 0.05$ uncorrected) differences between retest and test phase lag indices (PLI) in the high and low groups in five EEG bands (theta, alpha, beta-1, beta-2 and gamma). Numbers in brackets show number of electrode pairs which PLI changed from test to retest.
