### SUPPLEMENTAL METHODS

#### In silico data set

The Multi-Center Mutation calling in Multiple Cancers (MC3) data were generated using seven different mutation calling algorithms from four centers across 32 different tumor types, thus representing a uniform set of mutation calls across thousands of tumor/normal pairs. The authors reported they focused their analysis on independently determined consensus exome coding regions defined by CCDS (GRCh37.p13, GCF\_000001405.25) that were likely captured for each sample.<sup>1</sup> We extracted the variants in the mc3.v0.2.8.PUBLIC.maf file (https://gdc.cancer.gov/about-data/publications/pancanatlas) that overlapped with the CCDS, using bedtools<sup>2</sup> (https://bedtools.readthedocs.io/en/latest/content/bedtools-suite.html). The bed file was intersected (using bedtools -wa option) with the mc3.maf file. Finally, the data was filtered for any overlap or redundancy using the 'merge' function. The Consortium created a final bed file that covered 32.102Mb of the genome, which served as the denominator for calculating WES.TMB. Three different Consortium laboratories independently calculated TMB using the same dataset and analytical methodology with 100% concordance.

#### Statistical analysis

Statistical analyses began with descriptive numerical and graphical summaries of the data to interrogate the relationship between WES.TMB and panel.TMB values. First analyses focused on the combined data from all 32 tumor types. For each panel, a scatterplot was constructed with WES.TMB on the x-axis and panel.TMB on the y-axis, and Spearman R was calculated. Scatterplots and difference plots (panel.TMB minus WES.TMB on y-axis and WES.TMB on x-axis) were examined to assess linearity of the relationship between panel.TMB and WES.TMB and to evaluate whether variance of panel.TMB was constant across the range of WES.TMB values. These assessments informed modeling of the relationships between panel.TMB.

Descriptive analyses suggested that the 32 tumors could be divided roughly into three strata. Stratum 1 contained 8 tumors (Supplemental Table 4A-Stratum 1) that demonstrated TMB values spanning the full range 0-40. Stratum 2 tumors (Supplemental Table 4B-Stratum 2) had mostly low TMB values but an occasional TMB value in the upper end of the range. Stratum 3 tumors (Supplemental Table 4C-Stratum 3) had TMB values concentrated at the low end of the range. These characteristics suggested that regression models for stratum 2 tumors would likely be less stable than those for stratum 1 as they would be highly influenced by the occasional tumors with TMB values in the upper end of the range. Regression modeling was judged to be futile for the stratum 3 tumors which spanned such a narrow range of TMB values relative to variability in panel.TMB values, for a given value of WES.TMB, that any regression model would be highly unreliable. Consequently, it was judged that regression modeling for individual tumor types would focus on tumor types in stratum 1.

Regression modeling was conducted separately for each panel. First, a regression model was fit for the combined set of 32 tumors, and then models were fit separately by the three strata. Separate regression models were fit for individual tumor types in stratum 1, but tumor type-specific regression fits were considered unreliable for strata 2 and 3 for reasons discussed above. Since the variability in panel.TMB values about the fitted regression line was observed to increase with the mean (and with WES.TMB), the regression models allowed for heteroscedasticity in the errors but assumed independence between observations. Weighted least squares was used for the regression modeling to account for the observed heteroscedasticity in errors, i.e., the variability in panel.TMB values about the fitted regression with the mean (and with the mean fitted regression models allowed to increase with the regression modeling to account for the observed heteroscedasticity in errors, i.e., the variability in panel.TMB. For each regression,

the mean panel.TMB was modeled as a simple linear function of the WES.TMB, and five different models for the error variance were considered. Restricted maximum likelihood (REML) analysis using the gls function available in the R package nlme<sup>3,4</sup> was performed to estimate the model parameters and select a best fitting variance structure based on minimum AIC and BIC criteria.

The five different variance models that were initially considered in the REML analyses each assumed that residual errors followed a Gaussian distribution, but with different variance functions as follows:

- 1. Constant (homoscedastic) function:  $var(panel.TMB|WES.TMB) = \sigma^2$  where  $\sigma^2$  is the variance parameter that is estimated using R allowing the default equal weights option in the gls function call (equivalent to ordinary least squares regression).
- 2. Power function:  $var(panel.TMB|WES.TMB) = \sigma^2 |WES.TMB|^{2c}$  where 2c defines the power in the variance function and  $\sigma^2$  is a scale factor. These variance parameters are estimated using R, specifying

weights = varPower(form=~WES.TMB)

in the gls function call.

3. Exponential function:  $var(panel.TMB|WES.TMB) = \sigma^2 exp(2c * WES.TMB)$  where 2c defines the rate parameter in the exponential variance function and  $\sigma^2$  is a scale factor. These variance parameters are estimated using R, specifying

```
weights = varExp(form=~WES.TMB)
```

in the gls function call.

4. Constant plus power function:  $var(panel.TMB|WES.TMB) = (c_1 + |WES.TMB|^{c_2})^2$  where  $c_1$  and  $c_2$  define the location and scale parameters of the variance function that are estimated using R, specifying

weights = varConstPower(0.5,0.5,form=~WES.TMB)

in the gls function call (initializing each of the constants  $c_1$  and  $c_2$  to 0.5).

5. Cancer type-specific power function: Same as variance model 2 except that the power parameter, *c*, is allowed to depend on the cancer type. These variance parameters are estimated using R, specifying

weights = varPower(form=~WES.TMB|Cancer.type)

in the gls function call.

A linear form of the mean structure was found to provide a reasonable fit for each of the panels. The power variance model was found to provide the best fit or near-best fit variance structure (by minimum AIC and BIC criteria) across all regression analyses. A final model comprising a linear mean structure and power variance structure was fit by maximum likelihood for each regression. Using parameters estimated from these final models, 95% prediction intervals were constructed, as a function of WES.TMB value, to provide approximate bounds within which 95% of the panel.TMB values are expected to fall. The approximate 95% prediction limits (LL, UL) for the distribution of panel.TMB values expected when WES.TMB= $w_0$  are calculated as

$$LL = \hat{b}_0 + \hat{b}_1 w_0 - q_t (0.975, n-2) \hat{\sigma} w_0^{\hat{c}} (1 + 1/n + (w_0 - \overline{w})^2 / [(n-1)s_w^2]))^{\frac{1}{2}}$$

$$UL = \hat{b}_0 + \hat{b}_1 w_0 + q_t (0.975, n-2) \hat{\sigma} w_0^{\hat{c}} (1 + 1/n + (w_0 - \overline{w})^2 / [(n-1)s_w^2]))^{\frac{1}{2}}$$

where

 $w_1, w_2, \ldots, w_n$  are the *n* observed WES.TMB values;

 $\overline{w} = \sum_{i=1}^{n} w_i/n;$ 

 $s_w^2 = \sum_{i=1}^n (w_i - \overline{w})^2 / (n-1);$ 

 $\hat{b}_0$  is the estimated intercept of the regression line fit by gls;

 $\hat{b}_1$  is the estimated slope of the regression line fit by gls;

 $\hat{c}$  and  $\hat{\sigma}$  are the estimated parameters of the power variance function as defined in 2 above;

 $q_t(0.975, n-2)$  is the 97.5<sup>th</sup> percentile (0.025 upper quantile) of a t-distribution with n-2 degrees of freedom. For 99% prediction limits,  $q_t(0.995, n-2)$  replaces  $q_t(0.975, n-2)$ .

Supplemental Figure 4: Sensitivity at various target coverage values by allele frequency. Two contrived samples (mixes of 10 different HapMap cell lines) were created as described by Frampton et.al. (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5710001/) to create a pool of samples with variant allele frequencies ranging between 5% to 100%. These were sequenced using Agilent's SureSelect platform (v5) on the NovaSeq sequencing system generating 150bp paired-end reads. Reads were aligned to the hg19 reference build, generating >600X coverage for the targeted region of the exome (~80MB). A gold standard was also created for these samples by sequencing each cell line individually. The contrived samples were compared against the gold standard. At this high sequencing depth, the sensitivity achieved is >97% for variants with  $\geq$ 10% VAF and >91% for variants  $\geq$ 5% VAF. To check the sensitivity as a function of depth, these samples were down-sampled to FASTQ level using The Seqtk tool for 90%-5% of the original reads generating samples with median target coverage from ~580X to 40X. This plot shows the performance of a particular dilution for different variant allele frequency variants with  $\geq$ 10% variant allele frequency at sensitivity >90%.

Supplemental Figure 5: Scatterplot for panel TMB as a function of WES TMB for each participating laboratory for all cancer types in the validation dataset of the TCGA MC3 dataset. The black solid line represents the estimated regression line, and the red dashed line represents the 45° line. The dark gray and light gray dotted lines represent 95% and 99% prediction limits calculated from the fitted weighted regression models.

Supplemental Figure 6: Scatterplot for panel TMB as a function of WES TMB for each participating laboratory for only those cancer types in stratum 1 (most cancer types span the full range of 0-40mut/Mb). The black solid line represents the estimated regression line, and the red dashed line represents the  $45^{\circ}$  line. The dark gray and light gray dotted lines represent 95% and 99% prediction limits calculated from the fitted weighted regression models. Each color represents a different cancer type.

Supplemental Figure 7: Scatterplot for panel TMB as a function of WES TMB for each participating laboratory for only those cancer types in stratum 2 (most samples had low TMB values with occasional samples with values in the upper range, < 10 samples with TMB 10-40mut/Mb). The black solid line

represents the estimated regression line, and the red dashed line represents the 45° line. The dark gray and light gray dotted lines represent 95% and 99% prediction limits calculated from the fitted weighted regression models.

Supplemental Figure 8: Scatterplot for panel TMB as a function of WES TMB for each participating laboratory for only those cancer types in stratum 3 (most samples had low TMB values < 10 mut/Mb).

The black solid line represents the estimated regression line, and the red dashed line represents the  $45^{\circ}$  line. The dark gray and light gray dotted lines represent 95% and 99% prediction limits calculated from the fitted weighted regression models.

Supplemental Figure 9: 95% prediction intervals for panel TMB values estimated at discreet WES TMB values (5, 10, 15, and 20 mut/Mb), by stratum and laboratory. Blue arrows represent the estimated mean panel TMB for each laboratory. Red dashed line represents the discreet WES TMB value at which prediction intervals were calculated.

Supplemental Figure 10: 95% prediction intervals for panel TMB values estimated at discreet WES TMB values (Panels A: 5, B: 10, C: 15, and D: 20 mut/Mb), by cancer type and laboratory. Blue arrows represent the estimated mean panel TMB for each laboratory. Red dashed line represents the discreet WES TMB value at which prediction intervals were calculated.
