

99: *-.106*

In the framework of a project to reintroduce the European lynx, the criteria for the reintroduction of locally extinct animal species, the historical and current distribution of the lynx, its ecological requirements and population genetic aspects of a reintroduction were evaluated. The supply of the animals and a possible inclusion of zoo animals bred in captivity via adoption techniques were discussed.

109: *+.171*

After a sharp decline in numbers during the early decades of the 20th century, the last raven was found breeding in 1944 (fig. 1). In 1966, a re-introduction project was started. During 1966-78 ravens were imported from FRG (39), GDR (75), and Switzerland (2) (appendix 1). The imported ravens were partly kept in cages and partly released (appendix 1). Most young hatched in the cages were released (appendix 1). In 1976, the first free-living breeding pairs were observed (fig. 2). After a few years of increasing numbers, the population crashed (fig. 2). Since 1983-84, a strong increase takes place up to 17 breeding pairs in 1988. Most ravens breed on the Veluwe, a large area with coniferous and deciduous forests, and heather fields. One pair was recorded in the dunes (1979) and one on the Utrechtse Heuvelrug (1976-88). Since 1980, solitary ravens are recorded elsewhere in the country. In the first years, the breeding success was quite low, but improved with time (appendix 2). In 1976-88, 87 pairs raised 164 young, average 1.89/pair (s.d. 1.57). For the successful pairs (68%), the average was 2.78 young (s.d. 1.07). At present, the population comprises nearly exclusively of birds born in the wild. The decline in 1980-81 probably marks the extinction of introduced birds at a moment the numbers of free-born ravens were not yet large enough to fill the gap (fig. 3, appendix 1). In the Netherlands the Raven feeds, among other things as afterbirths of sheep and deer, and artificial feeding sites for game, on insects and their larvae, carrion, and rubbish. Around 1945, ravens only remained in Schleswig-Holstein, Poland, eastern Czechoslovakia, in the higher Alps, and along the western coast of France. After strong protective measures were taken, the species re-occupied several parts of western Europe (fig. 4). The re-introduction in the Netherlands was the first in western Europe, and was followed by successful ones in Belgium and FRG.

113: *+.116*

Lathyrus pisiformis was recently found at 14 localities in Poland (known from 21 localities altogether). 9 of them occur at the Kielce-Sandomierz Upland (central Poland), the other five are scattered in the North Poland. The latter ones are marginal, at the NW outskirts of the general distribution of this species. The distribution center of *L. pisiformis* occurs in the South Siberian province, in Europe it grows only at insular localities. The habitats of *L. pisiformis* are dry or fresh, moderately fertile, neutral or alkaline rendzinas or brown soils. It prefers places with some little shade. Its phytocoenotic optimum is in open thermophilous forests of *Quercus-Fagetum* class and in shrub communities, on their margins, and exceptionally it can be found on secondary habitats e.g. in ditches or on road escarpments. The loss of localities found recently (4 disappeared for certain, the other 3 probably), is restricted to the North Poland, and its direct reason is growing shadiness caused by the development of shrubs and trees. It is why this species requires the active protection on the localities still existing, and the reintroduction on a part of historical ones.

122: *-.121*

By help of questionnaires sent to the respective organisations maps on the present distribution of roe deer, fallow deer and red deer in Spain were elaborated. At the beginning of this century most of these species were extinguished because of bad hunting politics. They were reintroduced in the sixties and, together with rural depopulation and decrease of predators, spread widely.

126: +.171

In vitro seed germination of *Bletia urbana* was achieved on two basal media (KC and MS) with organic supplements. Cultures were maintained in three environmental conditions. Germination, defined as the presence of protocorms with one leaf primordium one month after culture, occurred under all the conditions levels, varying from 21-100%. Not all germinated seeds reached the adult stage (defined as plantlets with leaves at least 30 mm long, pseudobulbs, and roots). The best germination occurred on KC with 3% sucrose and 10% coconut water (CW) at 25 C \pm 2 and 16-hr photoperiods (1200 lux). Under these conditions all seedlings developed to the adult stage, forming leaves, pseudobulbs, and roots after 90 days of in vitro culture. The seedlings obtained were preadapted in a greenhouse where survival was 100% before transplanting them into their natural environment. One hundred and thirty-three plants were placed in the wild, protected with cages, and monitored for 90 days. Of the original seedlings, 56% survived in the field during this period. One year later, 15% of the seedlings started to grow and form new leaves and bulbs, suggesting that the reestablished plants are able to complete at least part of their life cycle.

127: +.088

Cupressus dupreziana has been proclaimed by IUCN as one of the twelve mostly endangered plant species on a world scale. Information is presented on the relict population in the Tassili Range in the extreme south-east of Algeria. Successful reintroduction of six-year-old trees from Czechoslovakia to Tassili is described. Dendrochronological investigation showed a very complex tree-ring structure. A xylotomical study proved that by means of quantitative xylotomy it is possible to distinguish the wood of *C. dupreziana* from the wood of other cypress species and several related taxa. Perspectives are mentioned of *C. dupreziana* further research and conservation.

133: +.316

Between 1967 and 1978, 145 Ibexes were reintroduced in Haute-Savoie. In 10 different sites. The choice of the massifs was governed by the ecological knowledge available about the species, but without any thorough study. In 1986, the National Research Program on the Ibex made it possible to evaluate this project. At present, the population is estimated to consist of 700 individuals, i.e. 36% of the national numbers. The animals were released on sites offering quite varied environmental conditions. This diversity of situation evidently resulted in variable "success rate", the analysis of which enables us to derive some experience for future prospects of reintroduction in the Alps.

141: +.166

Hawaii Volcanoes National Park has supported a Nene Reintroduction Programme since 1974. The Resources Management Division is responsible for the management and monitoring of birds within and adjacent to the Park boundaries. The management aim has been to work toward the production of a wild, self-sustaining population. The method employed in order to achieve this has been to release captive-bred Nene into the wild. To date, a total of 177 birds has been released and

monitored in and near the Park. This report summarises progress over the last 15 years.

142: +.122

Breeding results and recolonization data are reported for a ten-year project of the German nature conservation association, Bund Naturschutz, aimed at reintroducing the European wildcat (*Felis silvestris silvestris*) in Bavaria. Criteria for successful reintroduction of endangered animal species are discussed and their fulfillment in the wildcat reintroduction program is evaluated.

144: +.108

A survey of ibex (*Capra ibex ibex* L) habitat in the European Alps reveals for 1983 a total number of c. 18,000 animals. Of these, Switzerland and Italy account for respectively 56% and 25%, followed by Austria with 10% and France with 7%, while the remaining numbers occur in Germany and Yugoslavia. There is still a potential for further re-introduction of the ibex in five major mountain massifs in the franco-italian Alps and in South Tyrol. New insights in re-introduction techniques are discussed against the background of landscape ecology and behavioural ecology. In thriving populations, ibex numbers increase at an estimated annual rate of 11%. Hunting in Switzerland and in Austria, together with poaching are major man-induced regulating factors of ibex numbers. Nowadays the emphasis in ibex conservation and management has shifted towards population management and problems of local abundance. It is argued that management orientated research should be undertaken, and especially the monitoring of the impact of the ibex on habitat condition. Recent pressure to undertake culling in the largest ibex population of the Alps, the Gran Paradiso-Vanoise massif, is critically discussed.

148: +.020

The lynx (*Lynx lynx*, L.1758) was indigenous to the Black Forest until the 17th century. At the end of the 30-Year War, an increased persecution of the lynx by means of hunting began. This subsequently caused an almost complete disappearance by the end of that century and finally led to a total extinction during the 18th century. Derived from Wuerttemberg hunting records from the beginning of the reduction period, the former lynx density was 1.5 lynx/100 km². The present day suitability of the Black Forest as an appropriate habitat for the lynx has been concluded based on experiences made in neighboring countries with lynx populations. Accordingly, the Black Forest with its expansive forests (percentage of entire forest area is 66%) offers sufficient shelter and retreat space. Under such conditions, heavy tourism proves not to be problematic. Several east/west bound highways cut through the Black Forest, however, there is not enough traffic during the night to present a serious barrier to migrations, since the lynx roams mainly during twilight and at night. Nevertheless, roads and train tracks pose a latent threat. Thus, occasional accidental deaths can be expected. Roe deer (*Capreolus capreolus*, L.) (in high density) and brown hare (*Lepus europaeus*) (in lesser density) as well as the locally occurring chamois (*Rupicapra rupicapra*, L.), red deer (*Cervus elaphus*, L.) and wild boar (*Sus scrofa*, L.) are all suitable prey for the lynx. In the Black Forest, the population of the roe deer alone would be enough to satisfy the nutritional needs of a lynx population. In order to estimate the possible size of a lynx population in the Black Forest, a density of 1 lynx/100 km² was assumed. The Black forest area was divided into unsuitable regions (settlements, inclusive of a buffer zone, and non-wooded areas with widths of more than 1 km), partially suitable areas (regions with scattered forests), and suitable areas. Based on these criteria, 4100 km² are suitable habitat, and 1000 km² can be used for passage, respectively for hunting. The forest area of these two categories combined is 4500 km². Consequently, the Black Forest can accommodate at least 40 lynx. A population of this size can be

expected to survive, even without contact to neighboring populations. The impact of these lynx on their prey species would be small. The calculated lynx population needs 0,7 roe deer/km² annually or an equivalent amount of other prey. Such a loss of roe deer would probably fall into the range of compensatory mortality, thus reducing natural deaths, and therefore not affect the hunting yield. While roe deer are caught by the lynx more or less without selection, the hunting success of the lynx in the larger and stronger ungulates is shifting increasingly towards juvenile, overaged, weak and ill animals, which are of lower interest for hunters. The capercaillie (*Tetrao urogallus*, L.) and the hazel hen (*Bonasa bonasia*, L.) are not jeopardized by the lynx due to low population densities and a rich supply of alternative prey. The only danger for domestic animals is with sheep which are left unwatched overnight in enclosures adjacent to forest. Based on experience, a negative influence of the lynx on tourism is not to be expected. Since wild lynx are absolutely harmless towards people, their presence even might become a tourist attraction. The Black Forest offers favorable habitat conditions to lynx. Damage caused by these animals will be small. Therefore their reintroduction to the Black Forest is recommended. For release, a site in the northern part of the area should be considered.

151: +.202

Twenty-seven ponds were restored or created at Feyent Country Park, Middlesex, in the London Borough of Brent during the 1980s. The ponds have been colonised by 68 plant species, the distribution of which is described. Since the start of the pond restoration programme, several new species have been recorded in the ponds and many species have increased their range. About 22 species have been introduced. The results are discussed in relation to the conservation of pond flora.

162: +.124

Mountain sheep (*Ovis canadensis*) are closely associated with steep, mountainous, open terrain. Their habitat consequently occurs in a naturally fragmented pattern, often with substantial expanses of unsuitable habitat between suitable patches; the sheep have been noted to be slow colonizers of vacant suitable habitat. As a result, resource managers have focused on (1) conserving "traditional" mountainous habitats, and (2) forced colonization through reintroduction. Telemetry studies in desert habitats have recorded more intermountain movement by desert sheep than was previously thought to occur. Given the heretofore unrecognized vagility of mountain sheep, we argue that existing corridors of "nontraditional" habitat connecting mountain ranges be given adequate conservation consideration. Additionally, small areas of mountainous habitat that are not permanently occupied but that may serve as "stepping stones" within such corridors must be recognized for their potential importance to relatively isolated populations of mountain sheep. We discuss the potential importance of such corridors to other large, vagile species.

163: +.171

Efforts to restore the endangered masked bobwhite (*Colinus virginianus ridgwayi*) to its former range have required 1) habitat acquisition, restoration, and preservation; 2) captive propagation; and 3) reintroduction of captive-bred stock. In its role to recover the masked bobwhite, the Patuxent Wildlife Research Center (U.S. Fish and Wildlife Service) has refined captive breeding techniques; provided captive-produced stock for release; conducted field research on the distribution, limiting factors, and habitat characteristics of this species; and developed release methods. Techniques for the husbandry and captive management, breeding, artificial incubation and hatching of eggs, and rearing of young of the masked bobwhite have been developed.

Successful reintroduction techniques for the masked bobwhite have included prerelease conditioning and/or cross-fostering of captive-reared masked bobwhite chicks to a wild-caught, related, vasectomized bobwhite species and their release to the wild as family units. In addition, the establishment by the U.S. Fish and Wildlife Service of the Buenos Aires National Wildlife Refuge in 1985 has further enhanced the potential for establishing a self-sustaining population of the masked bobwhite in the U.S. Through continued releases and active management of habitat, therefore, it is believed that the masked bobwhite can become permanently established at the refuge to ensure its continued survival in the wild.

173: -.063

The cytogenetic survey of a captive population of Arabian Oryx (*Oryx leucoryx*) in Saudi Arabia has permitted the detection of a Robertsonian translocation involving chromosome pairs 17 and 19. This population has been constituted with animals from various arabian peninsula countries. The origin of this translocation is uncertain. Our results suggest that it originated from Qatar.

176: +.085

On July 11th 1990 beaver *Castor fiber* L., 1758 was seen in the river Rur, near Kuechelscheid in the Hautes Fagnes. To our knowledge this was the first beaver seen in Belgium since 1848. It seems very likely that the animal originates from a German reintroduction project in the northern Eifel.

177: +.054

The continuing loss of isolated headwater populations of brook trout (*Salvelinus fontinalis*) in the southern Appalachians [USA] cannot be attributed solely to competition from invading rainbow trout (*Oncorhynchus mykiss*). Brook trout in headwater habitats may even enjoy a competitive advantage over rainbows, yet they continue to experience local extinctions due to demographic stochasticity and natural catastrophes. Reintroduction of brook trout into headwater habitats currently occupied by rainbow trout may be a useful addition to current management policies designed to arrest the decline of brook trout.

178: +.094

Fishes of seven North Carolina and South Carolina [USA] river systems were sampled to determine the distribution and current status of two fishes, the sandhills chub *Semotilus lumbee* and the pinewoods darter *Etheostoma mariae* both endemic to the Carolina Sandhills area. A total of 261 localities in 15 counties was sampled. The chub was found at 53 of these localities, and the darter at 37. The chub could not be located at 11 (42%), and the darter at 9 (31%), of previously known localities. In many cases this was due to habitat deterioration caused man and the recent and highly successful reintroduction of the beaver. We found the chub at 38 and the darter at 17 previously undocumented localities. We took the chub in the Wateree River system, South Carolina, in which it was previously not known. Both species are present and are doing well, but, because of their limited distributions, their status should be monitored.

180: +.228

The inland waters of Australia have been colonized successfully by 20 species of freshwater fishes introduced to the continent, including 6 poeciliids, 3 salmonids, 4 cyprinids, 5 cichlids, 1 percid

and 1 cobitid, all of which reproduce there in the wild. The ecological and genetic consequences of fish introduction and translocations have concerned scientists and water authorities since the late 1960's, although the earliest introductions of salmonids for sport were made towards the end of the 19th century. Impacts of introduced fishes, including hybridization problems, habitat and water quality alterations, competition for space and food, predation and the introduction of exotic parasites and diseases are reviewed. Emphasis is placed on sub-tropical and tropical species, since they appear to present the greatest threat to natural ecosystems. Problems in the translocation of indigenous Australian fishes between drainage systems to supplement recreational fishing are noted; a review of the Lake Eacham rainbowfish, supposedly brought close, to extinction in its natural habitat by translocated Australian piscivores, demonstrates that unanticipated predator-prey interactions may result from the thoughtless addition of piscivores to an endemic community. A theoretical perspective on the assessment of candidate species for introduction and translocation is given, and areas of theoretical ecology that may assist in predicting future impacts of introduced species are discussed.

183: +.009

Beginning in the 1500s, over-exploitation and poaching led to a steady decline of ibex (*Capra ibex*) numbers in the European Alps. The use of ibex products in many folk remedies guaranteed high financial returns for the hunter and resulted in the relentless pursuit of this species. By the early 1800s, < 100 animals survived in a single population in the Italian Gran Paradiso mountain massif. The recovery to more than 20 000 animals today is the result of a four-stage conservation effort which returned alpine ibex to almost their entire original range of distribution: (1) effective protection of the last remaining population, (2) captive breeding of animals caught in the recovered last population, (3) reintroduction of captive-bred animals into protected original habitat, (4) translocation of animals from successfully established "reservoir" populations to uninhabited sites. Alpine ibex management faces two challenges today: (1) habitat destruction in areas of high population densities, and (2) low genetic variability possibly a result of inbreeding during a succession of four potential population bottleneck situations.

184: -.007

Przewalski's horses (*Equus przewalskii*) are believed to be extinct in the wild; the current known population of 797 animals exists wholly in zoos. The Species Survival Commission of the International Union for Conservation of Nature and Natural Resources is proposing to reintroduce this endangered species into its former Mongolian habitat within the next decade. Knowledge of the behavior of harem-forming equids in general and of Przewalski's horses in particular, is of great importance to the captive propagation and eventual reintroduction of this species. Horses are rarely solitary by nature. Solitary captive animals are prone to pacing. Juvenile male feral horses (*Equus caballus*) form bachelor herds upon dispersal from their natal band. Zoos can set up bachelor herds as a way of managing surplus males. The older, more dominant feral horse bachelors are the first to acquire mares. Bachelors do not generally obtain females until they are 4 or 5 years of age. The first females acquired are usually 1- and 2-year-old fillies dispersing from their natal band. Because of the age differential, the stallions are generally dominant to their mares. Behavioral impotence may result if captive stallions are given a harem at too young an age, especially if the harem contains older, more dominant, females. Typical harem sizes in the wild are 3-5 mares. Captive stallions with too large a harem may become either apathetic or aggressive toward their mares. Wild horses spend 60-70% of their time foraging. Captive animals may quickly consume their limited amounts of food and develop vices out of boredom. Provision of hay ad libitum reduces the amount of pacing seen in captive animals, and virtually eliminates

185: +.189

Natural populations of woody perennials on lead-mining sites in the Mechernich area of the Eifel Mountains were investigated with respect to soil factors determining the degree and type of heavy metal tolerance. *Salix caprea* L. (Goat Willow) grew on soils with up to 17000 mg kg⁻¹ total lead (ca. 4000 mg kg⁻¹ ammonium acetate-exchangeable Pb). *Betula pendula* Roth (Silver Birch) was found on soils containing as much as 29000 mg kg⁻¹ total lead (7000 mg kg⁻¹ ammonium acetate-exchangeable Pb). Other woody perennials, with the exception of the dwarf shrub *Calluna vulgaris*, were not found in the contaminated area even though they did occur in the immediate vicinity. The two lead-tolerant tree species did not form mixed populations. Because of a significantly lower Pb/Ca ratio in *Salix* soils (2.2) compared with *Betula* soils (7.4), a calcium-dependent mechanism of lead tolerance is suggested for *Salix*, but not for *Betula*. The *Betula* population could be divided into two groups, each showing a highly significant correlation between root-lead content and exchangeable lead amounts in the soil, but with different levels of lead uptake. The only soil factor distinguishing the two groups was found to be the level of soluble phosphate. A distinctly low level of soil phosphate correlated with a high lead concentration in roots of the one group (30000 mg Pb kg⁻¹ DW), whereas high phosphate amounts corresponded with a much lower lead concentration in roots of the other (12000 mg Pb kg⁻¹ DW). Since the correlation between lead in the soil and in plants was similar for the two groups, it is concluded that the type of lead tolerance in *Betula* is determined by the status of plant phosphate nutrition, rather than by simple phosphate precipitation in the soil. A comparison of growth between different populations of *Betula* seedlings on homogenized soils from the mining area revealed the Mechernich population to be a distinct ecotype with respect to lead tolerance. The control population obtained from a non-contaminated area exhibited a lower degree of lead tolerance coupled with a two-step strategy of adaptation to lead.

186: -.019

Jordan lies at a meeting-point of three zoogeographical areas: the Palaearctic, the Afrotropical, and the Oriental - circumstances which were conducive to habitat diversity in Jordan and hence the diversity and often abundant occurrence of different floral and faunal elements. The present paper gives information about the history and past occurrence of large mammalian species and their populations in Jordan, while also focusing on the present status of the large mammalian species, and gives the reasons for extinctions and the preventive measures that are being taken to conserve the populations remaining. In addition, this study gives a future prospective outlook for habitat and mammalian conservation, and the reintroduction programme that is being implemented in Jordan. The first part of the paper sheds light on the past existence of large mammals in Jordan. The historical sequence of events starting from the Upper Palaeolithic and continuing right up to the present, and the succession of civilizations, had a negative impact on the large mammalian populations. This section gives tabulated data on the past occurrence of 26 species, supported by evidence of their past existence such as bone remains, rock drawings, engravings, mosaics, and frescos, found in various archaeological sites in Jordan. The second part of the paper deals with the present status of large mammalian populations, their distribution being reflected through maps indicating recent sightings in some outstanding cases. Among those are reintroduced species such as the Arabian Oryx and the Syrian Wild Ass, and highly threatened species such as the Nubian Ibex. This part also investigates the reasons for extinction, which mainly link the destruction of habitats with the direct deterioration of mammalian populations. Habitat destruction was chiefly due to the rapid decline of the natural pasture areas, overgrazing, urban expansions, unorganized

construction plans, human impact, mismanagement of the highlands, fire, and hunting. All of these factors led to deforestation and soil erosion, resulting in a patchy, fragile ecocomplex. The decrease of rainfall assisted the severe deterioration of natural forests. The future outlook of this study includes plans to restore ecosystems and, with them, much of the overall ecocomplex. For this and other reasons it also stresses the urgent need to establish more reserves, both grazing and natural. This concluding part of the paper encourages the improvement of national parks, and urges the authorities to look seriously at the often disastrous effects of mismanagement. The importance of collaboration between Jordan and the various international agencies is emphasized, as well as the need to speed up work on the National Conservation Strategy of Jordan.

187: -.079

The proposition is examined that cytogenetic studies are needed in the conservation of wild captive animals. Several cases of polymorphic species have hybridized to produce infertile offspring. In several gazelle species, this accidental hybridization among look-alike animals has led to the extinction of zoo populations. The suggestion that this is always the result of inbreeding is thus erroneous. Cytogenetic study is also needed in animals that are destined for reintroduction, as accidental release of chromosomally different species is counterproductive to the reestablishment of wild stock. Several examples of mammalian species that have flourished from an extremely small founder stock are here examined to draw attention to the possibility that "inbreeding" is not invariably disadvantageous. The karyotypes of two hybridizing Kobus species with divergent chromosomal numbers are described.

188: +.091

The little spotted kiwi (*Apteryx owenii*) is probably extinct on both main islands of New Zealand. Its only known surviving population is on Kapiti Island (1,970 ha). Translocations to other offshore islands are seen as essential to the survival of the species. In this paper we discuss the criteria for assessment of islands for translocations, and the early results of two transfers. Only five of > 700 known islands were identified as potentially suitable. None was greater than 500 ha in size. Between 1982 and 1989 little spotted kiwis were transferred to three islands, Long, Red Mercury, and Hen Is. All, or nearly all, of the transferred birds survived on Long and Red Mercury Islands and have since bred on both. The result of the transfer to Hen Island has yet to be determined. The limited potential carrying capacity of these islands for little spotted kiwis, and the need for a new transfer to a larger island, are discussed.

189: +.029

The possible occurrence of low molecular weight, soluble ligands binding copper, zinc, cadmium and lead was investigated in *Rhynchostegium riparioides*, a widespread moss in flowing waters, which occurs at sites influenced by "heavy" metal contamination as well as ones free of contamination. In order to identify metal complexes with any such ligands, *Rhynchostegium* plants from an uncontaminated site were first incubated for 48 hr in medium including the metal (10 or 100- μ M) in question. Fractionation of cell extracts of this material by gel permeation HPLC revealed the presence of complexes with a similar retention time to poly(γ -glutamylcysteinyl)glycine metal complexes extracted from cell suspension cultures of *Datura innoxia*. However, the peaks corresponding to metal associated with these complexes in HPLC profiles of extracts from *Rhynchostegium* were low, so an acetone precipitation step was introduced to concentrate the bound metal. The estimated yield of Cu associated with low M(r) ligands following acetone precipitation was 65% for *Rhynchostegium* and 106% for *D. innoxia*;

the equivalent values for Cd were 25 and 40%, respectively. A Zn complex with a different apparent retention time was also present; the possibility that this might be an artifact associated with the extraction procedure is discussed. There was no evidence for intracellular binding of Pb by low M(r) ligands. Estimates of the amount of Cu and Cd associated with low M(r) ligands increased following incubation of *Rhynchostegium* from an uncontaminated site in media containing increasing concentrations (10, 50, 100- μ M) of metal. Similar complexes were also detected in populations of the same species taken directly from a contaminated site, i.e. without laboratory incubation in the presence of metal. Estimates of the proportions of Cu and Cd in *Rhynchostegium* from contaminated sites which were bound by these complexes, expressed as a percentage of the total metal accumulated by the moss, ranged from 0.06 to 0.65% for Cu and 0.24 to 2.08% for Cd.

190: +.223

The black-footed ferret (*Mustela nigripes*; Mustelidae) is a weasel-like carnivore that preys almost exclusively upon prairie dogs (*Cynomys* spp.; Rodentia) in central North America. This tightly coupled system and the endangered status of ferrets motivated our predation model. An age-dependent model is formulated, clearly stating and comparing assumptions with the actual biological system. Tenable parameters and values are built into the model in order to make predictions based on "real" data. Species-specific population data and energetic models, as well as general mustelid features, are the basis of ferret inputs. Extensive population data from several prairie dog species are used to create a "generic" prairie dog. A Holling type III functional response and sigmoidal birth and survival functions describe ferrets living in a single, very large colony of prairie dogs. The model consists of discrete-time equations for the annual birth pulse for each species, with the remaining year governed by a system of seven differential equations that allow both populations to decrease from predation and other mortality factors. The model is normalized, and it is shown that age dependence is destabilizing, except within a narrow range of values for ferret survival and birth functions. These values are close to but greater than the initial values. Sensitivity analysis reveals that general stability can be achieved by slightly increasing the hunting efficiency for the ferrets. It is suggested that higher prairie dog densities than previously predicted from energetic-based models may be necessary to ensure a stable ferret/prairie dog system. Finally, the results indicate that system stability is likely to be enhanced if patch dynamics are accounted for. Because wild black-footed ferrets are virtually extinct, these results may be a useful tool for black-footed ferret recovery efforts, particularly for planning reintroduction of captive-reared specimens.

191: +.116

Conservation strategies involving relocations, repatriations, and translocations (RRT) have been carried out, are underway, or are advocated for a number of endangered and threatened amphibians and reptiles. However, recent reviews of RRT projects involving birds and mammals suggest that the success rate is low and that the factors that lead to endangerment operate to impede effective RRT results. In this paper, we review available information on RRT projects involving amphibians and reptiles, examine the motives for advocating RRT strategies, and recommend biological and management criteria that should be considered prior to undertaking RRT projects. Most RRT projects involving amphibians and reptiles have not demonstrated success as conservation techniques and should not be advocated as if they are acceptable management and mitigation practices. We urge caution in accepting claims of success and urge colleagues to publish detailed methods and results of past and ongoing RRT projects.

192: -.218

Adult populations of water beetles were sampled in an upland loch subject to liming of its catchment prior to the reintroduction of brown trout. Populations generally declined and the commonest species, *Hydroporus palustris*, was temporarily displaced by *Potamonectes depressus elegans* before it too declined. The reasons for these changes are discussed.

193: +.199

During the past several millennia, hundreds if not thousands of Polynesian land bird populations have been reduced or eliminated by human activities—direct predation, habitat alteration, and introduction of predators and pathogens. Many of the surviving populations and species of Polynesian land birds, particularly pigeons, doves, parrots, kingfishers, and passerines, are likely to become extinct within the next few decades unless we intervene to save them. One strategy is to translocate species onto previously occupied islands, if the habitat is suitable and current human activities are compatible. In this study we evaluate a procedure for analyzing terrestrial habitats in a geographical information system (GIS) using aerial photographs, satellite imagery, topographic maps, and thematic maps. In the relatively simple island ecosystems of Atiu and Mitiaro (southern Cook Islands), mapping land cover and evaluating habitat suitability of land birds is straightforward; measures of the shape and spatial relationships of land cover patches are of limited value. Although the rate of land cover disturbance by people has not increased in recent times, even small disturbances can eliminate a significant proportion of preferred habitat for land birds. We suggest that, whenever possible, translocation efforts should focus on islands uninhabited by humans. The potential for successful translocation in the Cook Islands is limited to a few species. In Tonga, where more species of birds have been extirpated and where there are more uninhabited islands, the potential to reestablish viable land bird populations is much greater.

194: +.289

Over the past 30 years the black rhinoceros (*Diceros bicornis*) populations in Africa have dwindled dramatically. To enhance the survival prospects of the species, a national conservation strategy has been developed in South Africa. Its main goal is to formulate and implement policies to increase the southern African rhino population as rapidly as possible. This involves translocating animals from areas where the population is approaching the ecological carrying capacity and establishing new viable populations in other suitable reserves. A non-linear differential equation model for a population of black rhino was developed. The model is used with a combination of analytical and numerical techniques to investigate a number of issues relating to the translocation of rhino from well-stocked, high-density areas to low-density areas with small herds or no herds. Firstly, the model is used to determine the maximum sustainable yield from the well-stocked reserves. The model is then applied to a newly established population to determine optimal import policies. Finally, the model is extended to include both an established exporting population and a new understocked importing population. Simulations are performed to give an indication of the number and age of animals which should be translocated to maximise the growth rate of the total rhino population in southern Africa.

196: -.032

Northern Bald Ibis (*Geronticus eremita*) is a threatened species, one of the two remaining populations of which went extinct in Birecik in 1989. One of the main reasons for the extinction of this bald ibis population is DDT spraying carried out simultaneously by two government offices in

the 1950s. As a result of this insecticide application, 70% of the bald ibis population died because of acute poisoning and the reproductive success of the population fell to very low levels for the next 10-12 years. A conservation project initiated in 1973 its first goal of attracting the population away from the town, but failed in its more important aim of captive breeding and reintroduction. The main reasons of this failure are insufficient and inadequate nutrition, overcrowding in the captive population, and the indifferent attitude of the Forestry General Directory towards conservation efforts. In this article, history of the Birecik population and the ecology of the Bald Ibis are summarized, the changes in this population in the last 12 years are described, the reasons for the extinction of the population and for the failure of the conservation program are evaluated.

197: +.052

Species-rich meadows (Calthion communities) of the Oste valley in northwestern Germany (mowed twice a year) developed into stands of reeds and tall forbs (such as *Filipendula ulmaria*, *Glyceria maxima*, *Phalaris arundinacea* and *Urtica dioica*) with low species diversity when the management was abandoned. Changes in species composition and dominance, as well as a marked decline in the species diversity per plot are distinct. The change from marsh-marigold meadows (Senecioni-Brometum) to tall grass-reeds and/or tall forb communities proceeds rapidly: the expansion of some of the component species of the "initial floristic composition" occurred in the first years after abandonment. Dominant populations of the taller species inhibit succession both shortly after abandonment and over the long run. The major constraint on succession is shade: from the dominant plant species themselves as well as from a dense litter layer. These stands become slowly enriched, because environmental inputs are stored in the living plant material. Over a period of 3-5 years, a re-establishment of a mowing routine results in a rapid reduction of aboveground biomass, combined with a rapid increase in species richness. Decreases in available resources due to interruption of internal translocation inhibit the growth of the formerly dominant plant species. As result species of the Senecioni-Brometum meadows are able to become established. The ability to grow with fewer resources and the removal of the aboveground biomass (2x/year, fulfilling a demand for light) favour coexistence. The regeneration experiment has already been quite successful. Management costs may be reduced for some years by restricting the mowing frequency, without an ultimate loss in species diversity.

198: +.083

Because of their small size and limited mobility aquatic insects are seldom recognized as invasive species and only where verifiable historical data exist can introductions of exotic species be confirmed. Records of some generally considered cosmopolitan species could in fact be undocumented introductions. Of the entirely aquatic orders of insects only the Odonata are noted as regular invaders. Trichoptera, Ephemeroptera, Plecoptera and Megaloptera are all poor colonizers. In contrast, the Hemiptera, Diptera and Coleoptera have many species which show excellent colonizer and invader qualities. Diptera are recognized as the most deleterious of introduced aquatic insects because many of the species are pests and disease vectors of man and his livestock. Although no alien aquatic insect pests have been recorded in South Africa, the potential for the introduction of problem species exists. There are certain life history styles which make an aquatic insect predisposed to colonize a new region successfully. There are also qualities of the habitat which enable successful colonization of the region. Both of these aspects are discussed and demonstrated with case histories. Streams in the southern Cape contain a large number of biogeographically important palaeo-endemic aquatic insects. These animals have evolved without the presence of fish predators and their behaviour and life history styles would make them highly vulnerable to extinction by the introduction of alien fish predators or even

translocation of indigenous species. It is important to conserve this biologically important stock of invertebrates in as near a pristine state as possible and prevent all introductions or translocations of fauna alien to their streams or section of streams where natural barriers keep out fish.

199: **-.020**

The Cape Floristic Region (CFR) contains a disproportionate number of southern Africa's Red Data Book plants (70%), freshwater fish (57%), amphibians (43%), butterflies (38%), and reptiles (35%), relative to the small area (4%) of the subcontinent which it occupies. With the exception of reptiles, the vast majority of these species are endemic to the CFR, occurring mainly in mountain and lowland fynbos vegetation. Among the threats to the continued survival of these species, agriculture and alien invasive plants rank highest overall, although many scavenging birds and large mammals have been hunted and poisoned to extinction within the CFR. An active reintroduction of these large mammals from outside the CFR has been the dominant strategy of local conservation agencies. The focus on large mammals as target species for conservation strategies has been to the detriment of floral preservation. The geographical distribution of threatened species is not related to the extent to which vegetation types have been transformed. Thus renoster shrubland, which has been reduced to 6 per cent of its original lowland extent, contains few Red Data Book taxa relative to fynbos. By far the largest concentration of Red Data Book species of plants, butterflies, reptiles and amphibians occurs in the greater Cape Town metropolitan area. With 15.1 Red Data Book plant species per km², this area ranks as one of the most urgent conservation priorities in the world.

200: **+.084**

The so-called "Lage Fronten", situated in the middle of the city of Maastricht, consist of a few remains of 19th century fortifications (a moat, old walls and an earth ridge) and a deserted railway yard situated on the former main earth ridge. This small area (approx. 4.5 ha) is of particular biological interest, since it is one of the two remaining sites in the Netherlands where a small population of Wall lizards (*Podarcis muralis*) survives. A preliminary and hence incomplete survey of plant and animal species is presented. Table I lists about 200 plant species, 24 of which are under threat. The well developed mural vegetation is of particular interest. Furthermore, details are given about some invertebrate groups (aculeate Hymenoptera table II, and Lepidoptera), fish, herpetofauna, birds and small mammals. Protection of this site is extremely urgent, since the population of Wall lizards consists of only a few dozen individuals (table III). Due to the very low numbers in some of the colonies, there is a serious danger of inbreeding. Moreover, the population of Wall lizards is under serious threat, as is the entire biocoenosis, as a result of plans of the local authorities to develop the area for tourist, recreational, industrial and housing purposes. It is suggested, therefore, that the terrain should be given the legal status of "Protected Nature Reserve" immediately. Conservation measures proposed in this paper include the reintroduction of Wall lizards, the maintenance of the old walls as sunny, dry habitats and the (re-)creation of a fairly low, varied vegetational structure. Furthermore, if restoration of the walls is found to be necessary, this should be done in such a way that the crevice systems between and behind the bricks are preserved. Further conservation measures should be directed towards the preservation of other biological elements, including mural plants, Edible frog (*Rana kl. esculenta*) and Slow worm (*Anguis fragilis*). Habitats of both the Wall lizard and Slow worm ought to be protected against recreational activities.

201: **+.265**

Seventy-six greater prairie-chickens (*Tympanuchus cupido*) were trapped on leks during 1984 (36) and 1985 (40) and released on the Tamarack State Wildlife Area in northeast Colorado in an effort to establish a second self-sustaining population within the state. Leks were established, and reproduction and recruitment were documented. Fifteen different leks were located between 1984 and 1991; 13 were more than 4 km from the release site. The number of active leks located per year increased from two in 1984 to 11 in 1990. Since 1987, lek counts have averaged 5.0-6.4 males/lek. Plains sharp-tailed grouse (*Tympanuchus phasianellus jamesii*) were first observed on leks in 1989. Their numbers have slowly increased, but they are not considered a threat to the prairie-chicken population. Spring releases are recommended over summer releases based on trapping success, post-release dispersal patterns and survival, and genetic considerations.

202: +.143

During a 4-month study in French Polynesia, Pacific Ocean the authors visited 28 islands, seven of which had never been explored by ornithologists. They collected ecological data on endemic land birds, introduced animals and habitats, focusing particularly on the factors involved in population declines and extinctions. As well as hunting and habitat destruction, it appears that introduced predators play a major role, with the roof rat *Rattus rattus* being the most dangerous. Rapid action to eradicate introduced predators, coupled with translocations, would be the most effective way to ensure the survival of the remaining bird species.

203: +.092

Four 'rehabilitated' hedgehogs from an animal hospital were taken to Yorkshire (England, UK) and radio tracked for two weeks to determine their fate after reintroduction to the wild. One died for reasons not apparently related to the study. The other three (1 male and 2 females) successfully built natural nests, and soon learned the geography of their new environment. They integrated well with the wild resident hedgehogs and developed home ranges similar to what would be expected of wild hedgehogs in the same habitat. However, only one managed to maintain its body weight, the others lost significant mass. A longer study, with more animals is needed to confirm the success of hedgehogs released into the wild after a period of veterinary care.

204: +.082

In 1978, the re-introduction-project of the Bearded Vulture into the Alps was started. At that time, the principal purpose was to establish a breeding stock in European zoos as well as a central breeding station (Vienna Breeding Unit). Both WWF (WWF/IUCN-Project 1657/78) and Frankfurter Zoological Society (Project No. 832/78) support this project. The "hacking practice" proved to be the most suitable method to release young vultures. In this case, the birds are placed into an artificial nest-site, some weeks before they are able to fly. The young vultures are fed until they attain independence (at an age of about 6 months). Afterwards, addition feeding is stopped and the vultures are able to exploit the rich, natural food supply without any help. In 1986 the first release took place in the Austrian Alps (Hohe Tauern, Rauris), using 4 birds, bred in captivity. Until 1991, 35 Bearded Vultures have been set free in 3 different locations (Hohe Tauern, Austria; Hoch-Savoyen, France; national park of Switzerland). It was necessary to recapture 2 of them, 3 additional vultures died (disease, electric wire, avalanche) and 2 more birds disappeared. The released birds spread all over the Alps. Formation of pairs was observed in Austria and France and reproduction is expected in some years. The national park Argentera/Mercantour is designated as 4-th location for releasing.

209: +.067

A comparison between forest structure and use of forest by *Brachyteles* at Fazenda Montes Claros and Fazenda Esmeralda in Minas Gerais, Brazil indicated differences in the proportion of large trees available at the two sites. However, despite these differences in forest structure, *Brachyteles* at both sites showed similar preferences for feeding in trees greater than 25 cm in DBH. The results of this study suggest that forest structure, as well as forest species composition, must be evaluated before initiating efforts to translocate threatened populations of this endangered primate.

210: +.155

The cheer pheasant *Catreus wallichii* is an endangered species frequenting open habitats in the Himalayan foothills of Pakistan, India and Nepal. Part of this paper describes how early successional habitats used by cheer at one intensively studied site are maintained by a traditional form of scrub clearance and single-season crop growing on a long rotation, together with seasonal grazing. A review of the habitat characteristics and land-use patterns at a series of other present-day cheer sites reveals that, with the exception of a few small refuges, all component habitats are heavily disturbed. The history of a continuing reintroduction attempt for cheer in the Margalla Hills National Park in Pakistan is then reviewed in the light of these findings. We conclude that habitat management involving the rotational burning of a dense successional scrub is necessary if the released population is to have any prospects of becoming self-sustaining. A similar type of management needs to be maintained at sites still holding wild cheer in India and Nepal.

211: +.020

In 1977-78 some 40 Seychelles magpie robins *Copsychus sechellarum*, the entire world population, survived on Fregate island. These lived in 12 territorial groups of up to six individuals. Their range on Fregate was limited by the amount of feeding habitat, specifically bare earth and leaf litter which occurred under mature shady woodland and in cultivated vegetable gardens. Two attempts were made to reintroduce the species to Aride Island in 1978 and 1979. These were unsuccessful and the translocations had to be abandoned when a new threat impinged on the parent population of Fregate in 1980. By 1981 numbers there had declined to 18, with virtually no recruitment, and an increase in the feral cat population was implicated. A successful cat eradication programme by trapping and poisoning was carried out in 1981-82. By 1983-84 the population showed a recovery with recruitment again healthy, although the abandonment of agriculture on Fregate between 1979 and 1983 had caused a reduction in the amount of feeding habitat and in the carrying capacity of the island to around 25 individuals in eight territorial groups. A range of management options is discussed.

212: +.052

New data are presented on the foraging ecology, behavior, vocalizations, body masses, and soft part colors of the endemic land birds of Henderson Island (128-degrees-20'W, 24-degrees-20'S), southeastern Polynesia. Population estimates of species range from 720-1820 for Stephen's Lorikeet (*Vini stephensi*), 3240 +/- for Henderson Island Crake (*Porzana atra*), 3420 +/- for Henderson Island Fruit-Dove (*Ptilonopus insularis*), to 10,800 +/- for Henderson Island Reed-Warbler (*Acrocephalus taiti*). Conservation issues and translocation of species are discussed.

213: +.192

The reintroduction of plants will become an increasingly utilized strategy in plant conservation and protected area management. Reintroduction is the deliberate establishment of individuals of a species into an area and/or habitat where it has become extirpated with the specific aim of establishing a viable self-sustaining population for conservation purposes. Plant reintroduction can involve the establishment of an extirpated species into a relatively intact habitat or it can be part of the restoration of a degraded habitat. This will be performed as species become extinct for a number of reasons, such as collecting, introduced herbivores or pathogens and potentially climate change. Although plant reintroductions have the potential to play an important role in species' conservation the long term viability of many reintroductions has yet to be assessed. For the technique to reach it's full potential it requires greater integration with habitat management, restoration and increased international coordination between both the ex situ and in situ agencies. In addition the value of introducing stocks of endangered species lacking viable sites for reintroduction to non native sites is discussed.

214: -.023

During September 1989, 700 000 e of black liquor from a paper mill was spilled into the Elands and Crocodile Rivers on the Eastern Transvaal escarpment. The impact of this effluent on the fish populations of these two rivers was monitored. Observations three days after the spill indicated massive fish mortalities in both rivers for a distance of 40 km downstream from the point of discharge down to the town of Nelspruit. A detailed survey in October 1989 indicated that the fish in the River below the spill were largely decimated. Mortalities in the Crocodile River downstream to Nelspruit were lower. Downstream between Nelspruit and the Kruger National Park boundary, mortalities were observed in one species only. In total 14 fish species were affected in the river from die paper mill down to Nelspruit. One threatened species (*Chiloglanis bifurcus*) suffered serious mortalities while another (*Opsaridium zambezense*) was only marginally influenced. During November 1989 and March and June 1990, surveys were undertaken to assess the success of the natural recolonisation of fish in the affected areas. Surveys were primarily undertaken in fast-flowing water and indicated that, although recolonisation is taking place, the species richness and population density in the Elands River in particular is still considerably lower than the numbers found during surveys since 1978. An intensive survey, which duplicated that done in October 1989, was undertaken in September 1990. This survey confirmed that recolonisation of the affected area is taking place. A survey during October 1991 which was limited to the affected part of the Elands River, confirmed the results of the September 1990 survey in this section. It is estimated that the river will probably only recover after several years. Translocation of fish to the most damaged section of the Elands River is an option which will be considered if future surveys do not indicate improved recolonisation rates. The importance of conserving fish refugia as centres from which recolonisation can occur is emphasised by this disaster.

215: +.012

Three ecologically dominant coral species in a northern Philippine reef were compared in terms of growth and mortality, and responses to transplantation. The purpose of this study was to examine the feasibility of using the species concerned in establishing new coral populations through deliberate fragmentation. The species, *Acropora hyacinthus*, *Pocillopora damicornis* and *Pavona frondifera*, displayed distinct differences which could be related to their respective life-history strategies. *A. hyacinthus* showed tendencies towards an r-mode, with rapid linear growth but also high mortality rates. Response to transplantation was poor. *Pocillopora damicornis* had intermediate linear growth rates and relatively high mortality. Transplants fared poorly in the

initial part of the experiment, though they showed successful adaptation after a year. Mortality rates of both *A. hyacinthus* and *P. damicornis* were increased by high temperatures during certain times of the year. *Pavona frondifera* had the highest linear growth rates and no mortality, tending towards a K-mode of life history strategy. It showed the best response to transplantation. This species is thus a suitable candidate for large-scale reef restoration.

216: +.029

To help the recovery of a remnant grizzly (*Ursus arctos horribilis*) population in the Cabinet-Yaak Ecosystem in northwestern Montana, wildlife managers have proposed augmenting the population with bears translocated from a larger population. This proposal has raised fears that translocated bears might endanger human lives and livelihoods. To reconcile the biological needs of this grizzly population with the socioeconomic needs of the human population, we used a combination of decision analysis, consensus of expert opinion, and tradeoff analysis to design a pilot scale augmentation program to enhance grizzly viability while minimizing bear-human conflicts. The analysis incorporated objective and subjective information on the movements, behavior and reproductive potential of different age-sex classes elicited from a group of experts on grizzly biology and management. This information was used to rank the different age-sex classes according to three criteria: retention of translocated bears in the Cabinet-Yaak Ecosystem, conflict with human activities, and relative contribution to grizzly population growth. Subadult females were high in reproductive contribution and moderate in conflict, adult females were moderate in reproductive contribution and low in conflict, adult males were low in reproductive contribution and low in conflict, and subadult males were very low in reproductive contribution and high in conflict. These rankings were insensitive to minor changes in the expert judgments used in the analysis. Because the goals of maximizing population growth and minimizing conflict could not be met with any age-sex class, we used tradeoff analysis to establish minimum thresholds for retention and maximum thresholds for conflict and to characterize the experts' preferences among different combinations of reproductive contribution and conflict. A reranking of the age-sex classes based on the tradeoff analysis showed that 4- to 8-year-old females were most preferred. The analysis revealed that no more than one out of three translocated bears was likely to remain within the Cabinet-Yaak Ecosystem and that as many as one out of four might seriously conflict with human activities. These results prompted an intensive public education program to muster support for the augmentation program before any translocations were attempted.

217: +.303

Given the inconsistent history of successful reintroductions, and the likelihood that the use of reintroductions as a management tool will increase, the need for an accepted conceptual model for reintroduction planning seems apparent. This paper proposes the use of social theory for reintroduction planning. The social theory presented by Firey in *Man, Mind, and Land: A Theory of Resource Use* (1960) offers an appropriate conceptual framework relevant to reintroductions. Application of this theory to an existing reintroduction project demonstrates its usefulness. It is suggested that use of this theory in the planning stages of reintroductions may help to improve reintroduction success rates.

218: -.146

Translocation of wild ungulates is a common wildlife management tool and an integral component of game farming activities throughout the world. Elk (*Cervus elaphus*) are a primary species being moved, and the possibility of translocating a hazardous parasite led us to examine the potential for

elk to survive infections of meningeal worm (*Parelaphostrongylus tenuis*), to shed larvae in feces, and thus, to translocate the parasite. Twenty-six elk calves were exposed to 15-300 infective larvae of meningeal worm. All 13 elk exposed to greater-than-or-equal-to 125 larvae developed neurologic disease and died; 2 shed larvae in feces prior to death. At necropsy, numerous adult meningeal worms were found throughout the central nervous system of each elk. Meningeal worm established infections in all 8 elk exposed to 25 or 75 larvae: 6 calves developed neurological signs (4 recovered, 2 died), the remaining 2 elk did not exhibit any clinical signs. Seven elk given 25 or 75 larvae shed larvae in feces. None of 5 elk exposed to 15 larvae developed clinical neurological signs or shed larvae; meningeal worms were recovered from the central nervous system of only 2. The ability to survive exposure to small numbers of meningeal worms may explain the persistence of the few remnant populations of elk in eastern North America. The potential for larvae to be present in the feces of these animals (or captive elk in the same areas) leads us to recommend that elk not be translocated from eastern to western North America until a reliable diagnostic test or treatment for meningeal worm is available.

219: +.116

A nucleus population is a small captive population genetically supported by periodic importation of wild caught animals. Periodic importation will allow nucleus populations to maintain the same amount of gene diversity as larger captive populations that do not import wild caught animals. The function of nucleus populations as envisioned by the IUCN/SSC Captive Breeding Specialist Group (CBSG) is to make additional captive space available for endangered taxa not currently maintained in captivity. In this article, mathematical models are developed to assess the effectiveness of the nucleus population concept in reducing the population sizes necessary to maintain appreciable amounts of gene diversity in captive populations. It is shown that the Nucleus I population concept, as defined and promoted by the CBSG, requires an importation rate 10-20 times greater than they have indicated. Whereas nucleus populations are not appropriate for maintenance of significant amounts of gene diversity in long-term breeding programs, small populations can be valuable for research, education, and reintroduction projects with short-term goals. Decisions have to be made on which of the many endangered taxa will be maintained and for what purposes, if captive breeding is to be an effective component of species conservation. (C) 1993 Wiley-Liss, Inc.

220: -.427

Disease may play an important role in the decline or extinction of small, isolated animal populations. Disease also has thwarted attempts to reintroduce some endangered captive-bred species. Despite this, the impacts of disease rarely have been considered in the planning and design of reintroduction programmes. A remnant wild population could be decimated by a disease cointroduced with reintroduced animals. Alternatively, diseases that are endemic in wild animal populations could be fatal for those immunologically naive individuals that are reintroduced. We contend that the planning of reintroduction programmes should include an examination of the potential impacts of disease on extant populations and on animals targeted for release. A number of steps are outlined to reduce disease risk and to minimise the probability of failure of reintroductions because of disease.

222: +.066

The Raven became extinct in The Netherlands in the First half of this century, mainly as a result of human persecution. Regular breeding ended in most areas in the course of the 1920s. In 1966, a

reintroduction project was started that appeared to be successful. Since 1976 the Raven has bred annually on the Veluwe, a large wood- and heathland area (1240 km²). After a period of fluctuating low numbers, a marked increase took place from 1984 onwards (fig. 1, 2). In 1992, 50 breeding pairs and at least 31 territorial pairs were found, most of them on the Veluwe. Here, the species occurs in 65% of the 5 times 5 km squares. The spacing of territories is rather regular on the Veluwe, but highest densities occur in the central part of the area. Almost all breeding pairs are located in old pine forests *Pinus sylvestris* near heathland or drift sands. Since 1990 some pairs are breeding in fir-woods *Pseudotsuga menziesii*, damaged by gales. Breeding success is slightly lower than elsewhere in Europe, 2.1 young reared per breeding pair (calculated for pairs that started egg-laying only). It is expected that the Dutch breeding area will expand in the next decades, and that Dutch and German populations will interchange before the year 2000 (fig. 3). Territorial Ravens probably stay within their territories during the whole year. Non-breeders often birds occur in wandering groups. Non-breeding birds have been studied systematically since 1989. About 95% of all observations were made on the Veluwe (fig. 4). Since the winter of 1986/87 flocks of 30-50 non-breeding birds are found here each winter. Groups of 6-8 non-breeding birds are observed in the woodland area of the Utrechtse Heuvelrug (240 km²) since spring 1992. Despite the strong increase, Ravens are seldom seen in agricultural areas. The size and dispersion of the flocks of non-breeding birds on the Veluwe probably depends on the abundance of food. In early spring, flocks of up to 30 birds are regularly observed on heathland in the SE-Veluwe, often in the vicinity of sheep and feeding on still-born lambs and afterbirths (in this, they differ from the breeding birds that stay in pine forests and heathland in early spring, foraging on carrion and beetle-larvae, taken by slashing at putrefied trees). In April and May non-territorial Ravens occur all-over the Veluwe in flocks of 5-15 birds (up to 42 birds). Important food sources in late spring and summer are probably invertebrates, garbage left by tourists and carrion including animals killed by traffic. In autumn and winter up to 50 Ravens may occur near feeding places of wild boar and red deer, foraging on entrails left after hunting. In the course of winter the main groups seem to move from the northeast to the southeast of the Veluwe (fig. 5). In February, groups of 50 Ravens have been observed. In winter 1990/91 a roost (max. 38 birds) was studied on the SE-Veluwe in coniferous woodland, close to major feeding-grounds. Highest numbers were present in February (figure 6). Small roosts are likely to occur elsewhere on the Veluwe as well. In autumn 1992, the Dutch population was estimated at 400-475 individuals, about 95% of which on the Veluwe.

223: +.084

We removed eggs from bald eagle (*Haliaeetus leucocephalus*) nests in northern Florida from 1985 through 1988 to determine if pairs would lay again and to evaluate how egg removal affected subsequent productivity. Of 58 pairs that had first clutches removed, 45 (78%) laid a second clutch within an average of 29.4 days. In 1 study area, productivity of pairs that had their first clutch removed (1.00 young fledged/breeding attempt) was less ($P = 0.02$) than control pairs (1.47) that produced their clutches during the same time period. In contrast, no difference ($P = 0.75$) in productivity occurred between donor (1.17) and control pairs (1.09) produced during the same period in a second study area. Productivity of donor nests 1 year prior to egg removal was greater ($P = 0.03$) than 1 year after egg removal. However, a simple age-structured demographic model (RAMAS) revealed that population size after 25 years was only slightly higher for the control population. Consequently, egg removals over a limited number of seasons and nests were effective in providing large numbers of eagles for release, with limited adverse effects on Florida's donor population. An egg-removal program may be an effective alternative strategy to captive breeding and translocation of young in recovery actions among raptor populations requiring active management, particularly for tropical species that have long breeding seasons.

224: **-.017**

One hundred twenty-eight fecal examinations from 57 muriquis or woolly spider monkeys, *Brachyteles arachnoides*, and 62 fecal samples from 9 brown howling monkeys, *Alouatta fusca*, that coexist in the Atlantic forest in southeastern Brazil were examined for evidence of parasite infections. Hosts from 4 sites, 2 in Minas Gerais (EBC and FE) and 2 in Sao Paulo (FBR and PECB), showed differences in parasite prevalence and diversity. Neither muriquis nor brown howling monkeys from site 1 (EBC) revealed parasites. Monkeys from site 2 (FE) had only eggs presumed to be *Strongyloides cebus* and those from site 3 (FBR) had only *Trypanoxyuris brachytelesi*. Eggs and larvae presumed to be *Strongyloides cebus*, *Trypanoxyuris brachytelesi*, *Graphidiodes berlai*, and an unidentified digenean were found at site 4 (PECB). The 4 study sites differ substantially in size (40-37,000 ha), degree of human disturbance, climate, plant species composition, and muriqui densities. Contrary to expectations, muriquis from the largest and least-disturbed forest (with the lowest population density) had the highest prevalence and diversity of parasitic infection. A variety of factors, including vegetation and climatic differences, could explain this paradoxical pattern. However, the fact that PECB is the site least affected by human disturbance also suggests that the complex ecological web involved in parasitic transmission has been disrupted at the other sites. Our findings reaffirm the importance of using parasites as ecological indicator species in studies of wild primates and suggest that management plans which involve translocations must be sensitive to the potential effects of parasites on naive hosts.

226: **-.046**

Isolated and long established communities of plants and animals serve as natural laboratories for evolutionary studies. Snails of the genus *Partula*, indigenous to the tiny island of Moorea in the Society Islands, have been studied for over a century. Research on the separation of species by natural barriers, and on the effects of shell chirality, has provided the best information for understanding the evolution of the genus on Moorea. Unfortunately this field laboratory has been destroyed recently by the ill-advised introduction of a voracious predator.

227: **+.025**

A cytotaxonomic study was made of *Diplodus annularis* (Sparidae), *Serranus cabrilla* and *S. scriba* (Serranidae) and *Gambusia affinis holbrooki* (Poeciliidae). Inter-individual Robertsonian translocation occurred in *D. annularis* along with two other chromosome polymorphisms, one being attributed to pericentric inversion, the other involving both the number and location of nucleolus organizer regions (NORs). Polymorphism due to pericentric inversion occurred in the *G. affinis holbrooki* karyotype. *S. cabrilla* and *S. scriba* both showed heteromorphism in the size of the NOR region. Non-differential Giemsa staining, together with NOR-, C- and G-banding techniques in *S. cabrilla* indicated that this polymorphism was structural rather than functional.

228: **-.071**

In the last fifty years, 91 reintroductions and reinforcements of Alpine marmots have occurred in its mountainous areas. Most of the reintroductions failed except those attempted in the Alps and Pyrenees, probably because of no formal planning. Increase of species territory and lack of data on population dynamics suggest a limit to reintroductions and the maintenance of well-planned reinforcements.

229: **-.127**

The Anjouan Scops Owl *Otus capnodes*, not recorded with certainty since about 1886, was rediscovered in June 1992. It has usually been treated as a race of Madagascar Scops Owl *Otus rutilus* but, judging from plumage and especially voice, it is a distinct species. It is found only in the remaining patches of upland forest (above 800 m) on Anjouan (Ndzuan), Comoro Islands, where the population is estimated to be at least several tens of pairs, probably between 100 and 200 pairs. The species is highly endangered by accelerating forest clearance and capture for food by the huge and increasing human population. Long-term environmental programmes are essential but may be too late to save this and other endangered species on Anjouan. Species-specific actions are needed: for the owl, a translocation to the neighbouring island of Moheli should be investigated.

231: -.030

Geographic chromosomal variation, which in many instances does not correlate with variation in phenotype, is increasingly being detected within both large and small species of mammals. We argue that this cryptic chromosome variation can pose a significant threat to translocation practices involving the admixture of specimens between geographically distant populations. Matings between individuals characterized by different cytotypes can result in perinatal mortality or, at a later stage, in reduced fertility of offspring heterozygous for chromosomal rearrangements. This can thus impact heavily on the species, or population, that management is trying to conserve. Some of the more frequently encountered structural rearrangements in mammals and the possible deleterious effects that these can have in the heterozygous condition are reviewed and guidelines proposed for the use of cytogenetics as a conservation tool in wildlife management.

232: +.100

The Western Division of New South Wales is an administrative region of 325000 km² on the eastern fringe of the Australian arid zone. Since European settlement in 1788, 71 species of native mammals have been recorded in the Division, seven more have been documented only as sub-fossils, and a further 15 species occur within 100 km of the Division boundary. At least 27 of the original species have become regionally extinct, and a further 11 have declined in distribution. As in other regions of Australia, species losses have been greatest for rodents and marsupials in a critical weight range of 35–5500 g, and least for bats. However, percentage losses among the terrestrial fauna are high relative to other regions, and probably reflect both the early settlement of New South Wales and the marginal distribution in the Division of 49% of the original fauna. Feral cats are implicated in the regional extinction of up to ten species of native mammals prior to 1857. Subsequent extinctions and range reductions are attributed to combinations of causes, including predation from cats *Felis catus* and red foxes *Vulpes vulpes*, competition and habitat degradation from rabbits *Oryctolagus cuniculus*, stock and other introduced herbivores, clearing of trees, changes in fire regimes and human persecution. We identified 28 species of particular conservation concern in the Division based on low abundance, distribution or survival prognosis. Nine species are of national significance, four of state, and 15 of regional, significance. The major current threats to these species are from grazing by stock, interference from feral mammals and clearing. Further land reservation is an important conservation measure, but must be complemented by more effective management of non-reserved land and by broad-scale management of feral species and other threatening processes if the current species diversity is to be maintained. Long-term fauna surveys should be initiated throughout the Western Division to provide feedback on the effectiveness of management measures, and species reintroductions should be considered in situations where threats have been removed.

233: +.031

Population characteristics, breeding structure, and sources of mortality of wild water buffalo *Bubalus bubalis* were studied in Kosi Tappu Wildlife Reserve, a small reserve located in the southeastern lowlands of Nepal, during 1987 and 1988. Comparisons with an earlier census indicated that the population was growing over a 12-year time interval. However, observations on the physical nature of the reserve and known seasonal movements of buffalo suggested that the population is not viable for several reasons. Most mortality observed during the study took place over the rainy season, suggesting that flooding was the major source; half of the first-year calves disappeared during that time. Because the reserve was subject to extensive flooding during the rains, buffalo regularly left to reside in cane and sugar fields. Hence the reserve did not include the annual home range of any buffalo herds. In addition, thousands of domestic cattle and hundreds of domestic buffalo used the reserve illegally, which posed a risk of disease to wild water buffalo. Management recommendations, including a reintroduction of the species into Royal Chitwan National Park, are made in light of the analysis.

234: +.081

During the last decade some fanciful hypotheses about a presumed trend of Marsican Brown Bears spreading largely around, and abandoning Abruzzo National Park, have been suggested or admitted by some authors. To explain this alleged phenomenon various explanations, more or less synergic, have been developed: excessive and uncontrolled tourism and/or massive Wild Boars invasion, as a result of unsound reintroduction of these animals from Hunting Organisations in areas surrounding the Park. The authors doubt of these explanations, but on the other hand they collected many bear evidence signs outside of the Park. Cooperating with many other members of Italian Bear Group (Gruppo Orso Italia), a wide monitoring program was developed about bear signs outside of Abruzzo National Park. The aim of the project was to assess how consistent with the evidence might be the hypothesis of the periferic individuals and/or small populations still existing but remained unknown in the past time, depending on scarce interest of local authorities, limited availability of financial resources and so on. On the other hand this idea had been suggested by the founder of Abruzzo National Park Erminio Sipari already in the year 1926. The monitoring program covers the period from 1900 to the present time. More than 310 data have been collected with a good reliability. The percentages of those: 38.3% in the Maiella Massif, 18.8% in the Emici-Simbruini Chains, 8.9% in the Genzana Massif, 18.2% in the Velino-Sirente Mountains, 4.5% in the N-W of Molise Regione and further 8.3% in other spotted areas. The continuous evidence may confirm the original idea of several bear nucleons, which remained virtually unknown in the Park's surroundings. In the authors' opinion the hypothesis of bears "run away" from the Park may consequently be definitely dismissed. The results of the present research strongly support the ideas stressed in many occasions by the Park's Superintendent Franco Tassi, as well as all the conceptions that inspired the Park's policy during the past years: creation of a large Buffer Area around the Park, progressive inclusion of the most sensitive and pristine areas in the Park, development of a system of Protected Areas in the Central Apennines. In other words, the results of this report offer further scientific and ecological support to the project "Abruzzo South European Park": more than 500,000 hectares of magnificent wild areas in which all or most of the territories inhabited not only by bears, but also Abruzzo Chamois, Apennine Wolf and itself as the first wide wildlife management operation in Italy: a conservation scheme strictly connected with the ecological needs of some of the most significant species (from scientific and cultural point of view) of Italian big mammals.

235: +.191

The authors review the present knowledge on the distribution of *Pelobates fuscus insubricus* in north-eastern Italy and report the first results of a reintroduction programme of this species in the same area.

236: +.253

The value of the preservation of biodiversity, methods of conservation of rare or endangered plants and animals, the role of humans in the distribution of species through introduction (voluntary or involuntary) and reintroduction, and the paradox between natural isolation of species and ecological meshing are wildlife policy is the protection of endangered species in situ or the reimplantation of a plant or animal into an ecosystem regardless of several important factors (role in the ecosystem, chance of recovery, risk of genetic pollution, probability of success, etc.). The ethical aspects of reintroduction strategies are illustrated with examples such as the creation of "natural gardens," or of plant populations devoted to apiculture or to the biological control of agricultural pests. Such operations may seem legitimate from a human point of view but their objectives should not be confused with strategies of biodiversity restoration. Introduction and reintroduction no longer appear definitively as recommendable, acceptable or condemnable scientific techniques, but as decisions society must face at the intersection of conservation of original biodiversity and the "artificialization" of nature.

238: -.049

Data from a Badger sett survey undertaken in the mid-1980s were used to calculate the effects of past persecution and land-use changes on Badger numbers. The current British Badger population was estimated to be 41,894 +/- 4404 social groups; if the effects of past persecution were eliminated, the population could be 43,437 +/- 4731 social groups, an increase of 3.7%. Most of this increase relates to persecution in Norfolk and Suffolk last century. In Britain the Badger population is largely confined to those areas which are intensively managed, and the numbers and distribution of Badgers reflect patterns of agricultural activity. However, over-intensive use of the landscape is detrimental to Badger numbers. To quantify the impact of land-use changes on the British Badger population, a number of habitat features favourable to Badgers were identified; 1-km squares that contained five or more such features had significantly higher mean Badger densities. If all the 1-km squares were managed to include five or more of the habitat features favoured by Badgers, and the effects of persecution were eliminated, the Badger population could be 58,284 +/- 5640 social groups, an increase of 39%. The absence of semi-natural broadleaved woodlands in a 1-km square had the greatest effect in reducing Badger numbers, and tree-planting schemes may be beneficial in providing potential new sett sites. However, Badgers are poor colonists, and the construction of artificial setts and the translocation of displaced social groups of Badgers will greatly facilitate the colonization process. The value of such an approach for predicting the effects of future land-use policy on Badgers and other species, and for managing the British wildlife resources, is discussed.

239: -.073

The red swamp crawfish *Procambarus clarkii* (Girard) has been found in the sponge area of the headwaters of the Crocodile River in the Transvaal. Indications are that it occurs in relatively low numbers despite potentially favourable environmental conditions. Predators such as otters may play a role in its control. The danger exists that it may spread further downstream with time or be translocated to other localities by anglers visiting the site.

240: +.198

Germination of *Agrostis castellana* caryopses is not affected by arsenate. The viability of caryopses of tolerant *Agrostis castellana* is lower than that of sensitive populations. The possible relation with 'cost' of tolerance is discussed. Tolerant populations of *Agrostis castellana* and *Agrostis delicatula* are clearly distinguished by their maximum root growth (MRG) from sensitive populations. The sensitive population of *Agrostis castellana* reaches 50% MRG reduction at 25 μM As, that of *Agrostis delicatula* at 60 μM As. The tolerant populations of both species do not reach 100% MRG reduction below 1280 μM As. Among the tolerant populations of *Agrostis castellana* we distinguish a more tolerant population with no significant MRG reduction in the range of 0-40 μM As from two tolerant populations with 10-25% MRG reduction in the same range. 50% MRG reduction occurs finally in the more tolerant population at 580 μM As, in the other tolerant populations at 320 and 230 μM As, respectively. Tolerant and sensitive populations grown without arsenate do not show significant differences in MRG. The relation between MRG and tolerance mechanisms is discussed.

242: +.046

The Shoshone sculpin (*Cottus greenei*) is found only in springs of the Thousand Springs formation along the Snake River in Idaho. In 1983 a small population of Shoshone sculpin was introduced into an unnamed spring in the Thousand Springs formation in an attempt to increase the range of the species. Previously, the only sculpin in that spring was the mottled sculpin (*Cottus bairdi*). The Shoshone sculpin was able to establish itself and become the predominant fish within 5 years.

243: +.072

Loss of genetic variability in isolated populations is an important issue for conservation biology. Most studies involve only a single population of a given species and a single method of estimating rate of loss. Here we present analyses for three different Red-cockaded Woodpecker (*Picoides borealis*) populations from different geographic regions. We compare two different models for estimating the expected rate of loss of genetic variability, and test their sensitivity to model parameters. We found that the simpler model (Reed et al. 1988) consistently estimated a greater rate of loss of genetic variability from a population than did the Emigh and Pollak (1979) model. The ratio of effective population size (which describes the expected rate of loss of genetic variability) to breeder population size varied widely among Red-cockaded Woodpecker populations due to geographic variation in demography. For this species, estimates of effective size were extremely sensitive to survival parameters, but not to the probability of breeding or reproductive success. Sensitivity was sufficient that error in estimating survival rates in the field could easily mask true population differences in effective size. Our results indicate that accurate and precise demographic data are prerequisites to determining effective population size for this species using genetic models, and that a single estimate of rate of loss of genetic variability is not valid across populations.

244: +.117

The Insecta is the most speciose class in the Animal Kingdom. The insect-plant relationship is the dominant biotic interaction, yet plants have many times the biomass of all animals together. The functional significance of insects is enormous, owing to the large numbers of individuals and great intra- and interspecific variety. Lack of human appreciation of importance, coupled with the general disregard and dislike of insects, is an enormous perception impediment to their

conservation. This impediment coupled with the taxonomic impediment (at most only about 7-10% of insects are scientifically described) must be overcome for realistic biodiversity conservation. As it is not possible to know all the species relative to the rate at which they are becoming extinct, it is essential to conserve as many biotopes and landscapes as possible. These would be for typical species and communities, as well as for endemic sinks. It is also essential to preserve species-dynamo areas as an insurance for future biodiversity. Preserved areas must also be linked by movement and gene-flow corridors as much as possible. Recognition, functional importance, taxic uniqueness, typicalness, genetic variation and important behavioural traits place much more emphasis on qualitative biodiversity conservation than on quantitative approaches. Ecological entomologists play a significant double role, suppressing noxious populations on crops, livestock and other products, while at the same time identifying and using beneficial species. There are well-known inherent and environmental risks with many traditional control methods and high risks with the use of genetically engineered biopesticide baculoviruses. Preservation technologies, where individuals are held in suspended animation, must be developed soon. However, such technologies, as with restoration activities such as site restoration, captive breeding, reintroductions and translocations, all require considerable knowledge and economic input to be predictably successful. Ecological restoration involves so many biotic and abiotic interactions in even the simplest of communities, that predictiveness under all potential conditions is virtually unattainable. Instead, there should be strong focus on the preservation and conservation of as many, and as large as possible, pristine and near-pristine unique and typical landscapes as soon as possible.

245: +.093

Less of genetic variation due to population bottlenecks may be a severe threat for the survival of endangered species. Assessment and maintenance of genetic variability are thus crucial for conservation programs related to endangered populations. Scandinavian beavers went through an extensive bottleneck during the last century due to over-hunting. In Sweden the species became extirpated but in Norway extinction was avoided by legal protection. Following reintroductions of small numbers of remaining Norwegian animals in 1922-1939, the Swedish population has increased tremendously, now harboring 100,000 animals. We show here that this viable population of beavers possesses extremely low levels of genetic variability at DNA fingerprinting loci and monomorphism at major histocompatibility complex (MHC) class I and class II loci. A similar pattern was also evident among Norwegian beavers but low levels of genetic variability were not a characteristic of the species since Russian conspecifics displayed substantial DNA fingerprinting polymorphism. However, the Russian animals were monomorphic at MHC loci, indicating that the European beaver is exceptional in its low level of MHC variability. The results demonstrate that a conservation program can be successful despite low levels of genetic variation in the founder population.

246: -.066

Disease risks are an inherent part of captive breeding, translocation, and reintroduction Programs and of research involving contact between researchers and animals. Thus, quantitative assessment of the risks of disease should be an important part of developing conservation strategies. Population viability analysis (PVA) and the use of computer modeling allows conservation planners to examine the potential effects of both the catastrophic and subcatastrophic effects of disease on long-term population viability, measured as probability of extinction, and to explore strategies to mitigate unacceptably high risks. The effects of diseases on the demographic, environmental, and genetic aspects of a population should be examined. Metapopulation

management strategies that establish geographically separate populations are likely to provide protection against total population extinction due to single disease epidemics. However, to offset the genetic costs of smaller population size, movement of animals (under quarantined supervision) may be required.

247: -.116

Outbreaks of infectious disease can ruin conservation programs. In order to minimize catastrophic disease outbreaks, it is important to understand the dynamic relationship between populations of threatened hosts and their parasites. The dynamics of the host-parasite relationship are ineluctably linked to host-population density. Intensive conservation management programs are often characterized by small population size. In small host populations, the dynamics of host-parasite relationships are particularly fragile and disease outbreaks will tend to die out rapidly. The most significant disease risks for intensive management programs will probably occur when hosts are chronically stressed, when they are exposed to novel pathogens, and when herd immunity is lost. Biologically diverse parasites will never be entirely eliminated from intensively managed wildlife. Rather, one of the great challenges facing conservation biologists is to learn how to manage the natural and healthy relationship between parasites and their hosts. The population dynamics of host-parasite relationships must be integrated into species survival and recovery plans.

248: -.333

Conservation programs for captive breeding and reintroduction of threatened and endangered species need a means to assess the risk of introducing infectious diseases into or obtaining diseases from the reintroduction environment. Risk assessment is seriously hampered by insufficient knowledge of the diseases of these species. Acquisition of data on the infectious diseases of threatened and endangered species can be expedited through cooperative disease surveys of captive and free-ranging animals. Integrating information from various sources will be greatly facilitated by setting standards for data collection. Standard guidelines for monitoring, investigating, and surveillance of infectious diseases in captive animals are presented that will provide essential information for an infectious disease data base. A method for prioritizing infectious diseases by the degree of threat to a species or environment is also proposed, so that the limited resources for disease investigations can be appropriately allocated. Application of these methods to species targeted for reintroduction will reduce the risk of human-caused catastrophic epidemics in endangered species. Furthermore, these methods will significantly increase our knowledge of disease epidemiology in nondomestic species.

249: +.212

Diseases in free-ranging wildlife, other than those in species of economic importance or diseases of public health significance, have long been overlooked and thus are rarely monitored. Recent findings, however, demonstrate that disease agents must be considered as integral in shaping many aspects of wildlife behavior and ecology. Very few scientists are trained in or function specifically with the study of diseases of free-ranging wildlife, and funding for such projects is difficult to obtain. The application of new biotechnological tools will no doubt contribute considerably to the rapid advancement of this field. The consideration of disease in all stages of species conservation projects is especially important because of the possibilities of genetic depression of immunity and the introduction of diseases into wild of populations.

250: +.066

The relocation of wild mammals and birds for the reinforcement of a population or for the reintroduction of a species that has become extinct in its natural range has become a popular wildlife management technique. Concern has been expressed that these translocated wild animals, which often originate in captive-breeding facilities in a distant country, may bring with them diseases and parasites that could threaten the health of the valuable domestic livestock and wildlife resources of the recipient country. At present, the International Zoo-Sanitary Code of the International Office of Epizootics (OIE) in Paris, which is implemented by all 126 nation members of OIE, applies only to the important diseases of domestic livestock that may affect wild animals. However, proposals are now being made for the collection, through the OIE global network, of data on the worldwide occurrence of wildlife diseases. Following this initiative, regulations for the international movement of wildlife will be reviewed, as will proposals for the standardization of both diagnostic procedures for wildlife diseases and vaccination protocols for the immunization of wildlife. All veterinarians involved in wildlife translocation projects must cooperate closely with national and international animal disease control agencies so that regulations will be both effective and realistic.

251: -.144

Many organisms, from viruses to metazoan parasites, can be spread when domesticated or nondomesticated birds are moved from one locality to another. Theoretically, potential pathogens might establish themselves in released wild birds or be spread from them to other species. There are very few fully substantiated accounts of disease problems associated with translocation or releases of wild birds, and much of the "evidence" has been circumstantial. Serious study of the subject has been confined to Hawaii, Mauritius, and a few other locations. Although such research has added weight to the thesis that infectious disease may contribute to a decline in free-living populations, dissemination of organisms by released birds has generally not been confirmed. The paucity of sound data on this subject is probably attributable to the failure to adequately monitor pathogens and disease in birds prior to and following release. More rigorous research is needed to evaluate the true role of released birds in the introduction and dissemination of pathogenic organisms.

252: -.038

Health and disease are becoming extremely relevant issues for the conservation biology of members of all major groups of vertebrates. The importance of disease in captive propagation, relocation, repatriation, and translocation (RRT) programs is just being appreciated. All of us experience multiple diseases in our lifetimes. Reptiles are not different. They are susceptible to the range of infectious agents known to occur in other vertebrates. The causes of disease in captive reptiles are better understood than those in their wild counterparts. However, several important diseases have recently been documented in wild chelonians. One of these, upper respiratory tract disease in the desert tortoise (*Gopherus agassizii*) is thought to have been introduced into populations of tortoises in the Mojave Desert in the southwestern USA by release of ill captive desert tortoises. A similar situation appears to exist for certain populations of the gopher tortoise (*Gopherus polyphemus*) in Florida, USA. Although conservation strategies such as RRT programs have been implemented for a number of threatened/endangered reptiles, results indicate that the success rate is rather low. Because of this low success rate and the recent awareness of the possible introduction of exotic pathogens acquired in captivity, release programs should be scrutinized more closely.

253: -.262

The impact of some diseases on the translocation of African wildlife has been wide-spread. Rinderpest has remained in Africa since its introduction in 1888. The rigid control measures adopted to prevent the spread of rinderpest, foot-and-mouth disease, and theileriosis to domestic animals in Africa restrict the possible translocation of even endangered species. In some cases, the translocation of wild animals has resulted in the transmission of the disease. African horse sickness was carried to Spain in 1987 when zebras were translocated there from Namibia. When springbok (*Antidorcas marsupialis*) were moved to the Bontebok National Park, Republic of South Africa (RSA), they introduced lungworm (*Bronchonema magna*), which then infested the bontebok (*Damaliscus dorcas dorcas*). Translocated wild animals also succumb to endemic disease: heartwater in the Transvaal bushveld prevents the translocation of springbok into this area because this species is susceptible to this disease, and babesiosis has been reported in naive sable antelope (*Hippotragus niger*) imported into the RSA from Europe. Animals translocated into unsuitable habitats, e.g., roan antelope (*Hippotragus equinus*) translocated to the Percy Fyfe Nature Reserve, RSA, and gemsbok (*Oryx gazella*) translocated to the Orange Free State, RSA, do not thrive. Salmonellosis, apparently acquired while being held in enclosures, has been reported in African elephants (*Loxodonta africana*) and a black rhinoceros (*Diceros bicornis*). Feline infectious peritonitis has been described in captive wild-caught cheetahs (*Acinonyx jubatus*).

255: +.052

The farming of freshwater crayfish (astaciculture) is mainly carried out in the southern states of the USA, and in Australia and Europe. Production levels vary with climate but are in the region of 40000 to 60000 tonnes per annum. In addition, at least an equivalent amount is harvested from the wild, particularly in North America, China, Australia, Kenya, Turkey and Europe. Crayfish farming is usually either of an extensive (ranching) or semi-intensive nature, intensive methods being infrequent, except for the rearing of juveniles for stocking (or restocking of natural waters depleted of crayfish). As crayfish do not have larvae and are polytrophic, they are relatively easy to rear, although fecundity is much lower when compared with other cultured crustaceans. At least 85% of world production is based on the red swamp crayfish, *Procambarus clarkii*, mainly from Louisiana and other southern USA states, but also from China, Kenya and Spain, where it has been introduced. In Australia, three species are of aquacultural importance, the yabbie, *Cherax destructor*; the marron, *C. tenuimanus*; and the red claw, *C. quadricarinatus*. Some very large production units have been built but none have lived up to their promise. The red claw is thought to have considerable aquacultural potential, but, being a tropical species, needs warm water for good growth. In Europe, the only endemic species cultured to any extent is the noble crayfish, *Astacus astacus*, mainly as juveniles for restocking. It fetches a higher price than other crayfish. The North American signal crayfish, *Pacifastacus leniusculus*, has been introduced to most European countries, but farmed production is relatively low. About 98% of crayfish consumed in Europe come from extensive systems or the wild harvest. European crayfish markets were upset by the collapse of the Turkish crayfishery (based on *Astacus leptodactylus*) due to overfishing and disease in the mid-1980s. The environmental impact of crayfish farming is most noticeable in Europe. Crayfish plague, introduced from North America last century, has devastated populations of the native species in many countries. Its spread has been exasperated by the translocation of foreign crayfish (and probably by fish) for aquacultural purposes. In addition, introduced crayfish frequently escape into the wild and form large populations, often in direct competition with native species. Burrowing and prolific species, such as *P. clarkii*, can also do considerable environmental damage.

256: +.065

Strong Site tenacity might prevent Palila (*Loxioides bailleui*), an endangered Hawaiian honeycreeper, from repopulating favorable habitats in their former range. We used radio telemetry during the nonbreeding and breeding seasons to study movements and dispersal rates of 57 Palila. All Palila remained in the study area, and home range sizes and movement distances were small relative to the potential mobility of the species. Banding and nesting studies revealed that Palila show strong site tenacity. An inverse correlation between movements and elevation was related to an elevational gradient in food supply. Translocations of Palila into presently unoccupied areas in their range might speed the recovery of this endangered species.

257: +.125

An ecological collapse has precipitated pioneering conservation initiatives in New Zealand. Many terrestrial communities in the New Zealand archipelago have been devastated by over-exploitation, introduced mammals and habitat destruction. More recently, marine ecosystems have been depleted by over-harvesting. To mitigate against these losses, conservation in terrestrial environments has focused on protection of species and habitats. A similar approach is now under way in marine environments with the establishment of 'no-take' marine reserves. On land, conservation is now reaching beyond protection to the eradication of pests from islands and restoration of their terrestrial ecosystems. Restoration on islands not only reduces threats to rare species; it also raises opportunities to investigate how species interact. In the sea, marine reserves not only enhance the diversity of depleted marine communities; they may also augment stocks of commercially harvested species. These initiatives provide many lessons that could be applied to degraded habitats elsewhere.

258: +.215

Only over the last few decades has there been a concerted effort to develop and refine release methods for threatened species. With the goal of achieving self-sustaining wild populations, three main techniques have been employed: parent-rearing, cross-fostering, and isolation-rearing. Although there are many considerations in developing or selecting the most efficient method for any given species, the behavioral aspects of preparing birds for release are important. The concept of different life history strategies may also help in designing a preparation and release methodology. The degree of interspecific and intraspecific sociality also is important in the development of effective behavioral preparation of individuals for release. (C) 1994 Wiley-Liss, Inc.

259: +.051

The wild 'Alala (*Corvus hawaiiensis*) population has been declining for many years, and only a few pairs of birds are currently reproductively active on the island of Hawaii. A recovery program was initiated in 1993 which included removing eggs from wild nesting birds for artificial rearing and reintroduction. This paper describes the artificial incubation and hand-rearing techniques. Eleven eggs were removed from three nesting pairs; eight were fertile, and seven hatched and were hand-reared (fertility, 72.7%; hatchability, 87.5%; survivability, 100%). Eggs were incubated in a forced-air incubator at 99.5-degrees-F (dry bulb), 80.0-86.0-degrees-F (wet bulb), and hatched under still-air conditions at 99.0-degrees-F (dry bulb) and 88.0-90-degrees-F (wet bulb). Hatched chicks were hand-fed a diet of fruit, insects, and mouse pups. (C) 1994 Wiley-Liss, Inc.

260: +.021

In former times capercaillie occurred throughout the Sauerland, while today areas with suitable habitats still exist for this species. In light of this the Research Station for Hunting and Game Damage Prevention of North Rhine/Westphalia conducted reintroduction trials of this species from 1980 to 1992. These trials were located in the area around Hunau a secondary chain of mountains between Fredeburg, Bodefled, and Altastenberg. The birds were first hatched and raised in cages, and at the age of 16 weeks transferred to large flight cages for four weeks to adapt to free land conditions before being released. The goal was to release 50 individuals/year in this manner over a period of 10-15 years. For this purpose a breeding station was established at the research station. The planned number of capercaillie (15/year) released annually could only be attained in the last 4 years of the trial. A total of 393 capercaillie (226 cocks, 167 hens) were released during the trial period. A large proportion of the released birds succumbed primarily to predation; a few were killed by accidents. Sick or lost animals were not observed. Some of the cocks lived 5-7 years as could be ascertained by individual ringing. In 1986 a nest with 7 eggs at the foot of a spruce tree was found in the trial area, and repeated observations were made of free land raised young birds. In the spring of 1992 a population of 30-40 capercaillie over an area of 20,000 ha were present in the Sauerland due to the re-introduction trials. The establishment of a population of 30-40 capercaillie is a successful result. However, this population is still insufficient to perpetuate itself. The re-introduction of more birds is necessary. As of 1993 the Association for the Preservation of Capercaillie in the Sauerland, Siegerland and in Wittgensteinerland will continue the re-introduction trials.

261: +.132

The results of rarity species investigation of Kryvyi Rih urban flora are presented. The list of rare, endemic and vanishing plants of Kryvyi Rih urban flora numbers 82 species of 59 general 33 families and 3 sections. There are 16 species from the Red Book of the Ukraine (second edition) among them. Rarity of the species majority depends on the anthropogenous and technogenous factors first of all and on natural and historical ones at least. The analysis of rarity species for Kryvyi Rih urban flora, demonstrated the location of the third part of these species in the reserved territories and their protection from extraction. However, the species from the Red Book of the Ukraine *Cymbosoma borysthena*, *Caragana scythica*, *Genista scythica*, *Chamaecytisus skrobiszewskii*, *Bulbocodium versicolor* occurred outside the reserved territories. The registration and certification of these species localities have been carried out for the Purposes of their preservation. Necessity to decree the moratorium on economic activity for such a territories before the solution of problem have been decided. The question is raised about foundation of townspeople's reserve placed under the authority of Kryvyi Rih Botanical Garden, Academy of Sciences of the Ukraine. Flora and vegetation of the reserve will be the unique model for investigation of theoretical and practical problems of phytosociology under anthropogenous stress, industrialization and urbanization. Introduction of rare species in botanical gardens and re-introduction in natural and artificial phytocenoses, renewal of natural vegetation in anthropogenously transformed territories, organization of the bank for seeds of rare, endemic and vanishing species are the complementary measure.

262: +.034

The florosociological role of a small river basin under the conditions of anthropogenous transformation of the landscape is considered at the example of the Kazenny Torets (the north-western macroslope of the Donetsk ridge, the Don's system). The flora of the Kazenny Torets basin comprises 964 species which are divided into seven groups according to a degree of their modern distribution: 243 species occur everywhere (25%), 407 species are usual in specific

habitats (42%), 200 species (21%) are sporadic, rare species (up to 10 habitats) - 57 species (6%), 21 species (2%) occur in 2-3 habitats, 28 species (3%) are in 1 habitat, 8 species might have disappeared. 10 species are registered in the "European list" and 33 - in the Red book of the Ukraine. Methods of the comparative analysis have shown considerable anthropogenous transformation of the Kazenny Torets basin's flora, which reflected in impoverishment of the autochthonous nuclear, increase of the apophyte fraction share and significant perturbations of partial and florocenotic structures. It is dangerous that under the present conditions it is impossible to conserve the flora of the Kazenny Torets basin, because a share of species preserved on the territories of the nature-reserve fund (existing and which will be) does not exceed 40% and the rest unploughed plots do not meet the requirements of nature-protected territories. Revitalization of the vegetative cover of such plots as the Kazenny Torets basin requires considerable time and expenditure for reintroduction measures.

267: +.037

The Northern Hairy-nosed Wombat *Lasiorhinus krefftii* now survives only in Epping Forest National Park, central Queensland. The species was formerly more widespread in the Epping Forest region than at present. Its decline appears to have occurred in three distinct episodes of contraction, two of which were associated with prolonged drought. Indirect monitoring of abundance suggests that the population was stable from 1974 to 1981, when cattle were excluded from the Park, but has increased since 1983. A trapping programme between 1985 and 1989 suggests that the absolute size of the population may be about 70. The population contains approximately equal numbers of males and females; almost all females breed; and a large and apparently increasing proportion of the population consists of young animals. Further increases in density and range within Epping Forest National Park appear possible. Removal of some animals for translocation should be attempted when it is clear that such removals will not jeopardize the stability and vigour of the Epping Forest population.

268: +.190

A programme to improve the conservation status of Whitaker's skink (*Cyclodina whitakeri*), previously confined to <20 ha of usable habitat, is described. The programme involved eradication of introduced Pacific rats or kiore (*Rattus exulans*) from 18 ha Korapuki Island (Mercury Islands, north-eastern New Zealand), documentation of the response of five species of resident lizards to release from the effects of rats, and transfer of 28 Whitaker's skinks from nearby Middle Island between 1988 and 1990. Following removal of rats from Korapuki, resident lizard numbers at some coastal sites increased within 12 months and rose 30-fold over 5 years, but measurable increases of numbers of lizards in forest areas took up to 6 years. Fifteen of the founding Whitaker's skinks on Korapuki Island have been recaptured 36 times since their release, and five Korapuki-born young have also been caught. The population is now estimated as 33. The increase in number of resident lizards and the success of the introduction of Whitaker's skinks demonstrate that predation rather than habitat deficiencies were responsible for the depleted resident lizard fauna on Korapuki Island. Repatriation strategies for species with low intrinsic rates of increase are proposed.

269: +.157

Six species of *Leiopelma* frog endemic to New Zealand have been described, but three are extinct. Field surveys have extended the known contemporary ranges of *L. archeyi* and *L. hochstetteri*, though sub-fossils reveal that both *L. hochstetteri* and *L. archeyi/hamiltoni* were formerly more

widespread in New Zealand than they are now. A new North Island population of terrestrial *Leiopelma* resembling *L. archeyi* has recently been found. Introduced predators and food competitors, especially *Rattus*, have probably had a major detrimental impact on *Leiopelma*. No extant species is immediately at risk of extinction, but *L. hamiltoni* on Stephens and Maud Islands is very restricted in range and/or numbers. *Leiopelma* reaches high densities (up to 8 frogs/m²) in suitable rock-strewn habitats and can be relatively long-lived (*L. archeyi* 17+ years, *L. hamiltoni* 23+ years). Population levels of *L. archeyi* have fluctuated in a Coromandel study plot sampled approximately annually over 1982-93, but on Maud Island *L. hamiltoni* numbers were more stable or increased slightly over the years 1983-93. Experimental translocations of *L. hamiltoni* were made on Maud Island (1984-85) and on Stephens Island (1999). The new colony on Maud Island has bred successfully, and locally bred young have been recruited into the population.

270: +.277

Few guidelines address the considerations and criteria necessary for judging the appropriateness of translocating species onto designated conservation areas. This paper presents a dichotomous key that will assist natural resource decision-makers in assessing the biological and genetic needs and impacts of introducing, reintroducing, or augmenting species. I argue that each translocation decision should be well documented prior to action in a format that includes current and proposed site management information, consideration of the factors addressed in the key, and monitoring of translocated individuals or populations. Although translocation should not be viewed as an alternative to in situ conservation of species, this tactic may be necessary for conservation of species or processes in natural areas.

271: +.090

In the upper Great Lakes region, *Myriophyllum spicatum*, *Elodea canadensis*, *Potamogeton crispus*, and *Ceratophyllum demersum* are the most significant nuisances. *M. spicatum* and *P. crispus* have generally invaded lakes with hard water, abundant nutrients, and a history of disturbance or heavy human use. *M. spicatum* has declined in some Wisconsin lakes, but not in all that it invaded. The reason for declines was never satisfactorily explained. Following its decline in Madison, WI, lakes, the *M. spicatum* population never regained its former predominance. There are no long-term data to determine whether populations of native macrophyte species are expanding, stable, or declining on a regional basis, although diversity of the aquatic plant communities of Madison-area lakes has declined over the last 80 years. Most aquatic plant management in the upper Great Lakes region involves controlling nuisance species. Herbicides and mechanical harvesting are the primary means of management, although drawdowns, bottom blanketing, and other methods are also used. Minnesota and Wisconsin have public education programs intended to promote early detection of nuisance species and to minimize their spread. In Wisconsin, reintroduction of aquatic vegetation to lakes is being attempted on an experimental basis for a variety of reasons, including fish and wildlife habitat and water-quality improvement.

272: +.061

Zoos are becoming increasingly important as sites for captive breeding programs for endangered animals. The ultimate goal of many of these programs is reintroduction of these species into their natural or restored native habitats. This text presents a multidisciplinary review of captive breeding efforts, including philosophical, biological, and economic aspects. Thirty-one chapters are divided into four sections, covering general issues, reintroduction, case studies, and regional

approaches. Chapter topics include the role of flagship species, meta-populations, reproductive technologies, criteria for reintroduction, and conservation assessment and management plans. Much of the information contained herein was originally presented at an international conference on breeding endangered species held on the Isle of Jersey in 1992. The text is illustrated and indexed.

275: +.045

The Seychelles warbler *Acrocephalus sechellensis* was once a highly threatened single-island endemic species with a population of 26 individuals confined to Cousin Island in the inner Seychelles. Following long-term management of Cousin, the population steadily recovered to around 300-360 birds. Given the vulnerability of one small island in the Indian Ocean, the possibility of establishing the species on additional islands had been proposed as a priority conservation measure, in order to give the species the security of additional breeding populations, lest some ecological disaster should befall the parent population. Successful translocations of warblers to the islands of Aride and Cousine took place in September 1988 and June 1990 respectively. Given the presence now of three healthy breeding populations, it is considered that the Seychelles warbler will soon no longer be a globally threatened species. It is not often that people are allowed to pull a species so dramatically back from the brink of extinction.

276: +.175

The number of known sites (populations) documented by conservationists for the natterjack toad *Bufo calamita* between 1970 and 1990 in Britain rose from 21 to 40, excluding those resulting from translocations. The progressive reduction in rate of discovery of undocumented sites suggests that few further populations will be located. The real overall number of natterjack sites has probably changed little over this period, with successful translocations approximately compensating for the few (three to five) concurrent extinctions. More than 90% of natterjacks in Britain now live in the vicinity of just five river estuaries. Habitat protection, mainly the result of scheduling land as Sites of Special Scientific Interest (SSSI), has been increasingly effective in safeguarding natterjacks, the proportion of safeguarded sites rising from 60% in 1970 to 83% by 1990. However, the legislation for species protection has proved much less effective. Much of the recent damage on unscheduled sites was a result of agricultural improvements by landowners ignorant of the presence of natterjacks on their land. The breeding records from natterjack sites are used to examine the possible impacts of radioactivity and climate change, against which site protection alone is no safeguard. Recommendations are made for conserving natterjack populations in the future.

277: -.080

Examining the dynamics of naturally declining populations can be useful in understanding some of the problems encountered by endangered populations. A study of a declining population of vervet monkeys *Cercopithecus aethiops* provides a unique opportunity to examine factors associated with minimum social group size, a potentially key variable in population viability analysis. The minimum group size in vervets ranged from three to six individuals, but always with a minimum of two adults. Groups appeared to be stable as long as there were at least two adults, but ceased to exist as independent groups within days of losing their penultimate adult. For species with discrete group structure, population extinction could occur if all individual groups fall below a minimum social group size, even if the overall population is above a 'minimum' size. However, group fusions may minimize population losses. Group fusion in vervets is rare, and appears to

occur only as a behavioural response to minimum group size. We also review evidence of the costs vervets incur through movement into unfamiliar places or groups (analogous to translocation and reintroduction), and the benefits they can receive from living in proximity to humans.

278: +.038

One potential measure to counteract road mortality of common toads *Bufo bufo* is the establishment of populations at artificially created ponds by translocating adults. This is thought to be difficult because of this species' strong site fidelity. We describe here a successful resettlement of a substitute breeding pond in Northern Germany (Lower Saxony). We first created a barrier system made of used metal vehicle crash barriers which successfully prevented toads from crossing a road to reach a breeding pond. The toads were collected annually in pitfall traps and transferred to the substitute breeding pond. A majority of the adult population of common toads became attached to the substitute breeding pond after only two to three years. The migration directed at the old breeding site dropped to approximately 15% after four years and subsequently to less than 1%. Our findings show that the provision of substitute breeding ponds can be a useful measure for the protection of amphibians.

279: +.094

A survey of historical records revealed that the disappearance of characteristic rich-fen bryophytes such as *Scorpidium scorpioides*, *S. revolvens* and *Campylium stellatum* from the springs of De Mosbeek, the Netherlands, has taken place between 1951 and 1956. A study of the present ecohydrological situation suggests that the present water chemistry (pH, EC and Ionic Ratio) and trophic status (P concentrations) fall within the range suitable for *S. scorpioides* and that the water is well-buffered. To test the hypothesis that the present absence of rich-fen bryophytes is due to past habitat change rather than ecohydrological conditions, a transplantation experiment with *S. scorpioides* was carried out. Reintroduction of the species resulted in establishment of new shoots throughout the spring channel up to a distance of 2 m from the initial transplants within three years, which confirmed that the water composition is not detrimental to the species. It is unknown what caused the disappearance of the species in the 1951-1956 period. An unusual rainfall pattern, increased atmospheric deposition and changes in management all could have played a role. Historical data suggest a strong expansion of *Sphagnum* spp. and, via this, the disappearance of *S. scorpioides* and associated species. The present absence of *S. scorpioides* seems to be due to poor dispersal and establishment rather than habitat conditions.

280: +.225

We investigated the effect of five plant and habitat characteristics on the national distribution of scarce British plants defined as those occurring in 16-50 10 x 10 km squares ('loci'). In all 139 species considered loci were more aggregated than expected by chance. Habitat, dispersal ability and pollination type were significantly correlated with pattern of locus distribution. Seed size and life history were unrelated to the degree of aggregation of loci. The most important result from a conservation perspective is the tendency for plants with poor dispersal ability to have more aggregated distributions (i.e. they have loci closer together) than plants with good dispersal ability. One implication of this result may be that reintroduction or translocation could be useful techniques for supplementing natural dispersal in the management of such species.

282: -.010

The article briefly reviews one field of plant biotechnology, which can be used in conserving endangered plant species. Micropropagation could be applied to plant species which can not be efficiently propagated by conventional methods. *Rubus humulifolius* C.A. Meyer is a Rosaceae plant species, which became extinct in 1957 in its only natural habitat in Finland. In 1986 one specimen was taken from a forest, where about 10 individuals had been preserved. At 1500 plants were propagated from this individual through tissue culture. They were successfully reintroduced in the vicinity of the original habitat in 1988. This is probably the first reported case of large scale micropropagation of an endangered plant species for reintroduction.

283: +.110

In Finland, *Pseudophilotes baton schiffermuelleri* is an endangered blue butterfly associated with open and dry esker habitats. During this century *P. baton* has been recorded from about twenty sites, but only one population is known to have survived, at Sakyla, SW Finland. Forest fires and from 1963 onwards the military rifle and grenade shooting ranges have kept the southwestern slopes of the sandy esker open and suitable for the butterfly. The population size and movements of *P. baton* were investigated by mark-recapture method and its habitat preferences were studied. The total adult population size was estimated in 1990 at about 850 individuals. The number of males increased as the tree cover of the habitat decreased. The proportion of bare mineral soil and the coverage of the host plant *Thymus serpyllum* also contributed to the habitat preferences of the butterfly. Individuals flew on average more than 100 m, and females flew longer distances than males. A conservation programme is proposed for *P. baton*, including active habitat management and a reintroduction plan.

284: +.121

Gray wolves were systematically and fervently eliminated from the northwestern United States between the mid-1800s and early 1900s. Wolves disappeared from lower elevations first and generally persisted longer in more remote, mountainous areas. Preservation of large tracts of public land, primarily for commodity use, at the turn of the century, had the unforeseen effect of allowing conditions for wolf recovery to occur later. Improving attitudes toward the species and the recovery of ungulate prey populations from their turn of the century lows are the proximate factors making wolf recovery possible in areas with vast public lands. Planners for wolf recovery in the Northern Rockies identified three areas for wolf recovery, northwestern Montana, central Idaho, and the Greater Yellowstone area, because they consisted primarily of national parks, designated wilderness, and national forests. Those areas had previously been designated as public lands largely because they were too unproductive for agriculture; they consist in part of high elevation habitat that supports relatively few prey for wolves in winter. So far, recolonizing wolves have settled in lower elevation habitats where deer and elk are most abundant. Since private lands are most often in these lower elevations, they may be more important to the recovery and maintenance of viable wolf populations than was earlier envisioned. The negative symbolic nature of the wolf was a major factor in its eradication and continues to be a major factor in considerations of reintroduction and natural recolonization; the newer positive symbolic nature of the animal will ultimately facilitate its return and contribute indirectly toward long-term conservation of wild spaces and biodiversity in North America.

287: +.097

Some fern species form spore banks - reservoirs in the soil of viable spores which remain dormant while buried but germinate in light if brought to the surface. The recently discovered

characteristics of these spore banks are described. Enough is now known to suggest that they might have a role in the conservation of endangered fern species as alternatives to ex situ collections of sporophytes, gametophytes and spores, the relative merits of which are also considered. Mature sporophytes of several British species have now been raised from natural spore banks in soil samples; if this proves to be possible also for endangered species, some interesting options become available. The possibilities are discussed of augmenting surviving populations and increasing their genetic diversity, even perhaps of retrieving lost populations, by reintroduction of spore bank-derived plants or by stimulating regeneration from spore banks in situ. Botanic gardens are well placed to provide the further research, the regular monitoring of endangered populations, and the taxonomic and horticultural support required to realise these possibilities.

288: +.113

Fifty percent of all the mammal species to have become extinct worldwide in the past 200 years have been lost from the Australian fauna giving Australia the worst record for mammal conservation of any country or continent. Sixteen species from a mammal fauna of 245 are believed to be extinct, 26 species now occur only as remnant populations occupying <20% of their former ranges. Offshore islands, tropical Australia, and the mesic fringe of the continent have provided refuges where mammal communities have survived, relatively intact. The drier interior regions, which include cereal growing areas, intensive and extensive pastoral areas, and the little-used Triodia deserts, have lost many species. Extinctions and declines have not occurred equally throughout the Australian fauna, but have occurred at a disproportionately higher rate among medium-sized ground-dwelling mammals in the weight range 0.035-5.500 kg. Historically, conservation of mammals has concentrated on protection from hunting and trade, reservation of land as national parks and nature reserves, and faunal surveys to map distribution and abundance. These approaches have been necessary but insufficient to either stabilize the decline of endangered mammals or to promote their recovery. The past 20 years have seen many attempts to conserve endangered mammals, either by evading the presumed cause(s) of extinction or decline by translocation to islands, or by managing these causes within reserves by controlling exotic predators, controlling or excluding exotic herbivores, or applying a particular fire pattern or regime. The most significant successes have come with effective control of exotic predators, either by establishing populations of endangered species on predator-free islands or by the intensive use of 1080 poison to control exotic predators at mainland sites.

291: +.292

Re-introductions are increasingly used conservation tools. Often, criteria for re-introducing species are based on policies or politics and little attention paid, albeit theoretical, to understanding what ecological possibilities habitats may have in sustaining introduced animals. Assessing potential carrying capacities is complex but easier for grazers, since biomass of these herbivores is empirically correlated with habitat primary productivity. The case is made here that the Barbary macaque, *Macaca sylvanus*, a vulnerable North African primate with a large surplus captive stock, can be viewed as a grazer. Because of this attribute, and unlike congeners, it is possible to estimate potential densities in extant habitats in a fashion similar to predicting stocking levels for domestic herbivores. Thus, from values of consumable primary productivity for domestic stock in Mediterranean countries and the monkey's energy requirements, attainable macaque populations in studied habitats could be much higher than actual. Though these numbers may be unreachable in nature, this study shows that present macaque populations could increase after restorative management of habitats in which re-stocking with captive-born animals may play a part. However, since only 10% of potential monkey habitat in Morocco and Algeria is occupied by the species,

finding areas for releasing captive-born macaques is more advisable.

292: +.019

In Thailand, a predominantly Buddhist country, isolated populations of long-tailed macaques (*Macaca fascicularis*) especially may be found at temples in both rural and urban areas where they are provisioned by people making merit although the monkeys may be shot as agricultural pests in adjacent rice or corn fields in rural areas. At the same time, macaques and gibbons, especially the lar gibbon (*Hylobates lar*), have been kept as pets in both rural and urban areas. Gibbons even are reported to be the $\langle \rangle$. The number of primates being offered for sale has risen dramatically as legal and illegal timbering have reduced Thailand's forest cover to, perhaps no more than 12 %, peripheralizing primate populations and making them more vulnerable to hunting. A provision in Thai law permitted individuals to possess as many as two primates or other wild animals of the same species - $\langle \rangle$ - even though their capture and sale was prohibited. Changes in Thailand's wildlife laws governing private possession of wild animals have caused owners to abandon pets to government agencies and temples. Private rescue centers offer acute care and permanent shelter for some of these primates but cannot cope with the numbers involved. Pilot studies suggest that rehabilitation and reintroduction may be feasible alternatives for some former captive gibbons.

293: -.094

The European wildcat, *Felis silvestris*, faces a number of threats to its population in Scotland and continental Europe. Population minimums probably occurred in Europe at the beginning of the 20th century. Several populations have recovered since, due to some restoration of preferred habitat and a reduction in persecution. Our study of European wildcats in Scotland found that direct killing because of alleged attacks on gamebirds and livestock still occurred. Accidental killing by dogs, snares or poison baits is probably still common. Viral diseases, such as feline leukaemia have recently been identified. Low levels of dieldrin were detected in two wildcats, but few other toxic agrochemicals were found. A major threat to European wildcats is the loss of speciation due to hybridization with domestic cats. Many introgressive hybrids are now reported. These can be readily detected by skull measurements and coat markings. Major reintroduction programs are probably not necessary to "save" the wildcat, but local education of hunters, reductions in feral domestic cats and instigation of wildlife management procedures would greatly enhance the outlook for the species.

294: +.013

We conducted DNA fingerprinting analyses to ascertain the mating system and population genetic structure of the palila, an endangered Hawaiian honeycreeper, which occupies a fragmented range on the Mauna Kea volcano of the island of Hawai'i. DNA fingerprinting of twelve complete families from the Pu'u La'au population revealed no evidence of extrapair fertilization or intraspecific brood parasitism. Band-sharing coefficients from fingerprints produced with two probes revealed that the large Pu'u La'au population on the southwest slope of Mauna Kea, and a smaller, geographically separate population on the east slope (at Kanakaleonui) had relatively high and virtually identical levels of minisatellite variability (mean S of 0.27 for each population based on combined data of M13 and Jeffreys 33.15 probes). The two populations also had nearly identical allele frequencies based on their mean corrected similarity, S_{-ij} , of 0.98. These data suggest that the two populations have not been fragmented long and/or have sufficient current gene flow to ameliorate any effects of genetic drift. We conclude that present levels of inbreeding are low within both populations, and that proposed translocations of individuals from Pu'u La'au to

Kanakaleonui appear appropriate from a genetic standpoint.

295: +.173

Deliberate reintroductions of locally exterminated animal species to areas within their former ranges is an increasingly important conservation tool. Most reintroductions are fairly recent and still in an initial phase of population development. There are few long-term studies of reintroduced populations. The aim of this study was to see if the population development of the reintroduced European beaver (*Castor fiber*) population in Sweden exhibits the same pattern of population development as other introductions, in accordance with general theories, and to discuss possible management consequences. Since the European beaver was reintroduced to Sweden 70 years ago, the population has developed in a way predicted by the Riney-Cauchley model for introduced ungulates, exhibiting an irruption and a subsequent decline. In two study areas, the rate of population increase (r) turned negative after 34 and 25 years and at densities of 0.25 and 0.20 colonies/km², respectively. The data suggest that management policy for an irruptive species should allow hunting during the rapid-increase phase, thus maintaining food resources and avoiding uncontrolled population decline.

296: +.108

The dispersal patterns of radio-collared Corsican mouflon (*Ovis musimon*) ewes inhabiting a low Mediterranean massif in the south of France were followed. Despite spatial instability being more marked in winter and spring, females ($n = 17$) remained on a single home range. The changes in spatial behaviour which appeared in March did not seem to be linked solely to ecological parameters. The use of the spring range was particularly noticeable among the different seasonal ranges since it was characterised by long-distance movements ($n = 16$, $x = 740 \pm 320$ m) and the large overall area used ($x = 330 \pm 90$ ha). The age of individuals had an important influence on space use. With increasing age, spatial patterns became more firmly fixed, which appeared to be linked to a better understanding of the different ecological and social contexts occurring in the population. Some characteristics of spatial behaviour may create certain management difficulties in the introduction or reintroduction of the species. Age and season seem to have a strong effect on the organization of spatial patterns. Managers and hunters should therefore consider the implications of the age of individuals and thus their stage of development, and also of the season, to guide management decisions. For example, disturbance of young individuals must be strictly limited, particularly during the spring and the rut which appear to be important periods in the organization of spatial behaviour patterns.

297: +.021

In former times capercaillie occurred throughout the Sauerland, while today areas with suitable habitats still exist for this species. In light of this the Research Station for Hunting and Game Damage Prevention of North Rhine/Westphalia conducted reintroduction trials of this species from 1980 to 1992. These trials were located in the area around Hunau a secondary chain of mountains between Fredeburg, Bodefled, and Altastenberg. The birds were first hatched and raised in cages, and at the age of 16 weeks transferred to large flight cages for four weeks to adapt to free land conditions before being released. The goal was to release 50 individuals/year in this manner over a period of 10-15 years. For this purpose a breeding station was established at the research station. The planned number of capercaillie (15/year) released annually could only be attained in the last 4 years of the trial. A total of 393 capercaillie (226 cocks, 167 hens) were released during the trial period. A large proportion of the released birds succumbed primarily to predation; a few were

killed by accidents. Sick or lost animals were not observed. Some of the cocks lived 5-7 years as could be ascertained by individual ringing. In 1986 a nest with 7 eggs at the foot of a spruce tree was found in the trial area, and repeated observations were made of free land raised young birds. In the spring of 1992 a population of 30-40 capercaillie over an area of 20,000 ha were present in the Sauerland due to the re-introduction trials. The establishment of a population of 30-40 capercaillie is a successful result. However, this population is still insufficient to perpetuate itself. The re-introduction of more birds is necessary. As of 1993 the Association for the Preservation of Capercaillie in the Sauerland, Siegerland and in Wittgensteiner-land will continue the re-introduction trials.

298: +.046

Little is known of the life history of vultures. The reintroduction program of Griffon Vultures (*Gyps fulvus fulvus*) in the Causses (south of the Massif Central, France) and extensive monitoring by capture-mark-resighting of the released birds allowed us to obtain the first estimates of their survival. Adult survival rates are high ($\bar{x} = 0.987 \pm \text{SE of } 0.006$). A release effect on adult survival was detected (only 0.743 ± 0.006 survival during the first year after release). Young born in the wild (less than three years old) had an annual survival rate of 0.858 ± 0.039 . Mortality causes and erratic behavior of immature birds are considered in order to assess the effectiveness of this reintroduction program. Our results indicate that reintroductions of vultures and similar species should use adults that have bred in captivity within the target area rather than juveniles or immatures.

301: +.117

Predation by introduced foxes and cars is generally thought to be the main reason for the poor success rate of macropod reintroductions on the Australian mainland. Predator-prey theory suggests that predation may have particularly severe impacts on very small populations, especially if a more common primary prey species is present (such as the rabbit). Thus, a sufficiently large reintroduction may overcome predation and succeed where a smaller one would fail. The minimum viable population would, however, be much larger than that predicted by standard population-viability analysis. We use a simple stochastic model based upon the bridled nailtail wallaby to explore this possibility. Even very small amounts of predation (2-4 individuals per six months) can be sufficient to cause reintroductions of up to 50 animals to fail. No clear threshold population size beyond which reintroductions will succeed is evident and, for a given mean, the probability distribution of predation has a very limited impact on the success of reintroductions. In almost all circumstances, a single reintroduction of a given size is preferable to multiple reintroductions of the same total number of individuals.

302: -.087

Physiological responses of conserved plants (transpiration, irrigation, water deficiency in leaves) to the change of environmental conditions (illumination intensity, temperature, air humidity and soil moisture) caused by anthropogenic influence on phytocenosis were studied.

303: +.101

Ospreys historically nested throughout the wooded portion of Minnesota including the Minneapolis-St. Paul metropolitan area. They were eliminated as a nesting species in the southern two-thirds of the state before the turn of the century, primarily due to uncontrolled shooting. In

1984 a reintroduction effort was begun to restore breeding Ospreys to wildlife preserves in the western portions of the Twin Cities. In 1992, the program entered a new phase when efforts began to return Ospreys to urban metropolitan lakes. Osprey chicks were translocated from nests in north-central Minnesota at 5 1/2-7 weeks of age and released when they reached flight stage using modified raptor hacking techniques. A corps of over 75 volunteers was enlisted to monitor the fledglings from dawn to dusk for 4 weeks after their release. Between 1984 and 1993, we released 119 wild-caught Osprey nestlings at 5 sites in the Minneapolis-St. Paul Metropolitan area. The first nesting attempt took place in 1986. In 1993, 9 nesting attempts involving released birds were recorded. These resulted in 15 fledglings. We have recorded mortality of six birds in the vicinity of the hack box. An additional three post-fledgling birds have been reported dead from Central and South America. Ospreys learn to fly and fish without adult supervision. The Twin Cities Ospreys have become tolerant of human activity and the birds use perches in areas of moderate human activity, as well as in more secluded areas. Reintroducing Ospreys to a metropolitan area is an effective contribution to restoring an ecosystem, as well as educating the general public about raptors, wildlife, general ecological principles, and the human role in natural resources conservation.

304: +.175

After their extinction as a breeding species in 1916 Ospreys returned to Scotland in 1954 to breed with one pair. In 1959 the Royal Society for the Protection of Birds established a public observation post at this eyrie at Loch Garten and over 1.7 million visitors have viewed the nest since. Protection of the birds through guarding of eyries and the construction of artificial nests made the population grow to 94 pairs in 1994. Over the last 40 years at least 1281 young have been reared from a total of 995 nesting attempts, giving a productivity of 1.29 young per occupied nest. The population has been monitored annually, in 1967 a ringing program was started and since 1972 an annual newsletter has been produced. Ospreys in Scotland are breeding in small and loose 'colonies' with a mean distance of 39.7 km between each other (min. 12.5 km, max. 67.5 km). Over 90% of the new eyries are located in the East, which has a higher human population, although above 90% of the historical sites were in the western half of the country. The faithfulness of Ospreys to their natal areas results in a slow extension of the breeding range. Means for the restoration of the natural breeding range such as the provision of artificial nests and the translocation of young to potential nesting areas are discussed.

305: +.287

Brown trout population maintained by annual restocking were studied in Siena area. This species, introduced 30 years ago, showed a satisfactory growth even if, its reproductive capability is still unknown. However, according to previous evidences, the native trout in the Tyrrhenian regions probably is *Salmo (trutta) macrostigma*. This study indicates that *Salmo (trutta) macrostigma* is more suitable for environmental conditions of these streams and its re-introduction is suggested.

310: -.006

The biology of most of the indigenous parastacid crayfishes inhabiting the highlands of New South Wales is poorly known, but many species have very limited ranges. Analysis of these distributions in relation to the National Parks and State Forests shows that most species are protected in reserves; however, around and within these areas a large number of potential polluted sites have been identified. The effects of clearing, longstanding salmonid stocking and the potential problems of recent widespread introductions of non-indigenous *Cherax* species for

aquaculture are discussed. Recommendations for conservation and future management include: biological programmes to provide data on environmental preferences, interactions between indigenous and non-indigenous crays and influences of introduced salmonids; restoration and maintenance of riparian zones; surveys of polluted sites in, or adjacent to, very small ranges with initiation of remedial measures where necessary; more active policing of quarantine measures at aquaculture facilities; development of comprehensive, workable and enforceable policy on translocations; implementation of eel control measures at large impoundments on eastern drainages.

312: +.139

One of the most common tools in New Zealand conservation is to translocate species to new locations. There have now been over 400 translocations done for conservation reasons, mainly involving terrestrial birds. Most translocations have been done strictly as management exercises, with little or no reference to theory. Nevertheless, translocations always involve some underlying theory, given that people must inevitably choose among a range of potential translocation strategies. We review theory relevant to translocations in the following areas: habitat requirements, susceptibility to predation, behavioural adaptation, population dynamics, genetics, metapopulation dynamics, and community ecology. For each area we review and evaluate the models that seem to underpin translocation strategies used in New Zealand. We report experiments testing some of these models, but note that theory underlying translocation strategies is largely untested despite a long history of translocations. We conclude by suggesting key areas for research, both theoretical and empirical. We particularly recommend that translocations be designed as experimental tests of hypotheses whenever possible.

313: +.020

The wild alala *Corvus hawaiiensis* population has been declining for many years and only three pairs of birds are currently reproductively active on the island of Hawaii. At the recommendation of a committee formed by the National Academy of Sciences, a restoration programme was initiated in 1993 by The Peregrine Fund in collaboration with private land-owners, the US Fish and Wildlife Service, National Biological Service and the State of Hawaii. The restoration programme includes removing eggs from wild nesting birds for artificial incubation, handrearing and reintroduction. In two breeding seasons (1993, 1994), 17 eggs were removed from alala nests in the wild. Three eggs were infertile, 13 chicks hatched and 12 alala were successfully reared (hatchability: 93 per cent, survivability: 92 per cent). Four of these chicks were sent to the State of Hawaii's Olinda Endangered Species Propagation Facility, while four chicks from this facility were sent to the reintroduction programme. Twelve alala have been released by The Peregrine Fund: five in 1993 and seven in 1994. Three of the five birds released in 1993 and all seven of the birds released in 1994 are currently surviving in the wild.

314: +.093

The community status of 5,666 stocks of Arctic char (*Salvelinus alpinus*) in Norwegian lakes was monitored using interviews. A total of 228 stocks are extinct, and an additional 268 stocks are in differing stages of decline. Acidification is recognized as the most severe threat to Arctic char in Norway, and areas in southernmost Norway are seriously affected. The majority of the stocks in this region were affected after 1960, but the earliest indications of decline occurred in the early 1900s. Stocks in western Norway have experienced the most recent changes. Analyses of principle components, variance, discriminant and regression, indicated that pH and monomeric inorganic

aluminium were the water quality parameters most strongly related to char status. However, acid-neutralizing capacity (ANC), alkalinity and calcium were also correlated to char status. Arctic char appear to be more sensitive to acidification than brown trout (*Salmo trutta*) and perch (*Perca fluviatilis*), which occur most commonly in sympatry with Arctic char. The natural distribution of Arctic char in Norway extends along coastal areas throughout the country. However, translocations and introductions over the past 100-120 years have increased the distribution of the species significantly. This is particularly the case in some interior areas in southern Norway and in northern Norway, although exact data from the latter mentioned region are scarce. Most of the introduced stocks cited by Huitfeldt-Kaas (1918), have established self-sustaining populations. A conservation programme for Arctic char in Norwegian lakes is suggested. Unique stocks should be recognized and given priority for conservation. In acidified areas liming may save threatened stocks.

315: +.369

The Arctic Charr *Salvelinus alpinus* (L.) is the most northerly freshwater fish and occurs in many countries in the northern hemisphere - in Asia, Europe and North America. Worldwide, the status of the species is satisfactory but in a number of countries, especially those on the southern fringe of its distribution, many individual populations have been lost. The main threats to Arctic Charr are from acidification, eutrophication, pollution, hydropower developments, overfishing, genetic degradation from alien translocated *Salvelinus*, introductions of other, disruptive, fish species and possibly global warming. The Arctic Charr is an important species in the northern hemisphere and merits serious international conservation efforts to maintain its integrity and status. It is well known in some countries, but less well known in others. It is important to many native peoples in the arctic and more generally of value to anglers, to commercial netmen and, more recently, to fish farmers. Conservation management for this species varies widely and more programmes are needed at both national and international levels. Reliable inventories of individual populations in each geographic area are highly desirable. The main methods proposed for conservation include improved legislation, habitat management and restoration, and in some cases, careful translocation, captive breeding and cryopreservation. Improved education is also greatly needed in order to increase public awareness of this most attractive and valuable fish species.

316: +.028

Beavers were recently re-introduced in the Netherlands after the species had become extinct in 1826. Between 1988 and 1991, 42 beavers were released in the Biesbos (Rhine-Meuse estuary). In 1994, another 15 beavers were released in the Gelderse Poort, along the Rhine between Kleve-Nijmegen-Arnhem. Between 1990 and 1992, some beavers escaped from captivity in the Biesbos and in the provinces of Flevoland and Limburg. One animal found dead in Roermond (Limburg) in 1993 had probably dispersed from the Eifel (Germany), another re-introduction site. By the end of 1994, c. 70 free-ranging beavers were present in the Netherlands. As far as known, at present all free-ranging beavers in the Netherlands originate from the Elbe population in Germany.

317: +.254

We developed a spatially explicit modeling approach, using a county-scaled remote forest (i.e., forested area reserved from or having no direct human interference) assessment derived from 1984-90 forest resource inventory data and a 1984 black bear (*Ursus americanus*) range map for 12 states in the southern United States. We defined minimum suitable and optimal black bear habitat criteria and gee-referenced remote forest classification with existing black bear range.

Using a suitable habitat criterion, we classified 97.2% of occupied and 9.7% of unoccupied range (38.9% of the south. U.S. region's area). Using optimal habitat criteria, we classified 69.8% of occupied and 60.1% of unoccupied range (63.3% of the region's area), interpreted occupied range without optimal habitat and suboptimal areas (9.9% of the region's area), and unoccupied range with optimal habitat as areas with repopulation potential (26.8% of the region's area). There was a lack of high-density (greater than or equal to 34%) optimal habitat linkages among existing black bear populations, which we construed as a limitation on interpopulation gene flow. We recommend expansion of future regional land surveys to (1) address large carnivore mammal habitat and broad home ranges of other species that may conflict with humans or domestic animals, (2) include held inventories of woodland and reserved areas, (3) use standard measures to assess remote forests, and (4) organize available data in a geographic information system.

318: +.055

The butterfly *Euphydryas gillettii* (Barnes) lives in moist mountain meadows connected by riparian corridors, thus forming metapopulations in which local extinctions and recolonizations occur infrequently. Following the 1988 fires in the Greater Yellowstone Ecosystem, I chose 8 unoccupied patches of suitable habitat, 4 of which had been burned, and introduced a single eggmass into each. Larvae survived to diapause in at least 4 of the 8 sites, but only one introduction led to the establishment of a new colony the next year. This was at a burned site. The new population increased rapidly for 2 years but then declined and disappeared. These results suggest that: (1) a single, isolated eggmass is sufficient for colonization of open habitat; (2) most single, isolated eggmasses do not survive to produce adults the following year; and (3) recently burned sites provide acceptable habitat for this scarce butterfly.

319: +.250

We reviewed key features of the evolutionary biology of lake trout (*Salvelinus namaycush*) and their significance for rehabilitation programs in the Great Lakes. Despite repeated translocation by glacial advances during the Ice Age (the Pleistocene) that eliminated most populations, lake trout have genetic diversity comparable with other North American salmonines. Various embryological and adult features suggest lake trout had a long reproductive history in lakes, although river spawning may be a primitive feature of the species and may have been important in glacial refugia. Observations that hatchery-reared lake trout select mostly mainland shoals for spawning in the Great Lakes are interpreted by us to be a result of evolution in smaller lakes where the main source of spawning gravels is shoreline erosion. We hypothesize that longevity in lake trout (a record among chars) may have evolved because of a near absence of predation on adults in contrast to predation on juveniles that survived less well, in parr, because of cannibalism. Longevity, a physiological ability to colonize the coldest of waters during deglaciation, and an ecological role as a dominant piscivore in unperturbed systems all indicate that lake trout should fare best under conditions of low adult mortality and high biomass. Although the Great Lakes fish community is enriched compared with when lake trout populations were abundant or with where lake trout evolved, the species has the potential to suppress other fishes to its benefit. We provide ecological and ethical reasons why lake trout rehabilitation should be a priority for the Great Lakes: lake trout are particularly suited for the deepwater food chain, they are the only salmonine (among those currently stocked in the lakes) that have the potential to become self-sustaining at their current levels of abundance, and emphasis on stocked exotics reflects adherence to a scientifically obsolete philosophy of "wise use" that ignores evolutionary-ecological relationships. For fishery management we recommend greater use of genetic diversity and of life stages capable of being imprinted, maintenance of high adult survivorship and biomass, and expanded

communication with a wider array of clients. We also advocate lines of research that will test our management recommendations, including assessing the implications of attempting to keep the Great Lakes fish community in an early stage of succession.

320: +.158

Complete restoration of the Great Lakes is unlikely, due to naturalization of exotic species, habitat degradation and destruction, heavy fishing mortality, lack of native gene pools, and complicated political jurisdictions that rarely work toward a common vision. A more realistic goal is rehabilitation, a movement along the trajectory toward complete restoration. Proper rehabilitation employs an evolutionary-genetic perspective, which protects and works with the remaining genetic variation available in lake trout or other species of concern. A difficult question is how to define the units of genetic conservation; one answer is to determine Evolutionarily Significant Units. To do this, population structure must be defined, and various conceptual models are here presented that determine genetic population structure as a function of geographic structure of the habitat. Several concepts from the developing field of conservation biology should also be incorporated into lake trout rehabilitation. These include metapopulations—groups of populations that experience some degree of regular or intermittent gene flow, and that serve as recolonization sources after local extinctions. Related to this is "source-sink dynamics," a recognition that habitats typically are unequal in quality. Habitat fragmentation is also relevant because it can stop inter-population movement and disrupt metapopulation structure and source-sink dynamics. Finally, hatcheries should be used in rehabilitation only with great caution and skepticism. Hatcheries tend to address the symptoms, rather than the causes, of fish declines, and may mask the underlying problems by continually replacing declining fish. Improved habitat quality, rather than artificial production, is the key to rehabilitation of the Great Lakes for lake trout and other native species, and hatcheries should only be used as a stopgap measure to prevent further losses of genetic diversity.

321: +.137

The current status of Kakapo *Strigops habroptilus* and Takahe *Porphyrio mantelli* is described along with recent developments in programmes for their conservation. Both species were (at different times) thought to be effectively extinct, and both have been temporarily reprieved by the discovery of new populations. Population declines have continued, with Kakapo now reduced to less than 50 individuals and Takahe to about 150. Kakapo are especially at risk; 87% of the remaining birds are over 14 years old and only 17 females are known. Research on relict populations of both species has identified predation and competition from introduced mammals as major threats. Both species have high rates of egg infertility and low survival of young. Increasingly intensive management of both Kakapo and Takahe over recent years has included translocation to predator-free island refuges, supplementary feeding to encourage breeding, clutch manipulation, captive rearing and predator control. All known Kakapo have now been transferred to three island refuges, where the overall rate of population decline has slowed and supplementary feeding has apparently encouraged more frequent breeding attempts. Takahe conservation has concentrated largely on attempts to increase the population in Fiordland, New Zealand, through clutch manipulation and release of captive-reared young, but birds have also been released on four islands, which now hold 19% of the total population. The relict Fiordland populations of both Kakapo and Takahe were confined to apparently suboptimal habitat. Both species have successfully adapted to novel environments and foods when translocated, and the populations which now exist present improved opportunities for intensive management using a range of conservation techniques to enhance productivity and survival. Recent population trends of Kakapo and Takahe are reconstructed, and the contribution of research to their conservation is reviewed.

322: +.016

The establishment of large populations of common frogs *Rana temporaria* and common toads *Bufo bufo* was monitored for six years in a newly-created reserve, following stocking with spawn of both species and with toads rescued from a site to be destroyed. Frog spawn output reached a peak three years after the initial introduction. There was high mortality and/or emigration (64% loss) during the first year following translocation of over 5,000 adult male toads. Thereafter male mortality decreased and/or site fidelity increased: 39% loss year 2 to 3, 42% loss year 3 to 4. Comparable data were not available for the 795 females translocated, but there is no reason to believe their mortality was lower. Transfer of spawn is probably more effective as a means of establishing a new population of toads than transfer of adults. Counts of male toads peaked after three years, but delayed sexual maturity of females meant that counts of pairs and estimates of spawn output continued to increase for about six years. Age determination in a sample of 43 male toads showed that length was significantly related to age, but there were some notably disparate rates of growth. A sample of 16 females showed no correlation between age and length. The greatest recorded losses of naturally-laid spawn of both species (up to 16% in one year for the frog and 39% for the toad) were due to desiccation, presumed collection by people and fungal infestation.

323: +.235

The dominance of *Polygonum bistorta* in abandoned mountain meadows was studied. Successional and seasonal changes in biomass, nitrogen concentration and content were studied at the community level. During the succession, *P. bistorta* increases its biomass both in absolute and mainly in relative values compared to the surrounding species. Nitrogen stored in its rhizomes seems to be quickly translocated into above-ground parts at the beginning of the growing season. High amounts of nitrogen allow rapid growth of both vegetative and generative plant parts. The success of *P. bistorta* is probably the result of efficient use of stored nitrogen, suppression of surrounding vegetation by above-ground cover of leaves and by decrease in the level of soil nitrogen, and the effect of a large amount of litter. Management consisting in the combination of mowing and fertilization is proposed.

325: +.204

The activities of conservation of the flora of the Columbretes Islands Natural Park (UTM 31S CE 01, Castellon, Valencian Community, Spain) are exposed. Since 1987 it is being developed a conservation project of endemic species (*Medicago arborea* subsp. *citrina* and *Lobularia maritima* subsp. *columbretensis*) by means of "ex situ" conservation techniques (seed-banks) and also "in situ" ones (propagation and reintroduction of *M. a.* subsp. *citrina* in one of the islands of the archipelago, as well as recovery of the most important and threatened climactic arbustive species of these islands (*Chamaerops humilis*, *Pistacia lentiscas*, *Withania frutescens*, *Smilax aspera* and *Lycium intricatum*).

326: +.081

The development of a collaborative conservation project on Mauritius and Rodrigues (Mascarene islands, south-west Indian Ocean) is followed from its inception in 1972 to early 1995. The project has a tripartite structure, being run jointly by the Government of Mauritius, a local non-government organisation - the Mauritian Wildlife Fund, and international organisations including the Wildlife Preservation Trusts. Work has focused on the endangered endemic birds, bats, reptiles

and plants. Intensive management techniques, including in situ plant propagation, captive breeding, reintroductions of plants and animals, supplemental feeding and manipulation of the nesting biology of the birds to increase productivity, have proved to be very successful. These, together with pest control and the protection of native habitat, resulted in the increase of some of the rarest species and the restoration of small islands and areas of native vegetation. This work convinced the Government to establish Mauritius' First National Park. The interface between captive breeding and the management of wild populations is one that offers many possibilities. During the 1970s the future for many of the endemic species seemed hopeless; two decades later the long term conservation of many of the surviving endemic species is within our grasp. A bibliography of 447 titles of articles, papers and books that that directly influenced the project or have been generated or inspired by it, is included.

327: +.089

During the Kemp's ridley sea turtle (*Lepidochelys kempii*) head-start experiment, the National Marine Fisheries Service's Galveston Laboratory reared, tagged, and released 22,255 yearlings of the 1978 to 1992 year classes along the coasts of Texas, west Florida, and Campeche, Mexico. A total of 805 recaptures were recorded (3.6% of the yearlings released). Annual survival rate, S , was estimated from recaptures of successive age groups. Values of S_{2-3} (annual survival rate estimated from recaptures of age groups 2 and 3 years) were probably more reliable than those of S_{3-4} and S_{4-5} , because they were based on larger numbers of recaptures. For Texas releases S_{2-3} ranged from 0.10 in the 1980 year class to 0.43 in the 1986 year class. For Florida releases S_{2-3} ranged from 0.36 in the 1978 year class to 0.50 in the 1979 year class. With recaptures from year classes combined, S_{2-3} was lower for Texas releases (0.15) than for Florida releases (0.39). Because of tag loss and uncontrollable factors affecting the reporting of recaptures, S estimated from recaptures of foreflipper-tagged turtles are crude approximations which underestimate true survival at sea. A constant S of 0.45 would be required to produce one survivor at age 10 yr (assumed age at maturity) from the average Texas release of 1437 yearlings per year. If S were higher than 0.45 or increased with age, then more head-started ridleys could have survived. It remains to be determined whether head-started Kemp's ridleys survive to maturity and nest.

328: +.215

Research on birds has shown that familiarity between mates and neighbours leads to lower aggression and higher reproductive success. This study addresses the hypothesis that founder groups used for translocations will do better if made up of individuals that are familiar with one another. The study involved a translocation of a territorial forest bird, the North Island robin *Petroica australis longipes* to an offshore island. I created both 'familiar groups' (made up of birds that had been adjacent to one another at the source location) and 'unfamiliar groups' (made up of birds that had been widely separated). I released the groups in separate forest patches on the island, and assessed the effects of familiarity on aggression, dispersal, survival and pair bonding. While the study was limited by the sample sizes possible, there was no indication that 'familiar groups' performed differently than 'unfamiliar groups', or that familiarity at the source location affected behavioural interactions following translocation. Post-translocation familiarity was clearly important, for aggression declined according to how long birds had been neighbours at the new location. There was little aggression in general over the first two to five weeks, the period when an effect of prior familiarity on aggression may have been most important. In addition, breakup of 'familiar' groups by dispersal meant that there was limited opportunity for interaction among familiar birds. These results suggest that familiarity within founder groups is unlikely to have strong effects following translocation.

While ecological and conservation consequences of combining animals of varied genetic backgrounds have been widely discussed the demonstration of effects that stem from lineage mixing remains elusive. Since management agencies relocate populations or supplement them with individuals regularly, the opportunity for either inbreeding or outbreeding depression may be high; still, any putative effects will go unnoticed without detailed knowledge of life-history and behaviour. Here, we report potential consequences of lineage mixing in a restored population of North American *Bos bison* studied for five years. In 1984 two allopatric lineages became sympatric in Badlands National Park, South Dakota, they differed in both founding population size and the number of demographic bottlenecks experienced since 1907. Measures of reproductive variance in both sexes were employed to estimate effective population size based on 261 copulations and the survivorship of calves between 1985 and 1989. We assumed that the reproductive variance and mortality documented in this study are representative of the bison's recent past and based on this assumption we calculated N_e separately for each generation for which the lineages were allopatric. Four potential correlates of fitness were studied in the new sympatric population: (1) female fecundity; (2) juvenile survival; (3) growth rates, and (4) female age at puberty. Of these, neither female fecundity nor juvenile survival was associated with lineage but growth rates were more rapid and ages at puberty were lower for F-1 purebred (inbred) juveniles than for F-1 hybrid (outbred) juveniles. Possible consequences of this variation in the F-1 generation include (1) higher winter mortality in the slower growing line as well as (2) decreased lifetime production of young; both are life-history parameters that could be interpreted as long-term selection against outbreeding. However, these data by themselves do not constitute support for an outbreeding depression hypothesis. The failure of males from one lineage to mate at all prevented the possible combinations of the F-1 generation needed for the appropriate statistical contrasts. Nevertheless, these interpretations (1) substantiate a level of variation in life-history parameters stemming from lineage mixing; and (2) suggest that advice regarding prudent conservation strategies must be sought concerning the genetic histories of individuals and populations to be selected for re-introduction. This applies to both wild and captive populations. The prevalence of outbreeding and inbreeding tolerances within populations of managed and protected species needs verifiable documentation.

Conservation efforts for imperiled fishes in western United States have included numerous translocations, either among natural localities or from nature to propagation facilities then back into nature. The goal has been to increase population size and dispersion while maintaining genetic diversity, thus increasing probability of survival. Environmental laws governing translocations of fishes for conservation purposes involve complexities often equally as difficult to cope with as the biological problems of species' endangerment. Translocations perceived not to impinge on resource use or proprietary rights may be readily approved, while those which interfere with actual or projected development may meet strong resistance. Major biological considerations include the suitability and security of transplant sites (assurances that each meets a taxon's life-history and other requirements) and appropriateness of transplanted individuals (genetic and population structure, sufficient numbers of individuals, freedom from disease, etc.) for establishing new populations. Success of translocation is difficult to define and major inadequacies exist in information exchange - the latter can be remedied by publication in the peer-reviewed literature. It is anticipated that fish translocations and the technology required to support them will expand along with future needs and desires to re-establish native biotic elements in depleted communities and ecosystems.

331: **-.009**

Captive breeding and the release of captive-bred individuals into the wild are among the techniques used for the conservation of rare and endangered fish species. After a brief description of the methods of captive breeding and the establishment of breeding stocks, this paper provides examples of the application of these techniques to endemic fish species of arid regions in southwestern USA and examines some current cases and the future possibilities for their use in the Mediterranean region. Special attention is given to the analysis of the strict constraints imposed on fish breeding for conservation purposes, in which the aim is to produce fish with all the morphological, behavioural and genetic characteristics of the taxa to be conserved, and which are capable of effectively adapting to the natural environment when introduced. In terms of genetic management of captive populations, the fundamental problems which are faced involve the categorization of the species-resources to be conserved (identification of cases of inter- and intra-specific introgression), the establishment of founder stocks that contain the maximum genetic diversity depending on the genetic structure of the species (strong intra- or interpopulation variability), and the retention of genetic variability during captive breeding (the need to reduce to the minimum the phenomena of genetic drift, inbreeding and unintentional selection of non-adapted genotypes). Because of these difficulties and risks in terms of genetic conservation, captive breeding should remain a temporary safeguard measure, while awaiting the implementation of measures for protecting species in their restored original habitat or translocation to strictly protected substitute habitats. With this aim in view and in conclusion, the paper suggests methods for organizing a critical plan to safeguard the most endangered species or subspecies in the Mediterranean region by captive breeding.

332: **-.055**

There are 35 species and subspecies of fish and two lamprey species in the Adriatic catchment of Slovenia. Five have been introduced and five transplanted. None of the regionally endemic fishes nor the lampreys live exclusively in Slovenia. Of these, *Salmo marmoratus*, and *Lethenteron zanandreae* are threatened while *Chondrosoma genei* became extinct after the introduction of *Chondrostoma nasus nasus* into the area around 1960.

333: **-.010**

In Italy, as in several other circum-Mediterranean countries, there is a unique assemblage of endemic freshwater fishes. Speciation processes, especially of endemic primary or near-primary freshwater fish, most probably occurred during the Lago Mare era of the Mediterranean (about 5 million years BP). However, the present-day distribution patterns are surely the result of events that occurred more recently, from the Pleistocene until historical times. However, natural events are now being superseded by anthropogenic interference with fish faunas. Among the various negative human factors the most harmful is the introduction of non-native species, which in Italy are responsible for the present catastrophic situation. Of the 71 species currently with natural self-sustaining populations in Italian waters, only 45 are natives. Of the latter, only 16 (or fewer) have not been subjected to deliberate human transfers. In Italy there are about 28 endemic Mediterranean taxa, but most have either been deliberately or accidentally introduced to areas outside their natural range. The result of this persistent practice on a little known and unique fish fauna is zoogeographic pollution, massive cases of hybridization and loss of genetic identity by local native populations. The problem of freshwater fish conservation is not a matter of public concern in Italy. Sport fishing has a political and economic value and introductions are legally carried out and 'welcomed' by most fishermen; most biologists and conservationists are either unaware or

unconcerned.

334: +.081

Habitats used by most species are becoming increasingly fragmented requiring a metapopulation modelling approach to population viability analysis (PVA). Recognising habitat patchiness from an endangered species' point of view requires utilisation of spatial information on habitat suitability. Both of these requirements may be met by linking metapopulation modelling with landscape data using GIS technology. We present a PVA model that links spatial data directly to a metapopulation model for extinction risk assessment, viability analysis, reserve design and wildlife management. The use of the model is demonstrated by an application to the spatial dynamics of the helmeted honeyeater *Lichenostomus melanops cassidix*, an endangered bird species endemic to Victoria, Australia. We use spatial data, organised by a GIS, on the habitat requirements of the helmeted honeyeater to define the patch structure. We then combine this patch structure with demographic data to build a metapopulation model, and use the model to analyse the effectiveness of translocations as a conservation strategy for the helmeted honeyeater.

336: -.016

On mainland Australia the eastern barred bandicoot, *Perameles gunnii*, is confined to a relic wild population numbering less than 100 individuals in the city of Hamilton. Animals derived from this population are being bred in captivity in order to promote their recovery. The species also exists in Tasmania, where little is known of its conservation and taxonomic status. Mitochondrial DNA variability was compared within and between populations of *p. gunnii* using restriction fragment length polymorphisms. Genetic variability was found to be high among *P. gunnii* in Hamilton compared to those in Tasmania (higher diversity index, nucleotide sequence divergence and greater number of haplotypes), despite the known decline and subdivision of the Hamilton population. Restriction fragment length polymorphisms distinguished animals from the east and the west of Hamilton and from the north and south of Tasmania. Nucleotide sequence divergence was substantial (2.2-2.5%) between Hamilton and Tasmania. Implications are that captive breeding and reintroduction should be designed to genetically represent the structure within Hamilton in order to minimize inbreeding and that the introduction of Tasmanian *P. gunnii* would not benefit the Hamilton population. It is concluded that mitochondrial DNA markers clearly can provide useful information about the history and current status of endangered marsupial populations, to the benefit of conservation management.

337: +.008

On tropical Pacific islands, a human-caused "biodiversity crisis" began thousands of years ago and has nearly run its course. Bones identified from archaeological sites show that most species of land birds and populations of seabirds on those islands were exterminated by prehistoric human activities. The loss of birdlife in the tropical Pacific may exceed 2000 species (a majority of which were species of flightless rails) and thus represents a 20 percent worldwide reduction in the number of species of birds. The current global extinction crisis therefore has historic precedent.

338: +.109

At least 21 species of exotic arthropods have successfully established breeding populations in the Kruger National Park, South Africa. Of these, seven species were intentionally introduced as biological control agents of alien weeds, four species inadvertently accompanied vertebrate hosts

during game translocation, and the remainder are presumed to have gained entry through packing crates, human activities, or natural dispersal in some instances. The modes of entry of exotic species are discussed and, where known, the time of first appearance in the Kruger National Park recorded. The rapidly escalating practice of wildlife translocation within and between countries is discussed in relation to passive transfer of diseases and parasites, and reasons are listed why routine precautionary steps should be instituted to avoid transfer of non-target organisms during translocation operations.

339: +.010

Seasonal distribution, relative abundance, biomass production, population consumption, and energy storage in bay anchovy *Anchoa mitchilli* were estimated from midwater trawl surveys in the upper and mid Chesapeake Bay from April 1990 to October 1991. Abundance and biomass both peaked in late summer and fall before declining significantly in winter, a result of southward migration to lower Bay areas that were not sampled. Production also peaked between summer and fall, a consequence of rapid growth and recruitment of larval and juvenile anchovies. Annual production of young-of-the-year (YOY) anchovy was 856.69 g 100 m⁻³, 87.9% of which was produced in the first 3 mo of life. Production by YOY anchovy accounted for nearly all annual production (92.6%) in this short-lived species. Total annual production was estimated to be 233014 t wet wt in upper to mid-Bay regions. The production/biomass (P/(\$ over bar B) ratio for YOY anchovy was 8.07 when larval and early juvenile stages were included but only 0.97 without those stages. The estimated translocation of nitrogen biomass from the upper and mid Bay to the lower Bay via anchovy migration was 1027 t N during fall 1990, which is approximately 0.8% of the annual N input to Chesapeake Bay. Estimated population consumption (primarily zooplankton) by bay anchovy ranged from 5.29 to 12.81 g dry wt 100 m⁻³ d⁻¹ in August and from 5.35 to 6.78 g dry wt 100 m⁻³ d⁻¹ in October, suggesting that consumption by larvae and juveniles of this species could significantly impact populations of its plankton prey.

340: -.095

Population densities of terrestrial animals tend to be higher and less variable near the center versus along the periphery of a species' geographic range. If extinctions are tied to local population dynamics, geographic ranges of endangered species should collapse inward, with remnant populations persisting near the center of a species' historic range. Geographic-Information-System analysis of range collapse in nonvolant, terrestrial mammals reveals, however, that extant populations of 23 of 31 species were located along the periphery, not the center, of their historic range. In addition, range collapse appears to be independent of fragment area and has a directional bias from east to west. Persistence of endangered populations also appears to be greater on islands than on continents. These results contradict conventional wisdom in biogeography and macroecology and have important implications for conserving biodiversity. Because of their relative isolation from central populations and from a suite of anthropogenic disturbances, islands and other sites along the periphery of a species' historic range represent critical refugia for many endangered species.

341: +.074

Present knowledge about chromosomes and nuclear DNA of Crustacea is reviewed. Haploid chromosome numbers range from 3 (*Acanthocyclops*) to 188 (*Astacus*). Chromosomes are generally small to medium in size (1-5 μ m) and punctiform or rod-shape. Nuclear DNA amounts show a large range, lying between 0.37 (*Daphnia*) and 22.6 pg (*Decapoda*) per haploid

genome, 5.5×10^8 nt to 1.8×10^{10} nt. Highly repetitive sequences may represent as much as 30% of the genome and show a high degree of conservation in Brachyura, while some intermediate repetitive sequences are under-represented. The relationship between taxonomy and cytogenetics appears very complex in some taxa, such as *Artemia* (Branchiopoda). This genus includes bisexual sibling species with female heterogamety and parthenogenetic populations with different levels of ploidy, up to triploid and pentaploid. *Daphnia* presents diploid and polyploid strains, and parthenogenetic reproduction. Chromatin diminution occurs in Copepoda; in this group male and female heterogamety coexist with a ZO-ZZ type, unique among animals. Evolution in Copepoda tends to the reduction of chromosome number. Some parthenogenetic, freshwater Ostracoda have supernumerary chromosomes; Ostracoda also present complex sex chromosomes mechanisms (XO and XY, with cases of multiple X's and multiple Y's). Within Rhizocephala, chromosome numbers can be used to distinguish species of parasitic Crustacea, such as *Sacculina*. Robertsonian translocations are known in some Isopoda. *Jaera albifrons* presents a dine, diminishing from north ($n=13$) to south ($n=9$) along N-E European coasts. As in Copepoda, female and male heterogamety are present. Cytogenetics of Amphipoda is not well known, and many species have the same number; as much as 9 supernumerary (B) chromosomes have been reported. One of the highest numbers of chromosomes known for animals occurs in crayfish *Astacus* ($2n=376$). DNA amount in shrimps has the highest range in Crustacea (3-22 pg/c) and one of the highest for animals. Within several Decapoda groups, viz. lobsters, crayfish, scyllarids and hermit crabs, polyploidy may have acted as an evolutionary factor. Chromosome evolution within Decapoda is difficult to understand because the chromosomes are numerous, very small and punctiform; differentiated sex chromosomes have sometimes been reported, the male being the heterogametic sex. Somatic endopolyploidy is present in many groups mainly in the digestive tract; polyploidy in germ cells might have occurred in different groups during evolution.

342: +.229

Reintroduction is the release of animals into an area where they were extirpated or have significantly declined. Little is known about the factors that determine the success or failure of ungulate reintroduction. We studied the dynamics of a reintroduced Asiatic wild ass (*Equus hemionus*) population for 10 yr (1983-1993) following the first successful release into the wild. A total of 14 adult females and 14 adult males were released into a nature reserve in the Negev Desert of southern Israel. Over this 10-yr span the female population has grown to only 16 adults. Reproductive success of reintroduced females was low in the first 5 yr following release (0.0-0.8 foals . female(-1). yr(-1)), but increased to 0.5-1.0 foals . female(-1). yr(-1) in the last 5 yr. Reproductive success of wild-born females greater than or equal to 3 yr old was higher than that of reintroduced females of similar ages, and ranged from 0.5-1.0 foals . female .(-1)yr(-1). Our study and data from the *E. hemionus* studbook suggest that young nonprimiparous females produced primarily males, while primiparous and old females produced primarily females. We attribute the low reproductive success following reintroduction to the stress caused by capture, transport, and release procedures; we consider the age-dependent progeny sex ratio within the framework of Trivers and Willard's (1973) maternal allocation hypothesis. We conclude that the slow growth of the female population was due to: (a) low reproductive success of females in the early years following reintroduction, and (b) a male-skewed progeny sex ratio among prime-aged reintroduced females. A simple stochastic Leslie matrix model suggests that high survival and improved reproductive success of reintroduced females at later stages of the study, and the reproductive success of wild-born females, make the population relatively unsusceptible to extinction from random demographic processes. In-depth knowledge of the dynamics of reintroduced populations is vital for the correct assessment of their viability. We offer suggestions

for increasing the efficacy of future wild ass reintroductions.

343: +.101

Robertsonian polymorphism has been analysed in samples of successive ages of Atlantic salmon (*Salmo salar* L.) and brown trout (*Salmo trutta* L.). Polymorphism changed significantly with ageing, the standard $2n$ class increasing for each species ($2n = 58$ for Atlantic salmon and $2n = 80$ for brown trout), No significant within-population changes were found among same-aged samples from different generations. The results support the notion that selection favours a standard karyotype. On the other hand, permanence of polymorphic patterns within age groups in successive generations also was demonstrated.

344: +.127

Seven individuals of captive *Gazella bennetti* were found to have chromosomal complements of $2n=49-52$, and seven captive *G. saudiya* had complements of $2n=46-53$. G-banded karyotypes revealed that variation in diploid number was the result of an autosome-to-X chromosome translocation and four independent Robertsonian translocations. There were no fixed chromosomal differences between *G. bennetti* and *G. saudiya*, but two pericentric inversions distinguished Pakistani *G. bennetti* from Iranian *G. bennetti* and *G. sandiyya*. Several pairs of metacentric chromosomes of both species were monobrachially homologous with metacentrics of *G. dorcas* and *G. gazella*, indicating *G. bennetti* and *G. saudiya* are reproductively isolated from *G. dorcas* and *G. gazella*. As with other species of gazelles, chromosomal studies of natural populations are needed for these species.

345: -.158

Crop damage and livestock predation were a serious problem in three Village Development Committees (VDCs) situated adjacent to the Southwestern Part of the Royal Bardia National Park. The seriousness of crop and livestock losses varied considerably with the distance from the Park's border and the specific location of farms. This was explained by the variations in the distribution of animal wildlife inside the Park, the presence of natural and Man-made barriers, the availability of forested areas outside the Park, and the agricultural cropping pattern. Adjacent to the section of the Park with the highest animal densities, crop losses varied from 47% for Lentil to 24% for Wheat. Farther away, the extent of crop losses was reduced. In the 'Far' zone situated 2-8 km from the Park, only 3% of the Paddy was reported lost. Two wildlife species, Chital and Wild Boar, were responsible for roughly half of the total damage to crops by animals. Damage from a newly-introduced population of *Rhinoceros unicornis* was increasing, with Paddy (Rice) and Lentil the crops most affected by that species. The economic value of livestock loss to wild predators was estimated to be two percent of the value of total crop losses. The estimated value of grasses harvested by local villagers inside the Park, seen as 'compensation' for crop losses and denial of access to traditional resources, constituted only 10% of the total economic loss from crop losses and livestock predation. Due to rapid increase in the population of wild ungulates since the establishment of the National Park, and to the lack of functioning protective measures, the farmers' problems were increasing. The reintroduction of Rhinos, translocated from Royal Chitwan National Park, has further increased the problem. Local villagers so far have a positive attitude towards the Park, but this positive attitude may erode soon unless serious action is taken to reduce the problems of crop damage and livestock predation in the area.

346: -.021

Reintroduction to the wild of threatened species has become a modern additional justification for captive propagation. This conservation procedure is costly, and both economic resources and the absence of optimal conditions in the field limit the IUCN recommendations for reintroduction to a small proportion of potential candidate species. Furthermore reintroduction attempts often fail. In carnivores, reintroduction failure is attributed to unsuitable adaptation in the field by captive-reared animals, due to their lack of hunting skills, their tendency to leave the target area, their inadequate interaction with conspecifics or their excessive confidence in humans. This list of causes is based on very few studies of carnivore adaptation after reintroduction. In very rare and endangered species, monitoring individual case-histories is the only way to evaluate reintroduction success. We report a successful experimental release of an Iberian lynx (*Lynx pardinus*) which grew up in captivity. Careful feeding-training and avoidance of human contact during the captive phase, as well as good habitat quality and correct interaction with other wild lynx in the release site, seem to account for the observed success. Permanence of the lynx within the release area might be related to the availability of territory vacancies in the receiving population. Our results allow some optimism for future reintroductions of this endangered species in areas where it has become extinct recently.

348: -.006

Zoological parks are playing an increasingly important role in the management of threatened species through education, the maintenance of captive gene banks and the reintroduction of captive-bred animals into the wild. This paper discusses the suitability of amphibian species for reintroduction. The important features of amphibians for these programmes are highlighted, i.e., their high fecundity to allow rapid build-up of captive populations coupled with few behavioural problems with captive-bred animals, as well as the low cost of maintenance. The potential problems of inbreeding, poor retention of innate behavioural repertoires after multiple generation captive breeding, and the introduction of alien pathogens into wild populations are considered. Release programmes for two species, the Mallorcan midwife toad *Alytes muletensis* and the Puerto Rican crested toad *Peltophryne lemur*, are reviewed.

349: +.317

Growing deterministic and stochastic threats to many wild populations of large vertebrates have focused attention on the conservation significance of captive breeding and subsequent reintroduction. However, work on both gorillas and black rhinos questions this shift in emphasis. In these species, field-based conservation can be effective if properly supported and, although this is not cheap, per capita costs may still be considerably lower than for ex situ propagation in captivity. Here we attempt to broaden the scope of this debate by contrasting the breeding success and costs of in situ and captive programmes for a range of threatened mammals. Data are scarce, but we find that across nine large-bodied genera, in situ conservation achieves comparable rates of population growth to those seen in established captive breeding programmes. Moreover, comparing budgets of well-protected reserves with toes' own estimates of maintenance costs and the costs of zoo adoption schemes, we find that per capita costs for effective in situ conservation are consistently lower than those of maintenance in captivity. Captive breeding may be more cost-effective for smaller-bodied tars and will often remain desirable for large mammals restricted to one or two vulnerable wild populations. However, our results, coupled with the fact that effective in situ conservation protects intact ecosystems rather than single species, lead us to suggest that toes might maximize their contribution to large mammal conservation by investing where possible in well-managed field-based initiatives, rather than establishing additional ex situ breeding programmes.

350: +.093

The relocation of unionacean mussels is commonly used as a conservation and management tool in large rivers and streams. Relocation has been used to recolonize areas where mussel populations have been eliminated by prior pollution events, to remove mussels from construction zones and to re-establish populations of endangered species. More recently, relocation has been used to protect native freshwater mussels from colonization by the exotic zebra mussel *Dreissena polymorpha*. We conducted a literature review of mussel relocations and evaluated their relative success as a conservation and management strategy. We found that 43% of all relocations were conducted because of construction projects that were forced to comply with the Endangered Species Act 1973 and that only 16% were monitored for five or more consecutive years. Most (43%) relocation projects were conducted from July to September, presumably a period when reproductive stress is relatively low for most species and the metabolic rate is sufficient for reburrowing in the substrate. The mortality of relocated mussels was unreported in 27% of projects; reported mortality varied widely among projects and species and was difficult to assess. The mean mortality of relocated mussels was 49% based on an average recovery rate of 43%. There is little guidance on the methods for relocation or for monitoring the subsequent long-term status of relocated mussels. Based on this evaluation, research is needed to develop criteria for selecting a suitable relocation site and to establish appropriate methods and guidelines for conducting relocation projects.

351: +.096

We assessed the genetic structure of two subspecies of endangered Clapper Rails (*Rallus longirostris*) in Southern California using DNA fingerprinting to uncover variation in minisatellite DNA. Minisatellite DNA variation in the Salton Sen population of the *R. l. yumanensis* subspecies was at a level typical of outbred avian species (average proportion of fragments shared, or S , was 0.33). Variation was extremely low (S from 0.63 to 0.77), however, within four coastal, salt-marsh populations of the subspecies *R. l. levipes* located along a transect extending about 260 km northwest from the Mexican border. Between-population similarity (S_{ij}) was also high for the four *levipes* populations, although individuals of the small, isolated population at Mugu Lagoon consistently clustered separately in phenograms constructed using neighbor-joining or other algorithms. Individuals of *yumanensis* always clustered as a sister group to all *levipes* individuals. The minisatellite data were contrasted with the extremely low mtDNA and RAPD variation we found in both subspecies. We propose that variation in these less-mutable markers was lost in a bottleneck that occurred at least 1000 years ago, thus allowing sufficient time for recovery of variation in the rapidly mutating (μ similar to 0.001/gamete/generation) minisatellites ($t = 1/\mu$, or 1000 generations). A second more-recent bottleneck or series of bottlenecks within a metapopulation structure, likely resulted in the depauperate variation seen in *levipes* today. We suggest that translocations from large to small *levipes* populations could restore important genetic variation to the small populations and would not compromise genetic boundaries.

352: -.138

The process of ecological risk assessment should involve the ability to predict adverse outcomes of particular environmental contaminants or human intrusions. Ecological risk assessment generally focuses on populations, communities, and ecosystems, rather than on individual health. We explore the importance of life history strategies of aquatic turtles to their risk from environmental contaminants and other human activities using three examples: the wood turtle *Clemmys insculpta*, a freshwater species; the diamondback terrapin *Malaclemys terrapin*, a littoral species; and marine turtles as a group. These turtles are partly herbivorous and are at low or

intermediate levels on the food chain, yet are particularly vulnerable due to their life history strategies of being long-lived with relatively low survival of young. They suffer a variety of natural mortality factors that include predation, starvation, and disease, as well as inundation and destruction of nesting beaches and their eggs by storms. Yet they also face a number of anthropogenic hazards, including toxic chemicals and floatables (plastics); capture for food, other products, and pets; incidental mortality in fishing gear; disturbance while nesting or moving on land; injuries or death by collision with boats; and increased predator exposure because of humans. The three turtle species (or groups of species) examined have experienced these natural and anthropogenic pressures differentially, with resultant differences in the rates of population declines. Because they are lower on the food chain than other obligate carnivores, they are less vulnerable to toxics, and to date, toxics seem a relatively inconsequential environmental risk to turtles.

353: +.179

A small number of ancient lakes (mostly >10(6) y old) scattered around the globe contain an extraordinary percentage of the world's documented freshwater biodiversity. Endemic benthic invertebrates and fish in most of these lakes today face a variety of anthropogenic threats, including damaging fishing activities, water pollution, species introductions and translocations, climate change, and watershed disturbances. Lake Tanganyika, one of the oldest and most diverse of the ancient lakes, provides a model for studying the effects on endemic faunal diversity from watershed disturbances caused by deforestation. Increased erosion rates around the northern portion of the lake are associated with substantially lower diversity levels for both benthic invertebrates and fish. Disturbance processes in the biologically complex littoral region of this lake that are related to this excess siltation include reductions in light penetration (affecting algal habitat and herbivory), reductions in habitat heterogeneity and reduced connectivity between benthic habitat patches. Paleoecological data for readily fossilized taxa may be used in Lake Tanganyika to determine background levels and variability in diversity and the historical relationship between human activities in the watershed and changes in benthic community structure. Biogeographic and paleoecologic studies of endemic ostracodes demonstrate that many taxa have extremely patchy distributions which are consistent with metapopulation models of organization. The extremely high diversities encountered in Lake Tanganyika and other ancient lakes may be dependent on nonequilibrium interactions between patchily distributed species, which undergo periodic but uncorrelated extinctions and recolonizations of appropriate habitat patches. Conversely, excess sedimentation along rocky coastlines may reduce habitat patch interconnections and lead to local extinctions, even in areas that are not directly affected by damaging siltation. Paleoecological data may be used by aquatic conservation biologists to determine the history of this and similar problems and, more generally, to obtain a dynamic view of diversity change in lakes through time.

354: +.106

Red-cockaded Woodpecker (*Picoides borealis*) population trends and current management on four national forests in eastern Texas were evaluated from 1983 through 1993. Following years of decline, populations stabilized and began to increase after intensive management efforts were initiated. Management activities included control of hardwood midstory and understory thinning pines within woodpecker cavity-tree cluster areas, use of cavity restrictors and artificial cavities, translocation of first-year woodpeckers to replace lost breeders, and reintroductions of male and female first-year woodpeckers to form totally new breeding pairs. Most newly formed woodpecker groups were associated with midstory removal (30) and installation of artificial cavities (22).

Reversal of severe declines on the three small populations in eastern Texas suggests that recovery of other small populations throughout the south is an achievable goal if management is committed to recovery of the species.

355: +.224

This paper presents the results of a long-term study of changing predator densities and cascading effects in a Michigan lake in which the top carnivore, the largemouth bass (*Micropterus salmoides*), was eliminated in 1978 and then reintroduced in 1986. The elimination of the bass was followed by a dramatic increase in the density of planktivorous fish, the disappearance of large zooplankton (e.g., two species of *Daphnia* that had historically dominated the zooplankton community), and the appearance of a suite of small bodied cladoceran (zooplankton) species. The system remained in this state until bass were reintroduced. As the bass population increased, the system showed a steady and predictable return to its previous state; planktivore numbers declined by two orders of magnitude, large-bodied *Daphnia* reappeared and again dominated the zooplankton, and the suite of small-bodied cladocerans disappeared. Within each cladoceran species there was a steady increase in mean adult body size as planktivore numbers declined. Total zooplankton biomass increased approximate to 10-fold following the return of large-bodied *Daphnia*, and water clarity increased significantly with increases in *Daphnia* biomass and total cladoceran biomass. These changes in community structure and trophic-level biomasses demonstrate the strong impact of removing a single, keystone species, and the capacity of the community to return to its previous state after the species is reintroduced.

357: +.177

The lion tamarin was first described in the wild over 475 years ago, and there are records of the species being kept as pets as early as the mid-1750s. With such a long captive history, it is a sad reflection on our knowledge that, as recently as the early 1970s, so little success had been recorded with the maintenance and husbandry of *Leontopithecus* in captivity and the species seemed certain to disappear from zoos as well as from the wild. After a ban on exportation of the species from Brazil, the captive population of *L. rosalia* outside of Brazil decreased from a total of 102 in 1968 to 82 in 1976. Zoos rarely bred a second generation, and with no prospects of further imports from the wild, by 1977, the likelihood of the captive population becoming genetically unviable and going extinct was high. Fortunately, thanks to the development of a professionally coordinated and scientifically managed captive population and the research efforts of many individuals and institutions, both in Brazil and elsewhere, the future of the captive population has been ensured. The international efforts to save the golden lion tamarin through the collaborative work of the GLTCP represents a classic example of what can be achieved when various disciplines working for the conservation of a species cooperate and coordinate their activities in pursuit of a common goal. The majority of authorities now recognize that the future of animals in captivity will increasingly rely on national and international cooperation; much of this will depend on the integrity and goodwill of the people concerned. The development of international strategies to safeguard species survival increasingly relies on field workers, conservationists, educationists, academics and zoo professionals cooperating wholeheartedly. As KLEIMAN et al. (1986) have suggested, such cross-institutional collaborative efforts with *L. rosalia* represent a model for international conservation projects in the future. Since the June, 1990 *Leontopithecus* Population Viability Analysis (PVA) Workshop held in Belo Horizonte, Minas Gerais, Brazil (IUCN/SSC/CBSG 1991), the four International Management Committees for the Lion Tamarin genus have been recognised by Federal Brazilian law as technical advisors to IBAMA on conservation, research, and management of both the captive and wild populations of

Leontopithecus. Nearly 100 per cent of the tamarins that come under the committees' jurisdiction are the property of the Brazilian people through IBAMA; this transfer of title to IBAMA involved a renunciation of ownership of specimens housed at zoos internationally. For *L. rosalia*, ownership was turned over in 1991. We believe that this may be the first case of the international zoo community returning ownership of legally-held animals to the country of origin while continuing to maintain responsibility for their management. With the reintroduction programme for *L. rosalia* having resulted in an increase of protected Atlantic coastal forest, in the State of Rio de Janeiro, by about 38 per cent (2,300 ha). And with our growing understanding of the science of conservation today, the significance of the GLTCP's work with this endangered species (RYLANDS) highlights how well the adoption of 'flagship' species and publication of the plight of remnant populations in depleted environments can promote public attention and associated habitat.

358: +.151

The eastern barred bandicoot, *Perameles gunnii*, is functionally extinct on mainland Australia. Conservation of this unique taxon is dependent on reintroduction, based on a managed captive-breeding programme that provides founder animals. Existing reserves at which reintroduction has occurred are too small to support long-term genetically viable populations. Therefore, reintroductions must be made at a number of sites and the resulting populations managed as a metapopulation. A habitat-suitability model has been developed to assess and compare reintroduction sites. This is the first application of this concept to an Australian species. The model is composed of five variables—size, habitat structure, predation, shape and security—values of which are combined in a simple relationship to produce comparable mathematical statements for proposed reintroduction sites. The model has been applied to existing reserves to test their contribution to the recovery programme.

359: +.135

Introduced populations of birds and mammals may have genetic characteristics differing from those of naturally occurring populations. Such populations are often created by translocation of small numbers of individuals. This leads to founder effects and subsequent genetic drift, often resulting in larger differences in allozyme patterns between introduced populations than between naturally established populations. In many cases, a large proportion of alleles has been lost a few generations after the introduction. Under certain conditions, the mean level of heterozygosity is also severely reduced. Theoretically, a reduction in the number of alleles in a population will result in a lowered potential to track environmental changes, but there is scant evidence for this in introduced wildlife. Likewise, evidence is lacking for inbreeding depression occurring in introduced populations of birds and mammals in the wild. Finally, some conclusions are drawn concerning management strategies for wildlife introductions with respect to genetic considerations.

360: +.008

Molecular techniques show that hybridization can be a major conservation problem. Introgression can lessen genotypic variety and break up gene complexes coadapted to local environments. Gamete wastage can be a problem for hybridizing species even when gene flow does not occur. Birds and mammals introduced for game purposes have hybridized with native populations, a process often facilitated by habitat modification. Further, translocation and stock enhancement programs can lead to loss of well-adapted genotypes. These problems increase as populations become fragmented and isolated, because finding mates is harder and habitat differences that bar

reproduction are obliterated. What to do about hybridization is sometimes not obvious. Even if the problem is seen as important, often little can be done. Culling may be impossible because of difficulties in recognizing introgressed individuals. Wildlife biologists and managers should work to prevent introductions and translocations if hybridization problems cannot be ruled out. Further, wildlife professionals should educate the public about evolutionary aspects of introductions and translocations, including hybridization and introgression.

361: -.030

In the Bialowieza Forest, thermophilous oak forest, *Potentillo albae-Quercetum*, has its northern limit, while generally in Poland the community reaches the northwestern limit of its distribution. For last 30 years, the habitats of oak forest have been invaded by hornbeam; at the same time, European bison has returned to the forest (Kwiatkowska and Wyszomirski 1988). A proximate cause of the decline of *Potentillo albae-Quercetum* is hornbeam invasion (Kwiatkowska and Wyszomirski 1990). An increase in the proportion of hornbeam in the shrub layer of oak forests has also been recorded in other regions of Poland (Jakubowska - Gabara 1993). The Bialowieza Forest is a unique model object allowing the analysis of the causes of hornbeam invasion since (1) the direct and indirect human impact is small as compared to other regions of Poland, (2) the communities of oak forest and adjacent lime-hornbeam forest are natural to a high degree, (3) since the 15th century the area has been used for game hunting while logging has been restricted, (4) there are detailed records of the number of dominant herbivores covering the last two centuries, (5) long-term investigations have been carried here on a permanent plot for 25 years (Kwiatkowska 1994a, 1994b). The main factor disrupting the stability of phytocoenoses in the Bialowieza Forest has been the changes in the number and proportion of the dominant herbivores, European bisons and red deer (Fig. 5). At the end of the 19th century, the dominant herbivore was the bison, the diet of which includes 90% of herbs; the pressure on the perennials was therefore strong. Intense grazing might have created gaps in a dense ground layer while trampling produced hollows in a thick oak-leaf litter. In undisturbed patches of *Potentillo albae-Quercetum*, the microsites with a thick litter (more than 2.5 cm) and a dense ground-layer prevail (Table 1, Figs. 2 and 3). They may constitute more than 75% of all available microsites. The dense ground-layer and thick litter are mechanical barriers which make it difficult for light hornbeam seeds to reach the ground and for their short-rooted seedlings to get to the soil. Such places are, however, safe sites for juvenile oaks (Fig. 4), while the "demand" of hornbeam seedlings is oriented towards the sites with a thin litter and a loose cover of the ground-layer (Figs. 2 and 3). Grazing by bisons enlarged the "supply" of safe sites for hornbeam, and effectively increased the survivorship in the juvenile phase thus increasing the density of seedlings and saplings. This is confirmed by the age structure of hornbeam in the Bialowieza Forest, where 90-120 years old trees predominate at present (Fig. 6). Higher density of juvenile hornbeams on the turn of the 19th century meant more food for deer. The population of red deer grew rapidly and reached 6800 individuals in 1914 (Fig. 5a) changing the direction of the herbivore pressure', grazing by roe deer has never been more than 20% of the total pressure. The diet of red deer includes 66% of woody plants, their high number therefore helped to control the density of juvenile hornbeams and to limit the efficiency of colonization of new safe sites. After the reduction of game by poachers at the end of World War I, the density of juvenile hornbeams increased again, bringing about a consecutive growth in the number of red deer. Between the two World Wars, the red deer is the dominant herbivore and the pressure on woody plants is twice as much as that on perennials (Fig. 5b). Successive drop in the number of game following World War II, subsequent control of the deer population by man and a lower pressure on woody plants, and the reintroduction of the European bison contributed to the successful recruitment of the previously grazed juvenile hornbeams to the shrub-layer and to the creation of new safe sites for the seedlings. Between the years 1960 and 1990, due to a low and

similar pressure of the herbivores on perennials and woody plants, grazing did not control the density of hornbeam juveniles but continued to supply new safe sites for the species. Immediate recruitment of the previously grazed juveniles to the shrub-layer additionally contributes to the decline of the oak forest communities. The saplings shade the surrounding ground causing a withdrawal of the heliophilous perennials and a drop in the density of the ground-layer. Autumn mass fall of hornbeam leaves accelerates the decomposition of the litter, which effectively becomes thinner. In the patches of oak forest with high proportion of hornbeam in the shrub-layer (which is a phase of the decline of *Potentillo albae-Quercetum*), the litter is much thinner while the density of the ground-layer is lower (Table I, Figs. 2, 3, and 4). Eventually, the "supply" of safe sites is higher and higher and the process of hornbeam invasion progresses due to a positive feedback. The models explaining the effects of the differential pressure of herbivores on the oak forest communities have been proposed (Figs. 7 and 8). However, the mechanism initiating the invasion of hornbeam does not have to be set in motion exclusively by the action of animals. Every direct and indirect human activity leading to the creation of gaps in the ground-layer and the destruction of the litter of oak forests, such as raking of mulch, intense grazing by cattle, logging and the accompanying damage, may provoke similar effects as in the model in the Fig. 8.

363: +.206

This report is published under the auspices of the Cat Specialist Group of the International Union for Conservation of Nature and Natural Resources/Species Survival Commission. The report contains a review and analysis of the conservation status of the wild cats and a comprehensive strategic plan for increasing the effectiveness of conservation methods. The work is divided into 3 parts, an introductory section and 7 appendices. The introductory section consists of an executive summary plus 3 chapters covering the taxonomy of Felidae. Part I contains species accounts of the wild cats from sub-Saharan Africa, North Africa and Southwest Asia, Tropical Asia, Eurasia, and the Americas. Part II covers the major issues in cat conservation: cats and habitat loss, management of big cats near people, research, trade, cats in captivity, and reintroduction. The third part is an action plan for cat conservation. The 7 appendices are classically described cat subspecies, "Scientific Postmortem: A Protocol for Collection of Data and Specimens", scientific names of species mentioned in the text, species-habitat associations, cat specialist group members, a statement by the International Fur Trade Federation, and a list of maps, figures, and tables. The report is illustrated by color plates of each species, photographs, cladograms, and graphs.

366: +.036

The progress of studies on the minks in Poland resulted in an increased interest in these animals, both among professional zoologists, and hunters and anglers. The spontaneous expansion of the American mink in our country, signalled in various publications, still continues and appears to get out of any rational control. Moreover, our earlier postulates (Ruprecht et al., 1983) regarding the legal status of the American mink in Poland have never been executed in practice. First cases of killing the American mink in the wild in Poland were noted as early as 1954, and still happen at present. They are especially frequent in NE Poland, and no doubt associated with the natural expansion of *M. vison* which was introduced among others in Belarus in 1953-1958. Most of these animals, are however, killed illegally and the cases are prosecuted by law as poaching. It is impossible for the Police to adopt an unambiguous attitude because of the uncertain legal status of the American mink in Poland. Our postulates regarding the mink in Poland are the following: 1. Including the American mink in the list of game species with the whole-year protection period. Here we somewhat depart from our original suggestion which included a shorter protection period (March-September). 2. Maintaining the total protection of the European mink *Mustela lutreola* (L.,

1761) whose present occurrence in Poland cannot be excluded (it occurs in Kaliningrad district adjacent to Olsztyn and Suwalki voivodeships). Systematic research should be aimed at explaining the problem, especially in NE Poland. 3. The whole-year protection of the American mink remain stay in force till an unequivocal explanation becomes available whether or not the native European mink became extinct in Poland. In case of official hunting for American mink (attractive fur animal) a danger may appear of extermination of the last living individuals of the European mink, already on the brink of extinction. The danger will be all the more real, if reintroduction of *M. lutreola* based on young born in zoological gardens is accomplished (Ratajszczak and Smielowski, 1992).

368: +.104

Populations of the Carpathian lynx (*Lynx lynx carpathica* Kratochvil et Stollmann, 1963) became almost extinct in Slovakia, by shooting, 75 years ago. Subsequently, numbers of lynx in Slovakia have increased again and the distribution range extended, owing, to the introduction of legal protection. Protection of the lynx had been discontinued in 1955 and it was introduced again in 1975, as a consequence of the observed decline in numbers. The lynx is now protected from the 1st of March to the 15th of September. This period of protection, however, does not seem to be appropriate, and the period from the 16th of March to the 31st of December is now proposed. The present range of the lynx in Slovakia extends over an area of woodland of 13 700 km² and the total population size is estimated to range between 400 and 500 individuals. In 1955 to 1994, the annual mean harvest rate was 74.83 individuals i.e. one individual per 183 km² of woodland area on average. The total official bag was 2993 lynx during the whole period. Furthermore, certain individuals dispersed from Slovakia to Moravia and even to Hungary and Austria. Successful hunting management of this predator is believed to be feasible at this time. This is backed up by the fact that the bag of lynx increased 5.2 times during the period from the late 1920's to 1991 and, in the same time interval, production of hunted game ungulates increased 13.5 times. Roe deer (*Capreolus capreolus*) appears to be the preferred prey species of lynx and the losses caused by lynx to sheep breeding are low in Slovakia at present. Numbers of lynx now appear to have declined again in Slovakia, the annual harvest having decreased from 105 individuals in 1991 to 44 individuals in 1994. This decline is particularly caused by increasing hunting pressure, stimulated by the attractiveness of the rare and valuable trophy of lynx, and also by the rapid reduction in the food base, resulting from a decrease in numbers of grazing sheep. The main causes of the decrease in numbers of prey species are both poaching and the economic recession in agriculture. In this contribution, more effective protection and hunting management of the lynx is proposed. It is emphasised that were the source of individuals used in re-introduction efforts performed in Slovenia, Germany, France, and the Czech Republic (the Sumava Mts.).

370: -.008

Human persecution may have been the major cause of extirpation of the bearded vulture *Gypaetus barbatus* in the western Alps around 1920-1930. However, as shown in a previous work (Mingozzi & Esteve, 1996), historical information by itself is insufficient to uphold this hypothesis because the real extent of the shooting pressure endured by the species is not ascertainable. The aim of this paper was to test whether the rapid population decline (30-40 years) shown by historical data is consistent with human persecution. By making assumptions about hypothetical population size and natural survival rates, we tried to assess what rate of additional adult mortality caused by human impact would eventually have led to extirpation. The size of our hypothetical population was estimated by comparison between the current population size (number of breeding pairs) of the golden eagle *Aquila chrysaetos* in the Pyrenees and in the western Alps. All the life-history

parameters available in the recent European literature were used as reference data for a Population Vulnerability Analysis (PVA). A series of computer simulations was performed with R.C. Lacy's programme, VORTEX. Three different scenarios were explored: one without hunting persecution and two with different killing rates. The results suggest that the vulnerability of *G. barbatus* was extremely high and even a moderate rate of killing would have led to extirpation within a very few decades, as suggested by the historical data. Moreover, the species vulnerability shown by the simulations has led to cautious conclusions about the success rate of the current reintroduction project of the bearded vulture in the Alps.

371: +.019

The golden lion tamarin *Leontopithecus rosalia* is one of the most endangered primates in the New World. In order to assess the status of golden lion tamarin habitat, satellite images covering the original distribution of the species were analysed and the size of all forests measured. Effective size (N_e) of remaining populations was calculated and the time of isolation estimated for all subpopulations. Current threats were identified in each forest the species was found. Most of the remaining forests within the species' original distribution were in fragments smaller than 10km². The majority of the golden lion tamarins found were in forest fragments which have been isolated for more than 15 years. Today, the principal threats to the survival of the species are the small size and isolation of forest patches, and the small size of subpopulations. Threats such as deforestation and hunting have also been observed in all forests. The small number of remaining animals and their disjunct distribution will likely result in the loss of genetic variability and in inbreeding depression. Conservation strategies, such as translocation of isolated groups, reintroduction of more captive animals, protection of the forests, reforestation, and management of the subpopulations as a metapopulation, will be essential for the maintenance of the species in the wild. The larger and better-preserved forests without tamarins were suggested as potential areas for reintroduction and translocation.

373: +.242

The European beaver eliminated in Western Siberia in the XVIII-XIX centuries has survived only in the upper reaches of the Konda and Northern Sos'va rivers, where it is now under special protection. In the thirtieth-seventieth (the XX century), in the southern part of the region, there was conducted wide reacclimation work (beavers were brought from the European part of the country). The work has not affected the Khanty-Mansiisk Region, where there is also a possibility to restore the area. It is recommended to distribute beavers living in southern parts of the Tyumen' Region to the north. It also appears possible to use aboriginal population (the Konda river), but it should be done with extreme care.

374: +.099

Primula vulgaris is one of the endangered species in Poland. At present Debowka near Lublin is its unique natural locality in Poland. The adopted programme of active protection includes: reproduction in ex situ conditions (The Botanical Garden UMCS), reintroduction of the population in Debowka, and restoration of an extinct locality in Lancuchow (re-introduction of the species).

377: +.117

Fossils and other evidence from the Southern Cook Islands show that the Rimatara Lorikeet *Vini kuhlii*, known as the Kura, was widespread in the group during prehistoric times and, it was

probably extirpated due to exploitation for its red feathers. Today, it survives only on Rimatara in the Austral Islands, where it is known as the 'Ura. On Rimatara during 5-11 August 1992 we saw/heard 263 'Ura, and estimated the total population at 900 birds. The mixed horticultural belt, about 32% of the island, was the most favoured habitat at 2.2 birds ha⁻¹ and it supported about 61% of the total population. The species was uncommon in the coastal coconut plantations and central hills, and rare in the makatea/feo. Rats, especially *Rattus rattus*, have often been associated with the loss of forest birds on oceanic islands and *R. rattus* is thought to be responsible for the decline in other lorikeets of French Polynesia. A preliminary trapping study located *R. norvegicus* and *R. exulans*, but not *R. rattus*. The highest conservation priority should be given to confirming the absence of *R. rattus* on Rimatara and the implementation of a major quarantine programme to ensure that it is not accidentally introduced. We recommend reintroducing the lorikeet to islands within its former natural range.

378: +.160

After European settlement, the range of the Noisy Scrub-bird *Atrichornis clamosus* contracted and only the population at Two Peoples Bay survived. Management policy at Two Peoples Bay Nature Reserve has been one of wildfire prevention, which has created increased areas of suitable habitat for the species. Territories rose from 45 in 1970 to 189 in 1994. Habitat use was assessed by grouping the dominant vegetation associations in each territory in five categories, in descending order of suitability (assessed on breeding and feeding resources): low eucalypt forest, Agonis forest, tall thicket, low thicket and heath. Turnover rates in territory use gave the same habitat rankings. A range of values of N_e (effective population size) was calculated using assumptions about breeding potential of each habitat category. There may be insufficient habitat at Two Peoples Bay for the population to reach an N_e of 500. Successful translocation to Mt Manypeaks, and the establishment of three small populations by birds dispersing from Two Peoples Bay, suggest that an integrated regional population can develop with an N_e well in excess of 500. The management of areas with populations and the corridors linking them must include minimizing the incidence and extent of wildfires.

379: -.011

We monitored survival, reproduction and emigration of a translocated beaver *Castor fiber* population in the Netherlands for five years and used a stochastic model to assess its viability. Between 1988 and 1991, 42 beavers were released in the Biesbosch National Park. The mortality was initially high but gradually fell to normal rates. However, the breeding success was low, and we hypothesized that this was either a temporary phenomenon (the translocation hypothesis) or a permanent feature (the poor habitat hypothesis). According to the computer simulations, the isolated population was viable under the first but not under the second hypothesis. In the latter case, the prospects generally improved by the foundation of another population in the Gelderse Poort (100 km from the Biesbosch), However, this second habitat should be optimal for beavers in order to reduce the extinction probability of the Biesbosch population to below 10% in 100 years, the loss of genetic variability (1-2% per generation) was just above the applied tolerable risk (1%), but the effects of inbreeding are unknown in beavers. We conclude that the beaver population in the Biesbosch is not viable unless the reproductive success increases, either in the Biesbosch itself or in a nearby population. We recommend applying such viability analyses to evaluate the likely success of any translocation.

380: -.013

This paper reports the results of an aerial survey of a marsh deer *Blastocerus dichotomus* population occupying an area to be flooded by the construction of a hydroelectric power plant (Porto Primavera) in the Parana River, Brazil. Forty transects totalling 143 km were flown during the dry and flood seasons. Population size was estimated using the modified Petersen estimator, the line transect method, and two variations of the strip transect method. The results revealed mean densities of 0.50-0.54 deer/km² and a population of approximately 950 individuals, the second largest population reported for this vulnerable species in Brazil. Individuals were most commonly alone, but group sizes of up to five deer were observed. Newborn fawns were observed from September to November. The effectiveness of a rescue operation is discussed relative to the possible benefits for the species' conservation. Deer translocations have a high failure rate. Public pressure to translocate marsh deer is not likely to aid in their conservation but may actually assist to precipitate their decline locally. Instead, acquisition of suitable marsh habitat in which the deer already reside could be much more successful and less costly.

381: +.274

The Mala was once one of the most abundant and widespread macropods of central Australia but has declined to the point where it is now one of the rarest and most limited in distribution; Efforts to recover and conserve the Mala have been considerable and predate the national Endangered Species Protection Act 1992 which provides a framework for preparing and implementing recovery plans for threatened species and communities, The initial recovery plan for the Mala was developed in 1992 and focused on research and management actions related to the central Australian form of Mala. Implementation of this plan commenced in 1992 with ANCA funding to support major actions related to management and translocation of mainland populations, The formation of a recovery team in 1993 was the initial stage in the more formal review of the program. This review examined both progress towards implementing the plan and any need to refine existing actions and define new ones. Several program highlights were identified including establishment of captive colonies, implementation of translocation programs, co-operative programs with Aboriginal landholders and an enhanced understanding of the ecology of the Mala. A revised plan was finalized during 1995 providing a more national focus to the recovery effort, the critically endangered status of the Mala ensures that this effort will be ongoing. The development, implementation and revision of the Mala Recovery Plan has provided a useful insight into the potential achievements and shortcomings of the recovery process for conservation of threatened species.

382: +.302

With the aid of case studies, priorities for achieving practical conservation management outcomes from the genetic studies of rare plants are defined. In *Acronychia littoralis*, genetic analysis did not support the hypothesis that the species was a hybrid. Rather *A. littoralis* was found to be generically very similar to another species, highlighting the need for further taxonomic research. It is now apparent from a genetic study of *Haloragodendron lucasii*, that clonality is extensive with fewer than 10 genetic individuals represented among thousands of stems. Thus the location of new populations is now the highest management priority and is currently being attempted by an integrated conservation initiative. *Zieria prostrata* has been the subject of an ex situ and translocation program. Genetic study has revealed that the initial ex: situ collection may fail to adequately conserve generic diversity and has raised the possibility of mislabelled plants. Consequently, a postponement of the translocation program has been recommended. With respect to achieving practical conservation outcomes in future studies, we rank the genetic study of clonal plants, plants targeted for translocation, and plants of uncertain taxonomic status a high priority,

particularly when conducted within a hypothesis testing framework. In contrast, we rank other areas, including many of those proposed for genetic study in existing recovery plans, a lower priority. Clearly a more critical evaluation and justification of the need for conservation generic research on a case by case basis is essential for more effective recovery plans.

383: -.031

The discovery of the Wollemi Pine *Wollemia nobilis* in 1994 not only brought to light a new genus in the Araucariaceae and a conifer with at least a 91 million year old Gondwanan history, it also increased the threat to the two known wild populations of 40 adults and about 130 seedlings. Although growing in an inaccessible, warm temperate rainforest-lined gorge in a large national park, the impacts of visitation, and indeed researchers, could prove costly to the species. The main threats from people are trampling of seedlings, compaction of the ground and introduction of pathogens. Another threat is wildfire which has the potential to destroy much of the population in one catastrophic event. A range of *in situ* ecological research and *ex situ* botanical and horticultural research is being conducted on the species to aid its conservation. A species recovery plan has also been prepared. In the short term, a key research program aims to discover the most efficient way to propagate and cultivate the species to meet market demand for garden plants. This would remove the pressure of illegal seed collection from the fragile wild populations. Since the Wollemi Pine is a relic species, "recovery" is not the question. Management should aim to maintain the current population and genetic variation. Translocation may arise as an issue in the long run, but there would need to be sound reasons for it to be undertaken.

384: +.053

A species may be considered threatened if it (1) is represented by one or a few stable but small populations, or (2) was formerly widespread or abundant but is now in decline. In the first case, it may not be appropriate to attempt recovery of the species if it has not declined; monitoring and perhaps captive breeding should be the only management needed. In the second case, research is important to identify the processes causing population decline and to ensure that management for recovery is informed and effective. A rigorous scientific methodology is advocated to identify causes of declines and is applied in case studies of the Lord Howe Island Woodhen and a small dasyurid marsupial, the Mulgara. Four steps are involved: (1) establish the magnitude and rate of population decline, and list possible explanations for it (observations); (2) identify the most plausible threatening process or processes that may be causing the decline (model); (3) derive predictions from the models (hypothesis); and (4) test critically, using null hypotheses, whether the putative threatening processes identified in the second step are causing the observed population decline, by using mensurative or manipulative experiments. When one or more processes causing population decline have been identified, management should be initiated to alleviate them and subsequent population changes monitored. It is proposed further that scientific methodology be used to identify effective management techniques, evaluate contentious practices, and guide reintroduction programs. I discuss objections that science is sometimes irrelevant for recovery of threatened species, and propose that strengthened links between research and management would increase the effectiveness of recovery planning.

385: +.174

Species and populations are, and always have been, tied intimately to a geographical place. Much of what humans value in species/populations arises from their natural association with place. Translocation breaks forever the historical natural link between the organism and place. What then

are we really "saving" when we translocate them?

386: +.064

Microplanktonic red tide blooms (dominated by dinoflagellates) were observed in brackish water fish ponds of Terengganu between March 1992 to January 1993. The first short-lived bloom (2-3 days) occurred in October 1992 while the second long-lived bloom (6-7 days) occurred in January 1993. The dominant dinoflagellate species comprised of *Peridinium quinquecorne* (>90% total cell count) with considerable proportion of *Protoperdinium excentricum*. Ciliophora consisting of *Tintinopsis* sp. and *Favella* sp. were also present during the bloom period. The total ash, chlorophyll, phaeopigment, lipid and fatty acid content of the microplankton were studied. Considerable amounts (6-11% of the total fatty acid) of the polyunsaturated fatty acid 18:3w3 (linolenic acid) were present in the microplankton. However, high amounts of 20:5w3 (eicosapentanoic acid) and 22:6w3 (docosahexaenoic acid) were present with variable but usually high amounts of 22:4w6 and 22:5w6 acids. The latter microplankton bloom contained higher amounts of 20:5w3 and 22:6w3 acids than the earlier bloom. Lipid content were three to five times higher than chlorophyll a. There was an increase with successive day after bloom outbreak in the relative proportion of total C18, C20, and C22 fatty acid components. The algae microplankton contained the w3-polyunsaturated fatty acids (PUFAs) probably needed for the growth and survival rate of grazing pond animals.

387: +.241

Of 20 groups of Cape mountain zebras re-introduced into new conservation areas 12 have increased, 6 have remained stable or decreased, and 2 went extinct. One of the main reasons for the poor performance of some of the groups was that insufficient numbers were re-introduced. In those cases where the population increased the mean number originally introduced was 15.1. This is significantly higher ($P < 0.05$) than the number introduced in the cases that failed to increase (8.1). This is in accord with other studies that have shown that the success of re-introductions is closely linked to the numbers of animals re-introduced. The mean percentage annual increase of the populations over the first three to five years after re-introduction (0.4%) was significantly ($P < 0.05$) lower than that over the subsequent 3 to 5 years (9.3%). This probably reflects the effects of capture stress, break up of family groups and adaptation to a new environment. There was no significant relationship between maternal age and progeny sex ratio in Cape mountain zebra. A simulation modelling package, VORTEX was used as an aid to the management of Cape mountain zebra. Rates of population growth and sustainable harvests derived by means of the model were similar to those observed in the real population. The model is useful in analysing the poor performance of small populations re-introduced into new conservation areas, which may help to avoid unrealistic expectations on the part of new owners of mountain zebra herds and to underline the necessity of starting with a reasonable number of animals.

388: -.049

Previous studies demonstrated strong fertility selection for a self-fertile, homostyle morph due to pollinator loss in an isolated population of *Primula sieboldii*, an endangered heterostylous species. To predict genetic consequences of the selection we developed a deterministic genetic model based on a classical "super-gene" model and we studied the effects of pollinator availability and inbreeding depression on temporal changes of morph frequencies through model simulation. Because of the severe pollinator limitation experienced by the population fast, irreversible loss of the thrum morph from the population was predicted even if high inbreeding depression was

assumed To prevent the breakdown of the normal breeding system of the species, morph frequency monitoring for timely active management should be implemented Active management should include hand pollinations and pollinator therapy-reintroduction and reestablishment of suitable pollinator populations The method we adopted in this study to parametrize pollinator availability can be used widely in conservation modeling for a range of plant species that have multiple mating types with different degrees of self-incompatibility.

389: +.015

Transposition of diagnostic tests used in domestic livestock species to free-ranging and captive wildlife species has two problems. First, most existing tests have not been adequately validated in domestic livestock; Second, assumptions that a serological test will perform identically in wildlife and livestock species may not be correct, due to differences in pathogenic strains and serovars, host serological responses, and exposure to organisms of similar antigenic structure which produce cross-reacting;antibodies. Some assays require species-specific reagents/test components which might not be commercially available, and most assays have not been standardized The authors outline the principles involved in the evaluation of a serological diagnostic test, and provide examples of how knowledge of test sensitivity and specificity can be used to estimate true prevalence, to determine whether a population is infected, and to facilitate management decisions with regard to animal translocations.

390: -.065

In the second half of the 20th century, populations of many wild animal species have been established in captivity for various purposes (e. g education, conservation, research, farming) and many are kept as companion animals. With continuing human pressure on the environment, captive or semi-captive management is likely to become a component in the conservation of an increasing range of species throughout Europe and Asia. The management of small and divided populations (some of which may be in toes while some are free-ranging) requires careful control to minimise loss of genetic diversity. This, in turn, may require movements of animals or germplasm between sub-populations. A potentially serious hazard associated with these translocations is the accidental introduction of infectious agents into populations which have hitherto been geographically or ecologically isolated from these agents. When planning translocations, the state veterinary authorities of both importing and exporting countries should be contacted at an early stage for details of legal requirements in relation to animal health, welfare and conservation. Animal health legislation is mostly aimed at preventing disease in man and domestic animals, and further disease control measures may be required when translocating wild animals. In addition to the need for efforts in ensuring genetic diversity and disease control, good husbandry and welfare can often be challenging in species about which relatively little is known. A variety of organisations are involved in coordinating captive breeding programmes in Europe and Asia, and some of these organisations and the routes through which they can be identified are mentioned here.

391: -.166

Species Survival Plans in North America - and comparable programmes in other parts of the world - address the management issues related to maintaining populations of endangered species in captivity. The need has been recognized for universal methods of assessing, evaluating, monitoring and preventing the transmission of disease to naive wildlife by reintroduced species. Standardized protocols are presented for evaluation of the health status of captive animals

intended for release.

392: +.229

The eastern barred bandicoot, *Perameles gunnii*, formerly widespread on the volcanic plains of western Victoria, has been reduced to a single, rapidly-declining, remnant population at Hamilton. Recovery of this critically endangered species has included local management, in an attempt to stabilise the wild population, captive breeding and reintroduction to selected sites. Veterinary advice and assistance have been an integral part of the investigation, planning and implementation phases of the program. The development of appropriate, standardised techniques has enabled successful treatment of problems in the captive colony. Husbandry, including the hand-rearing of pouch young has been refined. Parasitism, identified as a contributor to poor health or death, has been investigated. Experimental development of techniques for the attachment of radio-transmitters to bandicoots has enabled improved field research to take place. Fox predation, a major limiting factor in the recovery program, has been studied in detail, in order to refine control protocols.

393: -.074

The Mexican wolf (*Canis lupus baileyi*), an endangered subspecies of gray wolf, was native to parts of Mexico and the southwestern United States. Currently, only a few individuals, if any, exist in the wild, so planned reintroduction programs must use captive-raised wolves. In only one captive population, however, designated the certified lineage, are all the founders ($n = 4$) known to be obtained from a wild population of Mexican wolves. Two captive populations were founded from individuals of uncertain ancestry and have not been included in the species survival plan. To preserve genetic diversity and reduce inbreeding so that fitness will be maintained, it would be desirable to include these two captive populations in the breeding program if it could be shown that they were derived from a wild population similar to the certified lineage. We compared allele frequencies of 10 hypervariable microsatellite loci in Mexican gray wolves with those found in a sample of 42 domestic dogs, 151 northern gray wolves, and 142 coyotes to determine if uncertified Mexican wolves had specific markers from these animals. We analyzed pairwise genetic distance measures to demonstrate that the three captive populations of Mexican gray wolves were closely related to each other and distinct from dogs and northern gray wolves. The three captive populations are genetically more similar to each other than to any other population of dog or wolf-like canid, and they shared alleles that were rare in other canids. The genetic distance between them is similar to that between closely spaced populations of northern gray wolves. As a group, moreover, they are the most genetically distinct population of North American gray wolf. Therefore, the three captive populations could potentially be interbred to augment the genetic diversity of the certified lineage. Source individuals for reintroduction should be derived from the captive Mexican wolf population rather than populations of captive or wild northern gray wolves.

394: +.176

The use of captive breeding in species recovery has grown enormously in recent years, but without a concurrent growth in appreciation of its limitations. Problems with (1) establishing self-sufficient captive populations, (2) poor success in reintroductions, (3) high costs, (4) domestication, (5) preemption of other recovery techniques, (6) disease outbreaks, and (7) maintaining administrative continuity have all been significant. The technique has often been invoked prematurely and should not normally be employed before a careful field evaluation of costs and benefits of all conservation alternatives has been accomplished and a determination made that captive breeding is essential for

species survival. Merely demonstrating that a species' population is declining or has fallen below what may be a minimum viable size does not constitute enough analysis to justify captive breeding as a recovery measure. Captive breeding should be viewed as a last resort in species recovery and not a prophylactic or long-term solution because of the inexorable genetic and phenotypic changes that occur in captive environments. Captive breeding can play a crucial role in recovery of some species for which effective alternatives are unavailable in the short term. However, it should not displace habitat and ecosystem protection nor should it be invoked in the absence of comprehensive efforts to maintain or restore populations in wild habitats. Zoological institutions with captive breeding programs should operate under carefully defined conditions of disease prevention and genetic/behavioral management. More important, these institutions should help preserve biodiversity through their capacities for public education, professional training, research, and support of in situ conservation efforts.

395: +.245

Whether or not a bird species will establish a new population after invasion of uncolonized habitat depends, from theory, on its life-history attributes and initial population size. Data about initial population sizes are often unobtainable for natural and deliberate avian invasions. In New Zealand, however, contemporary documentation of introduction efforts allowed us to systematically compare unsuccessful and successful invaders without bias. We obtained data for 79 species involved in 496 introduction events and used the present-day status of each species as the dependent variable in fitting multiple logistic regression models. We found that introduction efforts for species that migrated within their endemic ranges were significantly less likely to be successful than those for nonmigratory species with similar introduction efforts. Initial population size, measured as number of releases and as the minimum number of propagules liberated in New Zealand, significantly increased the probability of translocation success. A null model showed that species released more times had a higher probability per release of successful establishment. Among 36 species for which data were available, successful invaders had significantly higher natality/mortality ratios. Successful invaders were also liberated at significantly more sites. Invasion of New Zealand by exotic birds was therefore primarily related to management, an outcome that has implications for conservation biology.

396: +.130

The Karner blue butterfly (*Lycaeides melissa samuelis*) is listed as a federally endangered species in the United States. It occurs in oak savanna and pine barren habitats from eastern Minnesota to New Hampshire. In 1994, we successfully reared Karner blue larvae under controlled laboratory conditions for experimental purposes, and report on those rearing methods here. We collected 20 female Karner blue adults of the spring generation from two areas in Michigan, and housed them in cages in an environmental chamber at 24 degrees-26 degrees C for 5 days. The female butterflies produced 154 eggs, of which 72 hatched in an average of 4.5 days, and 68 first instars survived. Eggs, larvae and pupae were kept in a growth chamber at 24 degrees C. Developmental time from egg to adult averaged 26 days; the average duration of each instar ranged from 3 to 4 days, and the average pupal duration was 8 days. Thirty three laboratory-reared Karner blue larvae successfully completed the 4 instars, and were released as adults into maternal collection sites. Laboratory rearing may be a viable means of providing Karner blue individuals for reintroduction into areas where the species is extirpated, for supplementation of small populations, or for research. Ultimately, such methods may become an integral part in the recovery of this and other rare invertebrate species.

397: +.253

Experiences with the reintroduction of the takhi, or Przewalski horse (*Equus ferus przewalskii*), in Mongolia can serve as valuable lessons for reintroduction of ungulates in general. We discuss the present taxonomic, historical, and biological evidence and conclude that takhi should be viewed as a typical steppe herbivore. Its last refuge, the Dzungarian Gobi, should therefore be seen as a marginal habitat because it consists mainly of desert and semidesert. Since 1992 two reintroduction projects have been in the acclimatization phase in Mongolia. Despite promising developments, problems with cooperation, management, habitat choice, insufficient knowledge of the ethology of the species, and current land use within the different project areas could jeopardize the successful reintroduction of takhi. We review the conditions required for a potentially successful ungulate reintroduction. The planning of a reintroduction within the framework of safeguarding an entire ecosystem with an integrated management plan appears essential. Each potential reintroduction site should be assessed thoroughly for its suitability, including size, habitat types, current land use, socioeconomics, legislation, and potential problems. Each site should be provided with one or more acclimatization facilities to harbor genetically and physically healthy, socially adapted animals in biologically sound groups. An organization structure should be established for each reintroduction site. Its objective should be to develop an effective management plan and to carefully monitor the population and its surrounding ecosystem. Special attention should be given to local socioeconomic situations, community participation, and training of staff for management, research, and ranger and warden activities.

398: -.115

Fire suppression and habitat fragmentation during the twentieth century have generated many long-unburned stands of relatively isolated sand pine scrub. Such stands often lose most of their endemic herbs as woody species come to dominate. A sand pine scrub stand last burned in 1926 or 1927 was prescription burned in February 1986 after a 1985 vegetation census and then was resampled five times over a 7-year recovery period. In spite of a wide variety of recovery strategies to the low-intensity burn, there was little change in the floristic makeup of postburn stands compared to the preburn stand. Detrended correspondence analyses suggested that floristic composition and community structure of postburn stands shifted away from those of the preburn stand. However, this shift did not restore the populations of narrowly endemic scrub herbs. Instead, the change was toward xeric hammock, characterized by the persistence of woody understory species, the unsuccessful restoration of sand pine (*Pinus clausa*) as a canopy dominant, and the near absence of most herbs. These results suggest that long-unburned sand pine scrub will not return to typical scrub through the reintroduction of a single low-intensity, winter burn. This study demonstrates the necessity of monitoring the consequences of the reintroduction of fire to long-unburned vegetation associations and of recognizing variation in vegetative responses to different fire regimes.

The total population of the Seychelles Magpie Robin *Copsychus sechellarum* declined from 38-41 birds in 12-13 territories in 1977-1978 to 17-21 birds in eight to nine territories in 1988-1990 and was entirely confined to Fregate Island (210 ha) in the Seychelles. After a successful cat eradication program in 1981-1982, recruitment improved, although the abandonment of agriculture had caused a reduction in the amount of feeding habitat and hence in the carrying capacity of the island. The population declined because of the failure of recruitment to compensate for the annual adult mortality. Foraging activity of the Magpie Robin was greater in high-quality

territories (measured by soil invertebrates available), leading to increased reproductive success. Through supplementary feeding, five times as many recruits were produced. Of the 11.5 potential annual breeding recruits, 5.3 are required to compensate for adult mortality, and the other 6.2 recruits can be regarded as "surplus" contributing to an increase. Magpie Robins prefer to breed in rotten trees, which are a scarce resource. The greater the distance between the nest site and feeding areas, the less time was spent in incubation and nest guarding, resulting in greater egg loss. Because of lack of suitable areas for establishing territories, many young Magpie Robins became "floaters". Nest disturbance, both by these floaters and by the introduced Indian Mynah *Acridotheres tristis*, had adverse effects on the breeding success of robins. A recovery plan has been designed to save the Magpie Robin. Territories have been improved for feeding (by tree planting) and for breeding (by providing nestboxes and reducing nest disturbances). Given the vulnerability of one small island, the presence of surplus birds (supported mainly by supplementary food) and the suitability of neighbouring Aride Island (68 ha), successful translocations to this island took place in 1992 and 1994. Given the presence now of 47 individuals on two islands, it is hoped that the species will pull back from the brink of extinction.

400: +.046

Several conservation measures are intended to enhance the movement of individuals among populations. These include the establishment of wildlife corridors, captive breeding and release programs, and translocation of individuals among populations. Many metapopulation models show that increasing movement among populations reduces the chance of metapopulation extinction. However, epidemiological models indicate that increased contact among populations enhances the spread of disease and can trigger epidemics. I have synthesized elements of mathematical epidemiology with metapopulation models. An analytic model showed that highly contagious diseases of moderate severity spread widely, increasing the probability of metapopulation extinction. I also used a simulation model to examine four spatial arrangements of populations: island, necklace, loop, and spider. When infected individuals were allowed to move freely among populations, all of the arrangements exhibited qualitative behavior similar to that exhibited by the analytic models. The most dangerous diseases were those for which infected populations grew large enough to produce dispersers that infected other populations, but which also reduced the geometric rate of increase for infected populations to near unity. Under those conditions, random demographic and environmental events caused metapopulation extinction. Major differences among the spatial arrangements emerged when a quarantine population was established. A centralized quarantine in the spider and necklace arrangement yielded the most dramatic reductions in metapopulation extinction probability. A single quarantine patch was of little value in an island arrangement. These results have several implications for managing metapopulations. Most notably, some spatial arrangements of populations are more amenable to disease control than others, and establishing a quarantine population can increase the probability of detecting new diseases and reduce the impact of diseases that do appear.

401: -.000

Apalachicola rosemary *Conradina glabra* Shinnery is an endangered woody mint, endemic to the northwestern portion of Liberty County, Florida, USA. Because the few remaining populations of this species are on private silvicultural lands and subject to disturbance, *C. glabra* was reintroduced within its original range onto The Nature Conservancy's Apalachicola Bluffs and Ratlines Preserve. Forty-eight plots of nine rooted cuttings were planted in each of three sites at the preserve in 1991. All above-ground herbaceous and small woody vegetation was clipped monthly during the growing season around 24 of the plots at each site in 1991 and 1992. Removal

of competition resulted in significantly taller plants with more branches and flowers than in control plots across all sites. By the end of the second growing season, however, treatment effects diminished. Survival of planted cuttings was 94%, but was reduced by the prescribed fire management applied to two of the sites. Roughly 25% of the plants which had 50-100% tissue scorch in the fires resprouted. Seedling establishment was highest in the burned sites, and almost entirely limited to clipped plots. Evaluation of the success of this translocation effort will require long-term monitoring of these *C. glabra* populations and some reduction of fuel around plants prior to prescribed burning. 402: +.284

In 1993 we conducted a follow-up study of the 1987 survey by Griffith et al. (1989) of 421 avian and mammalian translocation programs in North America, Australia, and New Zealand to reassess the programs' status and the biological and methodological factors associated with success. Our survey response rate was 81%. Approximately 38% of usable programs in 1993 reported a change in outcome from 1987 (e.g., a translocated population was "declining" but now is "self-sustaining"), but the difference between the overall success rates was not statistically significant (66% in 1987 and 67% in 1993). Since 1987, an increase was observed in the median number of animals translocated per program (31.5 to 50.5), median duration of releases (2 to 3 years), and proportion of programs releasing more than 30 animals (46% to 68%). Multiple logistic regression analyses indicated that release into the core of the historical range, good-to-excellent habitat quality, native game species, greater numbers of released animals, and an omnivorous diet were positively associated with translocation success. Moreover, our results indicate that translocated birds were less successful at establishing self-sustaining populations than translocated mammals. Our findings using comparable logistic analyses, generally corroborate the results of Griffith et al. (1989). Variables not found to be significantly correlated with translocation success include species' reproductive potential (number of offspring and first age of reproduction), number and duration of the releases, and source of the translocated animals (wild-caught versus captive-reared).

404: +.025

For a number of decades, the lesser white-fronted goose (*Anser erythropus*) has been almost-absent from the Fennoscandian fauna and has a current population size of only about 60 breeding pairs, with fewer than 10 pairs in Sweden. During the period 1981-1991 more than 200 young have been reintroduced in northern Sweden. However, the origin and possible relatedness of lesser white-fronted individuals were unknown when the breeding program started. We have used DNA fingerprinting to assess the similarity of 18 individuals, i.e., the entire captive population used for breeding in 1991 and about 60% of the captive population used in 1981-1991. Minisatellite probe 33.15 provided an index for an average similarity of 0.39 between the mates of the 12 breeding pairs used for producing offspring for reintroduction. This is a higher similarity than in natural populations of birds in general but lower than in populations that have passed through serious population bottlenecks. Individuals originating from different breeders are more dissimilar than those from the same breeder. However, the close relationships (similarity, 0.5-0.6) found in a group of five individuals from different breeders show that selecting individuals from different breeding groups is not sufficient to prevent mating between closely related individuals.

405: +.086

The U.S. Fish and Wildlife Service (USFWS) was directed by Congress to study the feasibility of

including Colorado in the Northern Rocky Mountain Wolf Recovery Plan (U.S. Fish and Wildl. Serv. 1987). A mail survey of Colorado residents was conducted during the summer of 1994 to determine the social acceptability of gray wolf (*Canis lupus*) reintroduction. Results showed strong support for reintroducing wolves into Colorado, as well as generally positive attitudes toward wolves. As expected, attitudes toward wolf reintroduction were predictive of how an individual would vote on this issue. Those with negative attitudes toward wolf reintroduction considered it undesirable based on beliefs it would likely result in wolf attacks on livestock, financial loss to ranchers, wolves wandering into residential areas, and large losses in deer and elk. Those with positive attitudes considered reintroduction desirable based on beliefs it would keep deer and elk populations in balance, preserve the wolf as a wildlife species, return the environment back to the way it once was, help people understand the importance of wilderness, and lead to greater control of rodents. Respondents in densely populated areas east of the continental divide were more supportive and positive toward wolf reintroduction than those in the predominately rural areas west of the continental divide.

406: +.029

From the study of parasitic results, concerning 236 digestive tracts and 262 pulmonary tracts of Chamois (*Rupicapra rupicapra*), we can classify helminths on the basis of their geographic distribution and host specificity. The distribution of the 53 identified species is apparently closely correlated to biogeographic and anthropic factors. The particular role of domestic ruminants in widespread parasites on mountain grazing pastures is pointed out. As parasites are concerned in regulating ecosystems, since transhumance in protected areas and wildlife reintroductions are likely to induce artificial migrations of pathogens, we insist about taking pathology into account, in wildlife and grazing livestock management.

408: -.007

Conservation of the endangered red wolf (*Canis rufus*) has become a controversial issue because its genetic and morphological composition has been altered by hybridization with coyotes (*C. latrans*) and possibly gray wolves (*C. lupus*) making its evolutionary origins difficult to ascertain. The evolutionary hypothesis based on morphological data is that the red wolf had an Early Pleistocene origin and was the predecessor of both modern coyotes and gray wolves. After 1940 red wolves hybridized with coyotes as the species vanished from the wild. In contrast to this ancient origin-recent introgression hypothesis, molecular data are more consistent with an origin through hybridization between gray wolves and coyotes. Interspecific hybridization may have occurred repeatedly over time prior to European settlement in the southcentral United States or may have been induced recently by anthropogenic changes. We review recent molecular evidence and present new results from the analysis of mitochondrial and nuclear DNA markers in pre-1940 populations of red wolves. Our results are inconsistent with an ancient origin of the red wolf and support the hybridization model. We discuss possible hybridization scenarios and reasons for the red wolf reintroduction program to be concerned with the effects of genetic introgression from coyotes.

409: +.042

Ecology is a subject where theoretical predictions are often difficult to test experimentally in the field. To address this challenge, the Ecological Society of America suggested exploiting large-scale environmental management decisions in a scientific way. This 'adaptive management' constitutes one of the purposes of the Sustainable Biosphere Initiative. Meanwhile, in the current

context of the biodiversity crisis, translocations and particularly reintroductions of threatened species are becoming more numerous. It is time for ecologists and wildlife managers to collaborate on these unique opportunities for large-scale studies.

410: +.187

Numerous methods have been proposed for enhancing species viability. Much attention has been given to the minimum required number of individuals, size and number of nature reserves, and value of habitat corridors. Surprisingly, however, the potential value of active management of a population through a program of translocations has only rarely been suggested, and explicit formulations of a theoretical basis for such a program are nonexistent. By drawing on the mathematical optimization technique known as dynamic programming, I develop an optimal dynamic strategy for translocation in a model population. I demonstrate this approach using a simple model for a hypothetical remnant population with two available habitat reserves incorporating demographic, environmental, and catastrophic forms of stochasticity. I then generalize the results by examining the effect on the cost and effectiveness of optimal translocation management of reserve size, population growth rate, environmental stochasticity, catastrophe size and frequency, translocation mortality rate, spatial correlation of population dynamics, and reserve size asymmetry. Simulated application of the optimal strategies, under a wide range of conditions, demonstrates that managed translocations averaging between 1 and 6 individuals/yr might dramatically enhance the probability of species persistence and reduce the required size of nature reserves, potentially by >1 order of magnitude. Given prohibitive financial and political costs of land acquisition for nature reserves, this technique could provide an important alternative for saving many endangered species.

411: +.156

During 1992 and 1993, 14 reintroduced Przewalski Horses or Takhi (*Equus ferus przewalskii*) were studied in the Hustain Nuruu Mountain Steppe reserve in Mongolia. Most of the individuals did not know each other before reintroduction. These Takhi were the first of five groups due to be released in the reserve after an acclimatisation period of at least 1 year. During acclimatisation the Takhi, lived visually and acoustically separately, in fenced enclosures of approximately 45 ha each. The observations, mostly scan-sampling, were carried out in each season. The observation bouts were divided over six periods and over two harem herds. Two of the periods were in the same consecutive seasons, so comparison over the years was possible. Social integration within the Takhi herds was very high from the beginning, as described by the spatial relation and synchronisation data. Between 50 and 89% of the observation time, the behaviour of all herd members was synchronised. The amount of time spent grazing by the Takhi (30-68% of the daylight period) was similar to that of feral horses and Takhi in captivity and semi-reserves. The Takhi tended to rest in the morning and have a bimodal period of grazing at dawn and in the afternoon. The Takhi displayed clear habitat preferences for certain activities. They had a strong preference to rest at the highest point in their enclosure. They fed preferably on two or three different vegetation types (with five types available in each enclosure). The amount of time spent grazing during the non-growing seasons (49 +/- 15%) indicates that the feeding value and availability of food were sufficient. Health changes were detected adequately using condition scoring sheets. No supplementary food or water was supplied during the harsh winters. Moreover, low mortality rates and high reproductive success show that the mountain steppe is a habitat which is potentially suitable for establishing a healthy Takhi population. Takhi is the first species to return to its native habitat after living only in zoos for so many generations.

412: +.188

We assessed the potential for reestablishment of endangered piping plovers (*Charadrius melodus*) at selected Great Lakes beaches by comparing invertebrate biomass and abundance with that at alkali wetland beaches occupied by breeding plovers in the Great Plains. We measured invertebrate occurrence using sticky traps secured to beach foraging substrates. Diptera (especially Chironomidae and Ephydriidae) comprised from 45 to 99% of invertebrate abundance and 24 to 53% of the biomass at six separate sites in the Great Lakes. Coleoptera (< 1-17% abundance; 28-54% biomass) and Hymenoptera (< 1-10% abundance; < 1-9% biomass) also were frequently detected on beaches at the Great Lakes sites. At alkali wetland beaches in North Dakota, Diptera (Ephydriidae and Chironomidae) comprised 95% of the invertebrate fauna numerically and made up more than 80% of the biomass. The mean invertebrate biomass at two Great Lakes beaches (Platte Bay, MI = 0.16 g/m²/hr; Long Island, WI = 0.11 g/m²/hr) was similar ($P > 0.05$) to that at North Dakota alkali beaches (0.09 g/m²/1 hr) occupied by breeding piping plovers. However, at four other Great Lakes beaches, we measured 3 to 6 times less (0.01-0.02 g/m²/hr; $P < 0.01$) invertebrate biomass than at the alkali wetland beaches. Mean invertebrate abundance showed similar patterns among the sites. Food availability may limit the reestablishment of piping plovers at some Great Lakes beaches. We recommend that invertebrate abundance and biomass be measured at currently occupied piping plover nesting areas in the Great Lakes and be assessed at any sites proposed for reintroduction of piping plovers.

413: -.027

Four native fish species exist in the spring-fed, perennial lower 21 km of the Little Colorado River (LCR), Gland Canyon, Arizona, but only speckled dace (*Rhinichthys osculus*) is present in the entire reach. The other three species, humpback chub (*Gila cypha*), bluehead sucker (*Pantosteus discobolus*) and flannelmouth sucker (*Catostomus latipinnis*), are present only in the lower 14.2 km below Chute Falls. During base flow, unfavorable water chemistry (i.e., high CO₂) and the physical obstacle of Chute Falls may limit the distributions of the three large-bodied native fishes to below Chute Falls. We sampled benthic algae and invertebrates and analyzed water chemistry downstream (Reach 1) and upstream (Reach 2) of Chute Falls to determine whether the disparity in fish distributions could be attributed to these factors. Algal biomass (chlorophyll a) and density and biomass of invertebrates used as food by fishes were greater in Reach 2 than Reach 1. Free carbon dioxide (CO₂) and alkalinity generally decreased from Reach 2 to Reach 1, whereas dissolved oxygen, pH and specific conductance generally increased. To determine if water chemistry above Chute Falls was unsuitable to native fishes other than speckled dace, we relocated age-0 (post-larval) and age-1 humpback chub and age-1 bluehead suckers from Reach 1 to three sites in Reach 2 and held them in cases for 3 days. All age-1 fish survived the experiment, although some individuals of both species experienced short-term respiratory stress. Age-0 humpback chub experienced significantly higher mortalities, and exhibited more stress behaviors at the most upstream relocation site than at other sites. We conclude that neither food resources nor water chemistry limit these native fishes to Reach 1. Translocation of fish to the reach above Chute Falls, or breaching that barrier, may be feasible management actions to increase available habitat for the endangered humpback chub and other native fishes in the LCR.

414: +.161

Six south Florida populations of the endangered red-cockaded woodpecker (*Picoides borealis*) were sampled to examine genetic diversity and population structure in the southernmost portion of the species' range relative to 14 previously sampled populations from throughout the species

range. Random amplified polymorphic DNA (RAPD) analyses were used to evaluate the populations ($n = 161$ individuals, 13 primers, one band/primer). Results suggested that south Florida populations have significant among population genetic differentiation ($F_{ST} = 0.17$, $P < 0.000$), although gene flow may be adequate to offset drift ($N-m = 1.26$). Comparison of Florida populations with others sampled indicated differentiation was less in Florida (F_{ST} for all populations = 0.21). Cluster analyses of all 20 populations did not reflect complete geographical predictions, although clustering of distant populations resulted in a significant correlation between genetic distance and geographical distance. Overall, results suggest populations in south Florida, similar to the remainder of the species, have low genetic diversity and high population fragmentation. Exact clustering of distant populations supports the ability of RAPDs to differentiate populations accurately. Our results further support past management recommendations that translocations of birds among geographically proximate populations is preferable to movement of birds between distant populations.

415: *-.013*

1. The recent recovery of the wolf in southern Europe has not yet removed the risk of local extinction. Wolf populations are fragmented and often comprise fewer than 500 individuals. In North America, northern and eastern Europe, wolves feed mainly on wild herbivores. In southern Europe, this canid has apparently adapted to feed also on fruit, rubbish, livestock, small and medium-size mammals. 2. The main conservation problem lies with predation on domestic ungulates, which leads to extensive killing of wolves. The reintroduction of wild large herbivores has been advocated as a means of reducing attacks on livestock, but predation on the latter may remain high if domestic ungulates are locally abundant. 3. Our synthesis of 15 studies, published in the last 15 years, on food habits of the wolf in southern Europe, has shown that ungulates have been the main diet component overall. A significant inverse correlation was found between the occurrence (%) of wild and domestic ungulates in the diet. The presence of relatively few wild ungulate species was necessary to reduce predation on livestock. 4. Selection of wild and domestic ungulate prey was influenced mainly by their local abundance, but also by their accessibility. Feeding dependence on rubbish was local and rare. In Italy, the consumption of rubbish/fruit and that of ungulates was significantly negatively correlated. Diet breadth increased as the presence of large prey in the diet decreased. 5. The simultaneous reintroduction of several wild ungulate species is likely to reduce predation on livestock and may prove to be one of the most effective conservation measures.

416: *+.229*

Samango monkeys inhabit the highly fragmented forests of the midlands of Kwazulu-Natal, South Africa. Not all forest patches are occupied and the survival of monkey populations in the face of further fragmentation provides the motivation for a theoretical consideration of metapopulation persistence under different management policy conditions. The primary aims of the model are to examine the influence of connectivity on metapopulation persistence and also to provide a temporal scale for metapopulation persistence in the case of this species. We develop a stochastic, spatial population model, in which we model edge and core troops in a patch separately, and take into account the effect of demographic and environmental stochasticity, as well as the impact of natural catastrophes. The effects of different levels of connectivity between forest patches are investigated, and we allow for a variable number of patches in the metapopulation. We compare the management options of reintroduction of troops and of providing corridor links between patches in a metapopulation. The model shows that neither management option has any meaningful effect on short-term (<200 years) survival. In the long-term, however, corridors

significantly improve metapopulation persistence. In the absence of interventive management to improve connectivity, samango monkey metapopulations (typically 8 forest patches) show poor persistence probabilities, less than 0.75 to 800 years and less than 0.34 to 1500 years. In contrast these survival probabilities are 0.9 to 800 years and 0.8 to 1500 years when connectivity is provided. The creation of corridors are of the utmost importance for the long term survival of the species.

417: +.082

Techniques for captive-rearing and releasing piping plovers (*Charadrius melodus*) were developed using a surrogate species, killdeer (*Charadrius vociferus*). We compared captive- and parent-reared killdeer, and parent-reared piping plovers and determined that growth and behavior were similar. After surrogate trials determined that captive-rearing was feasible, we used the same methods to raise piping plover chicks from salvaged eggs. For captive-reared chick of both species, survival to fledging was higher than and behaviors similar to parent-reared chicks in the wild. Rearing techniques were fine-tuned, and ten piping plover fledglings were released to the wild. Based on our results, we developed recommendations for captive-rearing piping plovers using salvaged eggs to enhance productivity of small populations. (C) 1997 Wiley-Liss, Inc.

418: +.041

The otter has gone extinct in the Netherlands (1989). Reintroduction of the otter is considered. In this study the feasibility of a reintroduction is assessed using the stochastic computer program VORTEX. Various scenarios have been tested applying feasibility criteria of a minimum of 90% survival over 100 years and a minimum of 90% retained genetic variation over 100 years. Reintroduction in the present situation (scenario 1), in a situation with increase in carrying capacity (scenario 2) or when restocking after an initial release (scenario 3) is not feasible.

419: +.129

Mounds of the western pebble-mound mouse, *Pseudomys chapmani*, are found throughout the species' Pilbara range in areas with iron-ore deposits of economic significance. Translocation techniques are being examined as a means of minimising the impact of mining on this species. In the absence of detailed information on the biology of *P. chapmani*, translocation is inadvisable. To provide such basic information, animal densities, mound demographics and population sizes, and home-range and core-area sizes were obtained by a combination of trapping and radio-tracking. Mounds of *P. chapmani* were found to be inhabited by social groups of up to 12 animals. Estimates of home-range size gave mean (\pm s.e.) values of 14.4 \pm 6.7 ha and 4.6 \pm 2.7 ha for males and females, respectively; core areas were recorded at 0.93 \pm 0.29 ha for males and 0.29 \pm 0.16 ha for females. Considerable overlap of home ranges was recorded between individuals from the same and different mounds. Overlap at the core-area level occurred only between individuals from the same mound. The high level of social complexity and mound fidelity indicates that translocations should be directed at the level of the social group rather than at the level of the individual.

420: +.091

Nesting in trees is an ecological peculiarity of certain Peregrine Falcon populations, a species which primarily nests in cliffs or on the ground. Worldwide there were only three regions where breeding in trees regularly occurred. The largest such population was in Europe, from northern

Germany to western Russia. It became extinct in the mid 1970s, partly as a consequence of excessive pesticide use. A recovery project started in 1990 by the "Arbeitskreis Wanderfalkenschutz" and "Deutscher Falkenorden" resulted in the first pair of Peregrines breeding in a tree nest in northern Brandenburg in 1996. Both adults were colour-ringed and had been released in 1994 as part of a reintroduction program. They bred successfully in an old kite *Milvus spec.* nest in a pine tree. The nest site resembled the classic type used by the extinct population, 580 hours of nest observation enable us to give a detailed account of the activities of the pair and its young. The key points were: adults first seen at breeding site on 1st March, incubation started 18th March, first chick hatched 19th April (incubation period about 33 days); three young hatched; one chick died (probably fell off the nest); the young male left the nest at the age of 42 days (31st May) and first flew at 45 days; the young female also first took flight three days after leaving the nest (7th June); last sighting of a juvenile was on 3rd August; adults returned regularly to nest site from beginning of September. Peculiarities of the breeding record are discussed, e.g. the young age of adults (both two years old), early start to age-laying despite winter weather conditions, special hunting strategy (largely hunting from perches) with high success rate, prey including bats and insects. There were suggestions of potential tree-breeding pairs at four other sites in north-eastern Germany. The situation in 1996 gives cause for optimism regarding the potential for recovery of a tree-nesting population of Peregrines within its former range.

421: +.009

The Yellow Eyebright *Euphrasia scabra* was widespread in northern and eastern Tasmania in the nineteenth century and the first half of the twentieth century. Today, only two populations are known, and both have declining numbers. This annual species tends to occur patchily and returns each year to approximately the same locations, which have a distinct species composition in contrast to the closely cropped herbfield and grassland that is its normal habitat. Recent apparent extinctions and the current decline in the numbers of the species may relate to increasing shrub cover. Reservation, fire management and ex situ cultivation, including reintroductions, may be necessary to maintain the species in Tasmania.

422: +.145

In 1935 the Juan Fernandez Islands in the Pacific Ocean were declared a Chilean National Park to protect the unique flora and fauna, and later given status as a Biosphere Reserve by IUCN. Exotic plants deliberately and inadvertently introduced are threats to the natural vegetation. We review the introduced and/or adventitious flora of the archipelago in this paper. We report 21 recent arrivals, eight earlier introductions from the mid-1700s to the 1900s that have not been recognized before in the flora, six misidentified taxa, and five taxa present earlier but now reported from another island, resulting in a total of 227 introduced and naturalized species. Each species is discussed briefly with its native distribution, uses, first arrival in Chile and/or the archipelago, and comments on conservation impact. Identities of some previously cited taxa are clarified (e.g., *Cupressus macrocarpa* appears to be a misidentification for two other species of the same genus). Other noxious weeds known worldwide have recently been deliberately introduced, especially as garden ornamentals. Two of the most serious potential pests are the bird-dispersed *Lantana camara* and *Lonicera japonica*. We recommend immediate eradication of these two taxa and restriction on reintroduction. A conservation program emphasizing strong physical and biological methods is urgently needed to control the introduced species.

423: +.309

In 1991 the British Population of the field cricket *Gryllus campestris* was close to extinction with fewer than a hundred individuals remaining in the single surviving colony. A key component of English Nature's recovery programme for the species involved the creation of six new colonies in areas of the cricket's former UK range. This objective required the establishment of a captive-breeding programme to provide the large number of animals needed to found the new colonies. Between 1992 and 1995 gt 4000 captive-bred nymphs were released into five new sites. Monitoring confirmed that the release populations are becoming successfully established.

424: +.162

The appearance of new species in nature development areas may be indicative for the success of nature management. The absence of species, however, can be due to both unsuitable environmental conditions or shortage of dispersules. Specific knowledge of the chance that species are present in the seed bank or able to enter an area is therefore necessary for evaluating management measures. This knowledge may also be important when reintroductions are considered. In this paper the methods and the practical implications of research on seed dispersal, seed persistence, seed rain and seed banks are discussed. It is emphasized that it is only possible to generate roughly estimated chances of establishment on a landscape scale. In many situations this will give enough information to answer questions about the possibility of establishment of a given species, when combined with knowledge of the landscape and data on population dynamics of the species. An example is given of a hypothetical situation in which persistence and dispersal data are used in estimating the chance of establishment.

425: +.138

To develop successful restoration programs for wildlife, conservation biologists should consider features of animal behavior to help design restoration plans. This paper presents case studies of the first restored colonies of Arctic Terns (*Sterna paradisaea*), Common Terns (*S. hirundo*) and Roseate Terns (*S. dougallii*), Atlantic Puffins (*Fratercula arctica*) and Leach's Storm-Petrels (*Oceanodroma leucorhoa*). These restoration projects are based on the use of two fundamental and commonly occurring features of colonial waterbird behavior: social facilitation and philopatry. Social facilitation, the influence of one animal's behavior on that of its associates, was adapted for conservation purposes by placing decoys and sound recordings at historic nesting islands to simulate established colonies. The use of decoys and audio recordings to simulate and encourage social facilitation is referred to as social attraction. Philopatry, the tendency for young birds to recruit to nesting populations at their natal home, was adapted for conservation purposes by translocating puffin chicks from a large colony at the center of the range to historic nesting islands at the southern, historic limit of the puffin's range where they were extirpated nearly a century, earlier by excessive hunting for food and feathers. Young puffins, reared and released from artificial burrows at two historic sites learned the location of the release sites and eventually returned to the long-extinct colonies rather than their hatching place. To restore colonies of terns and puffins that were displaced by Herring and Great Black-backed Gulls, nesting population of these gulls were reduced at Eastern Egg Rock and Seal Island National Wildlife Refuge (NWR) to encourage recolonization by terns and puffins. Common, Arctic and Roseate Terns were attracted to island recolonization sites off mid-coast Maine, USA using decoys and 24-hour playback recordings. By 1996, Seal Island NWR was the largest Arctic Tern colony in Maine with 956 pairs and Eastern Egg Rock was the largest Roseate Tern colony in the state with 126 nesting pairs of this endangered species. These successes using social attraction are compared to tern restoration on Petit Manan Island, Maine where gull control alone resulted in recolonization. In this example, terns were absent for only 4 years and many were still living with a memory of nesting on the

island. After gull removal, these birds quickly recolonized in the same year that gull control began. In contrast, using gull control and social attraction, it took 3 and 5 years respectively for terns to re-colonize Eastern Egg Rock and Seal Island NWR (where terns had not nested for 44 and 36 years). In these cases, no living terns with a memory of nesting on these islands were available for recolonization. Puffin colonies at Eastern Egg Rock and Seal Island NWR were restored by translocating 3-40 (average 17) day-old puffin chicks from Newfoundland, Canada (approx. 1610 km distant). A total of 954 and 950 chicks were translocated to Eastern Egg Rock and Seal Island NWR respectively. These were captive-reared in individual sod burrows which were opened at their entrance after the first week. The chicks were banded and permitted to fledge into the adjacent ocean. Translocated puffins began to return when two years old; many also visited nearby puffin colonies where some eventually nested. Re-colonization at the historic nesting sites occurred in 1981 and 1992 respectively at Eastern Egg Rock and Seal Island NWR- in both cases 8 years after initiation of translocations. Four pairs nested in 1981, a number that increased to 19 pairs by 1985 and has remained constant at 16-19 pairs, due to recruitment of native-hatched chicks. At Seal Island NWR, 7 pairs nested in 1992 and increased to 40 pairs by 1996. The rapid increase at Seal Island was due largely to recruitment of native-hatched puffins from nearby colonies which comprised at least 68% of breeders by 1996. Social attraction, consisting of playback of recorded Leach's Storm-Petrel calls and artificial burrows were used to encourage Storm-petrels to establish new colonies. A colony of Leach's Storm-Petrels was established in the first year using playback burrow calls near artificial burrows on Ross Island and a second colony was established in the second year of playing burrow calls at Old Hump Ledge, an historic nesting island. Fifteen years after suspension of the attraction program, at least three pairs of storm-petrels were nesting in natural burrows near the site of artificial burrows at Old Hump Ledge.

1. Information on the approximate number of individuals released is available for 47 of the 133 exotic bird species introduced to New Zealand in the late 19th and early 20th centuries. Of these, 21 species had populations surviving in the wild in 1969-79. The long interval between introduction and assessment of outcome provides a rare opportunity to examine the factors correlated with successful establishment without the uncertainty of long-term population persistence associated with studies of short duration. 2. The probability of successful establishment was strongly influenced by the number of individuals released during the main period of introductions. Eighty-three per cent of species that had more than 100 individuals released within a 10-year period became established, compared with 21% of species that had less than 100 birds released. The relationship between the probability of establishment and number of birds released was similar to that found in a previous study of introductions of exotic birds to Australia. 3. It was possible to look for a within-family influence on the success of introduction of the number of birds released in nine bird families. A positive influence was found within seven families and no effect in two families. This preponderance of families with a positive effect was statistically significant. 4. A significant effect of body weight on the probability of successful establishment was found, and negative effects of clutch size and latitude of origin. However, the statistical significance of these effects varied according to whether comparison was or was not restricted to within-family variation. After applying the Bonferroni adjustment to significance levels, to allow for the large number of variables and factors being considered, only the effect of the number of birds released was statistically significant. 5. No significant effects on the probability of successful establishment were apparent for the mean date of release, the minimum number of years in which birds were released, the hemisphere of origin (northern or southern) and the size and diversity of latitudinal distribution of the natural geographical range.

The methods used to assess a red squirrel *Sciurus vulgaris* reintroduction experiment at Parco Groane, northern Italy, are described. Population size at the removal site was estimated (c. 2400 squirrels) using drey counts, to evaluate the effect of removing animals for reintroduction. Suitability of the release site was investigated in two ways: (1) beforehand, by comparing tree seed abundance with that at the removal site, (2) retrospectively, by comparing drey-site choice between removal and release site. Increase and dispersion of the reintroduced population were monitored using drey counts and searching for species-specific feeding signs. Although only eight squirrels could be released (four males, four females), the experiment was successful and by 1996 all wooded habitats at Parco Groane were inhabited by squirrels.

The Mallorcan midwife toad *Alytes muletensis* is a species with which the Jersey Wildlife Preservation Trust (JWPT) has a long standing involvement. The month of July 1997 was spent in the Sierra de Tramuntana mountains of Mallorca carrying out fieldwork with essentially three aims: 1) release of captive-bred toads into the wild, 2) a survey and census of all current toad sites in the wild, and 3) capture of wild toads for further captive breeding. This paper describes the details of this fieldwork and discusses the history, current status and possible future of the Mallorcan midwife toad recovery programme.

433: +.104

After having been absent from the Danish fauna for exactly 100 years, the Eagle Owl began breeding again in 1984 when a pair was discovered in southern Jutland. Since then, the species has become established in most of Jutland south of Limfjorden, with an estimated population of 25-30 pairs. The recolonization of Denmark was a direct result of a reintroduction program in Schleswig-Holstein, northern Germany, where a total of 563 young birds were released into the wild between 1981 and 1995. Eagle Owls are doing surprisingly well in the modern Danish landscape and are quite capable of rearing young in populated areas (Tab. 1). Six of nine nesting areas in southern Jutland were in gravel pits, with the nest typically placed on a ledge on the bank of a disused and partly revegetated part of the pit. Another nest was on a natural steep slope in a wood clearing, and three (in two different territories) were placed in old Goshawk nests. The owls are opportunistic feeders, taking a variety of mammals and birds weighing up to 1.5 kg. Samples from five territories included the remains of 13 species of mammals and 21 species of birds; the most important among the mammals were hedgehog *Erinaceus europaeus*, brown rat *Rattus norvegicus*, water vole *Arvicola terrestris*, and small *Apodemus* and *Microtus* rodents, while the commonest bird species were Mallard *Anas platyrhynchos*, Coot *Fulica atra*, Woodpigeon *Columba palumbus*, and Crow *Corvus corone*.

434: +.168

The Berry Botanic Garden is a small, non-profit organization in Portland, Oregon, that is strongly committed to conserving rare and endangered plants of the Pacific Northwest. Toward that end, the Garden has operated a regional seed bank for rare and endangered plant species since 1983. The Garden is the participating institution in the Pacific Northwest of the Center for Plant Conservation. Garden staff also conduct a wide range of conservation related scientific research on rare plants, a small portion of which will be described in the context of how stored seed might be used for reintroduction. Banking seed begins with the choice of species, and proceeds through

collection and transportation to the seed bank, where initial drying, cleaning and seed counting are done. It culminates when seeds are packaged and placed in frozen storage. Germination and growth trials follow. Stored seed are a means to an end—the conservation of rare and endangered plant taxa and populations in the wild. Our work is intended to offer a complementary tool to increase the chances that irreplaceable on-site efforts by land managers will succeed. The conservation value of stored seed can be realized in a variety of ways. Only if appropriate collections exist can stored seed be used to reintroduce extirpated populations or extinct species. Stored seed can also be used to augment (i.e., increase population size and growth rate) of extant populations. Reintroduction may have considerable conservation value in recovery, but is less likely to be of benefit and may even be harmful if used to mitigate and thus facilitate habitat destruction. A framework for getting the most out of reintroduction is discussed, as are several means stored seed might be used to intervene demographically.

437: -.110

The Ultramarine Lory (Ultramarine Lorikeet, Marquesas Lorikeet, Pihiti) *Vini ultramarina* is one of the most threatened insular Lory species. Endemic to the Marquesas Islands, where it probably once ranged throughout the archipelago, it has been nearly extirpated from all but the tiny island of Ua Huka. Given the vulnerability of a single population inhabiting one small island, and the decline of the species in recent years, establishment of the Ultramarine Lory on another less disturbed island within its historic range has been proposed as a conservation strategy. This paper describes a 1991 survey evaluating the status of the Ultramarine Lory in the Marquesas Islands, and three subsequent translocations of birds from the island of Ua Huka to the island of Fatu Hiva. Twenty-nine birds were relocated during the period from 1992 to 1994 at the request of the Delegation de L'Environnement, French Polynesia. A preliminary survey, prior to the third translocation, indicates that previously transferred birds are surviving and may be reproducing; an intensive survey is planned in 1997.

438: +.084

We reintroduced the endangered Baton Blue butterfly (*Pseudophilotes baton schiffermuelleri*, Bergstrasser) from its last known Finnish population to a site where it had become extinct. The butterfly is associated with dry and open eskers, but because of drastic habitat degradation only one population is known to have survived in Finland. The main reason for habitat loss is succession of pine forests. The last verified records of the species at the site of reintroduction date from 1984. The habitat was managed by the selective logging of pines in 1992. In 1994, after vegetation followups, 10 female baton blues were translocated. The introduced population was studied with the mark-recapture method in 1995-1996. Its size increased during this period to ca. 50 butterflies in 1996. Reintroduction, accomplished in close cooperation with forest industry, administration authorities and environmentalists, has diminished the probability of extinction of the baton blue in Finland.

439: -.275

The Lord Howe island Woodhen is a flightless rail endemic to Lord Howe Island that became endangered due to human over-exploitation and predation from wild pigs. It has recently recovered from a population size of 20-30 to around 200 as a result of a captive breeding and reintroduction programme. Its classification has been downgraded from endangered to vulnerable, but no quantitative assessment of its future prospects had been undertaken. A population viability analysis (PVA) was performed on the Lord Howe Island Woodhen to project its possible fate using

VORTEX, a package that realistically reflects the woodhen's recent history. Prospective analyses showed the woodhen to be acutely sensitive to minor changes in mortality and fecundity, and to catastrophes, due to exotic species, inbreeding, or disease. A remote population needs to be established if the likelihood of the woodhen's extinction is to be minimized. According to the most recent IUCN Red List categories, the woodhen satisfies the criteria for endangered status.

440: +.130

Introduced species of mammals have now been removed from many islands around New Zealand, thus providing singular opportunities for ecological restoration. If island restoration is to be attempted, the way island biota originate and the precise effects of introduced organisms must be identified. Plants introduced to the New Zealand archipelago may have transitory effects, but others may modify forest structure and disrupt succession. Goats have been the most destructive introduced herbivore on islands. Among introduced predators, cats have extirpated colonies of seabirds, and rats (depending on species) affect invertebrates, lizards, and birds. Ecological theories and concepts that may help with island restoration projects include: the keystone species concept, in which the effects of one species on others is disproportionate relative to its abundance; the "intermediate predator" hypothesis, where removal of the top introduced predator may lead to rebound effects of intermediate predators; and ecological chain reactions, where local extinction of some species can cause complicated multiple effects. Problems with restoration of islands may be encountered because of meager data on the previous effects of pests (such as predators), use of non-seral species in revegetation projects, proliferations of indigenous or introduced species that have unforeseen community effects, and inexplicable difficulties with some translocations. A restoration case study in the continental Mercury Islands and on Cuvier Island showed success with removal of introduced mammals and demonstrates the various effects of introduced browsers, grazers, and predators. A contrasting case study is provided by oceanic Mangere Island in the Chatham Islands where 22 species of avifauna have been lost, seven as permanent extinctions. Restoration targets for some New Zealand islands can be clarified by palaeoecological studies of Maori (Polynesian) middens and natural deposits. Understanding the role of disturbance in island systems may also help clarify restoration targets. When exotic keystone species are introduced, physical disturbance may be overridden by biotic disturbance. This replacement in turn has implications for trophic structure. With high levels of biotic disturbance, continental islands may be changed from relatively species-rich bottom-up food webs to species-poor top-down trophic cascades. These possibilities can be tested with an experimental approach to restoration, although such experiments may be hard to interpret because of difficulties with replicates and controls. Ecological restoration on New Zealand islands has potential to replace damaged or lost communities, expand the ranges of relict populations, reduce the selective influence of exotic (keystone) species on indigenous species, help in understanding how the systems are formed, provide opportunities for educational and scientific investigation, and act as a testing ground for new technologies against pests.

441: -.050

Koala (*Phascolarctos cinereus*) populations in southern Australia have a history of bottlenecks earlier this century the species became extinct in South Australia, and almost so in Victoria. Subsequently large numbers of animals from island populations (founded from very few animals) have been translocated back to mainland sites and to other islands in the region. As part of a larger study of the genetic structure of koala populations in southern Australia, we have undertaken a survey of mitochondrial DNA restriction fragment length polymorphism (mtDNA-RFLP) variability. Genomic DNA from 91 koalas from five populations was examined using 23 restriction

enzymes, and mtDNA fragments were detected using a domestic cat full-length mtDNA clone. Only one of the enzymes, TaqI, revealed polymorphism - a relatively low amount of variation compared with other mammals, although low mtDNA-RFLP variation has also been reported in Queensland koalas. French Island and populations established predominantly from French Island immigrant koalas, either directly or via other island populations, were indistinguishable by haplotype frequencies. The mtDNA data are thus consistent with the interpretation that the koala translocation programme has homogenized gene frequencies amongst those populations involved. South Gippsland is not recorded as having received translocated koalas directly, and has significantly different mtDNA-RFLP haplotype frequencies from all other populations examined. The fact that this distinction was not previously observed in nuclear gene frequencies may reflect predominantly male-mediated dispersal in koalas.

442: +.181

We asked whether the reproductive capacity of the endangered *Cordylanthus maritimus* ssp. *maritimus* (salt marsh bird's-beak) at Sweetwater Marsh (San Diego Bay, California) was sufficient to provide a self-sustaining population, as required by a mitigation agreement under the Endangered Species Act. After seeds were sown for three consecutive years (1990-1992) to an upper intertidal marsh where the historical population was last seen in 1987, the number of plants censused rose from approximate to 5000 in 1992 to approximate to 14 000 in 1995. The transplanted population initiated fewer seed capsules per flower (mean 0.2-0.4 capsules in 1992-1994) than the donor population (up to 0.9 capsules in 1991). Pollen supplementation (hand-pollination) treatments increased the number of capsules by 89% in 1992, and by 52% in 1993. Abundance of pollinators appeared to be less important than the relative abundance of particular genera (i.e., *Anthidium* and *Bombus*). However, in areas where pollen supply was sufficient, nitrogen availability seemed to limit capsule set. Plant growth rates of the transplanted population compared favorably with those of the donor population (mean height 12-13 cm). At Sweetwater Marsh, larger plants produced more flowers, and aboveground dry mass of plants correlated strongly with inorganic nitrogen in the soil, which was > 71% sand. Nitrogen fertilization treatments increased plant size, foliar nitrogen content, and mean seed mass. Even though the population produced > 1.5×10^6 seeds from 1992 to 1994, it is not clear that *C. m. maritimus* will be able to sustain itself at Sweetwater Marsh. The number of plants in 1994 was < 3% of the estimated seed production in 1992-1994. Opportunities for seed germination and seedling establishment may be more limiting than reproductive capacity. The most difficult challenge to habitat managers may be maintaining ecological relationships that are dependent on external factors, i.e., pollinators, nutrient inflows, and canopy disturbances (from debris or mammals) that create the necessary openings for seedling recruitment.

443: +.083

Between May 1989 and October 1990 a highway was constructed through the core area of one of the largest French populations of *Testudo hermanni*, a species seriously threatened by habitat loss and habitat fragmentation. Two general strategies were used to alleviate negative impacts of the highway on the tortoise population: first, 300 tortoises, that were directly, affected by the highway, construction, were temporarily maintained in outdoor enclosures and relocated after construction was completed; secondly, attempts were made to reduce traffic impacts on the tortoise population, including the use of fences to keep tortoises off the road and the construction of culverts and a tunnel under the road to provide for movements of animals between the separated habitat areas. The short-term outcome of this conservation exercise was a success: the annual survival rate of 78% observed in reintroduced tortoises was comparable to published results of translocation of

other tortoise species into unfamiliar habitat, traffic mortality of tortoises in the 4 years following highway, construction was low and mark-recapture results indicate a stable adult population and the use of the culverts and the tunnel by tortoises to cross the road. Translocations of rare and endangered species face significant valuational and organizational challenges; however, these dimensions are rarely discussed in the translocation literature. We employed a 98 question sample mail survey to assess these variables and received 131 responses from 110 individuals in 10 nations. In contrast to the literature which suggests that most translocations fail, a large proportion of the programs surveyed were perceived as being successful and most respondents identified relatively few valuational or organizational problems or difficulties in their translocation programs. While perceived local support was correlated with perceived translocation success, the presence of public relations/education programs was not. Therefore, simply having a public relations/education program is no guarantee that public support will increase or that a translocation will be more successful. Organizationally, translocations which established special groups or teams were perceived as increasing innovation, but not in improving program organization, nor decreasing conflict. Further, the presence of special groups or teams was not correlated with translocation success. Finally, translocations with the objective of augmenting populations were perceived to suffer from more problems, including greater local opposition, poorer public understanding, less money, and poorer leadership, than were translocations aimed at establishing or re-establishing populations. The results illustrated the difficulty of analyzing valuational and organizational aspects of conservation programs using questionnaires. Copyright (C) 1996 Elsevier Science Limited

445: **+.028**

Propagation of the endangered hemiparasite *Schwalbea americana* was conducted in the presence of several species of potential host plants. Seeds were germinated and the seedlings transferred to pots containing potential host plants. Potted seedlings and potential hosts then were transplanted to field sites adjacent to a population of *S. americana* from which the seed had been collected. Germination of seedlings was >90% after a wet-cold treatment; a dry-cold treatment resulted in low germination. Seedlings grown in association with seedlings of the grass *Schizachyrium scoparium* did not differ in size or longevity from seedlings grown alone. Growth of seedlings was slightly greater in the presence of host plants than without, but seedlings still achieved only limited size in greenhouse conditions before transplantation (2 to 4 mm in width and height). After transplantation to the field the majority of seedlings died rapidly, but several persisted for over 45 days without showing appreciable growth. Poor seedling establishment and survival are believed to contribute to the rarity of this species. The development of improved methods for the propagation and transplantation of *S. americana*, and the greater understanding of the causes for the rarity of this endangered species, will increase options for recovery strategies.

446: **+.117**

The Hawaiian monk seal (*Monachus schauinslandi*) is a critically endangered species that has failed to recover from human exploitation despite decades of protection and ongoing management efforts designed to increase population growth. The seals breed at five principal locations in the northwestern Hawaiian islands, and inter-island migration is limited. Genetic variation in this species is expected to be low due to a recent population bottleneck and probable inbreeding within

small subpopulations. To test the hypothesis that small population size and strong site fidelity has led to low within-island genetic variability and significant between-island differentiation, we used two independent approaches to quantify genetic variation both within and among the principal subpopulations. Mitochondrial control region and tRNA gene sequences (359 base pairs) were obtained from 50 seals and revealed very low genetic diversity (0.6% variable sites), with no evidence of subpopulation differentiation. Multilocus DNA fingerprints from 22 individuals also indicated low genetic variation in at least some subpopulations (band-sharing values for "unrelated" seals from the same island ranged from 49 to 73%). This method also provided preliminary evidence of population subdivision ($F'(st)$ estimates of 0.20 and 0.13 for two adjacent island pairs). Translocations of seals among islands may therefore have the potential to relieve local inbreeding and possibly to reduce the total amount of variation preserved in the population. Genetic variation is only one of many factors that determine the ability of an endangered species to recover. Maintenance of existing genetic diversity, however, remains an important priority for conservation programs because of the possibility of increased disease resistance in more variable populations and the chance that inbreeding depression may only be manifest under adverse environmental conditions.

447: +.087

Sea Otters (*Enhydra lutris*) ranged historically across the north Pacific from the central Pacific coast of Baja California, to northern Japan. An intensive fur hunt in the 18th and 19th centuries extirpated the Sea Otter from much of its range. The species was protected in 1911, and now occupies approximately half of its historic range. Presently, the worldwide population of Sea Otters is thought to be about 150 000 animals. The British Columbia Sea Otter population, originating from 89 animals reintroduced to Vancouver Island from 1969 to 1972, has increased at a finite rate of 18.6% per year, a rate similar to reintroduced populations in Washington and southeast Alaska. In 1995, a minimum of 1522 Sea Otters were found in British Columbia. Most of these animals occurred off Vancouver Island, but at least 135 Sea Otters were found near Goose Island, 125 km north of Vancouver Island. The origin of this latter group is uncertain. Sea Otters are presently classed as threatened in British Columbia and are protected under Federal and Provincial regulations.

448: +.103

During the last century, the decline of the apollo butterfly in the Pieniny mountains has been observed. This decline is attributed to environmental pollution, shrinkage of the area of open habitats inhabited by the species (as a result of introducing new, more expansive varieties of spruce in the area of Pieniny mountains), genetic erosion affecting small populations, and decimating this butterfly by collectors. The programme of the reintroduction of the apollo butterfly in the Pieniny National Park includes three main areas of activity: captive breeding of specimens to reinforce wild populations, preparation of habitats once inhabited by the apollo butterfly, including the removal of trees and shrubs and implanting the host plant, and research work. This was concerned with the ecology and dynamics of wild and reintroduced populations of the apollo butterfly, description of the decline process and explanation of its causal factors, and evaluation of the state of their habitat with special regard to the abundance and ecology of their host plant - *Sedum maximum*. The five-years' reintroduction work has resulted in the triple growth of the native population inhabiting the massive of Trzy Korony (from c. 20 in 1991 to c. 60 in 1995); moreover, butterflies raised in captivity were released in four new, reconstructed localities. In 1995 migrations of specimens between all but one localities were observed.

450: +.222

A programme for the re-introduction of the European beaver in to the Litovelske Pomoravi, Danube (Morava) river basin is described. Beavers were released in to prepared artificial lodges in 1991 and 1992. the programme appears to have been successful to date, population growth has started and new sites have been colonized.

451: -.045

The aims of this study were to determine whether translocated noisy miners *Manorina melanocephala* were assimilated readily into noisy miner populations resident at release sites and, secondly, whether the number of birds in a release group influenced the subsequent behaviour, movement patterns and fate of translocated individuals. Birds were released in duos (n=5) or in groups of six (n=5). One bird in each duo or group was fitted with a radio transmitter. Although most translocated birds survived at least a month following translocation, they were not assimilated readily into resident populations of miners, but instead wandered much further (mean maximum distance from release site=4.2 km) than the average diameter of the species' home range (similar to 200 m). At least two of the 40 translocated birds returned to their capture site; a distance of 18 km. The distances travelled by radio-tagged birds from their release sites rendered invalid the assumption that one release group/duo did not influence how another group/duo behaved. The difficulties such widespread dispersal pose to attempts at experimental examination of factors influencing the success of translocations are discussed. (C) 1997 Elsevier Science Ltd.

452: +.120

1. To determine the effect of grassland gap size on patterns of seedling recruitment and juvenile establishment of the endangered composite *Rutidosia leptorrhynchoides*, seed and transplants were introduced irate artificially created canopy gaps in both a 'short' and 'tail' temperate *Themeda triandra* tussock grassland in southern Victoria, Australia. Square gaps of 0 sm (undisturbed control), 15 cm, 30 cm, 50 sm and 100 cm width were created by removing the dominant grass, and the emergence, survival and growth of *R. leptorrhynchoides* were followed for 1 year. Survival and performance were compared with light quantity at ground level and soil moisture differences between the gags.2. Emergence of seedlings was greatest in large gaps (30 cm, 50 cm and 100 cm) but survival was restricted primarily to the 100-cm gaps in both grasslands.3. Survival of transplants to 1 year occurred in 30-cm, 50-cm and 100-cm gaps, suggesting that juvenile plants tolerate competition for resources better than germinating seedlings do. Survival, rate of growth and total number of inflorescences produced, however, was significantly greater in 100-cm gaps.4. There were few differences in the seasonal pattern of soi moisture between gaps in bath grasslands. The amount of light at ground level was significantly greater in the short-grasslands. and in large gaps (30 cm, 50 cm and 100 cm) at most times during the year. Differences between gaps in total soil moisture and light levels, however, only partly explain the patterns of transplant survival and growth observed. Sail moisture variability is suggested to have been an important factor influencing transplant survival over summer.5. These results confirm that *R. leptorrhynchoides* is a gap-sensitive species, with recruitment and survival unlikely to occur in canopy Sags less than 30-50 cm in diameter. Management of remnant populations needs to ensure that large canopy gaps are regularly maintained to maximize successful seedling recruitment and maintain the standing population. This may be achieved by burning the grassland at 3-year intervals. In the absence of the frequent burning of productive grasslands, localized extinction is likely.6. Reintroduction of the species into secure grassland reserves is likely to be problematic given the paucity of large *Themeda*-free gaps in these grasslands. Alternative strategies for

conserving the species include its introduction into grassy woodlands where gap closure rates are likely to be slower.

453: +.256

1. Native species are translocated for conservation, commercial, amenity and research purposes. These activities are related, and need to be considered and planned in terms of their effects on biodiversity. 2. Procedures for assessing, implementing and regulating translocations have, however, been subject to largely uncoordinated development; recommendations or guidelines being produced separately for each area of expertise. There is a need to pull together the profuse information concerning specific translocations in order to present a broad approach to the general problems and concerns. 3. Here, the extent and nature of translocations of native species within the UK are reviewed, and recommendations for policy and legislation are made in the context of those currently in use in the UK. The recommendations include the following: (i) improvement of the ways in which relevant information is disseminated; (ii) ease of implementation should be a prime consideration; and (iii) formation of new policy and guidelines should include all UK and international organizations involved in carrying out, advising on, or licensing translocations.

454: +.097

A discrete-time reaction-diffusion model for black-footed ferret release, population growth, and dispersal is combined with ferret carrying capacity constraints based on prairie dog population management decisions to form a spatial optimization model. Spatial arrangement of active prairie dog colonies within a ferret reintroduction area is optimized over time for maximum expected adult ferret population. This modeling approach is applied in an exploratory case study to a black-footed ferret reintroduction program in Badlands National Park and Buffalo Gap National Grassland, South Dakota. The model is currently being used to evaluate prairie dog population management alternatives and captive-bred ferret release locations for the Buffalo Gap National Grassland. This approach is also being adapted for use on other grasslands and with other species in the northern Great Plains.

455: -.213

A fungal infection was identified as the cause of a high mortality rate of captive wartbiter cricket (*Decticus verrucivorus*) nymphs at the London Zoo (United Kingdom) in 1994. This species is threatened with extinction in the United Kingdom and the animals concerned were part of a captive breeding and reintroduction program. Following these findings, reintroductions were postponed and release sites were used only where there were no extant wartbiter crickets.

457: +.224

1, Establishment patterns of reintroduced European otters *Lutra lutra* are described from a behavioural and a conservation perspective. 2, Thirty-six 1-year-old otters, 11 wild-caught and 25 captive-bred, were released and radio-tracked in Sweden between 1989 and 1992. 3, Movements after release depended on whether the release area was already occupied by other otters. 4: Establishment occurred in areas that were unoccupied or were occupied by otters of the opposite sex. 5, Females established exclusive home ranges and remained in these areas on attaining maturity. 6, There was a tendency among males to expand their home ranges coincident with sexual maturity; no such range expansion was observed among females. 7, Competition for resources largely explains the movement and establishment pattern in released otters. Competition

for mates over-rides competition for other resources in adult males,⁸ A distance of c. 10 km between the release site and areas occupied by other otters is recommended.⁹ Areas occupied by otters were associated with lakes and rivers with high biomass production.

459: +.031

Because populations in zoological parks and nature reserves often are derived from only a few individuals, conservationists have attempted to minimize founder effects by equalizing family groups sizes and increasing the reproductive contributions of all individuals. Although such programs reduce potential losses of genetic diversity, information is rarely available about the actual persistence of family groups or genetic lineages in natural populations. In the absence of such data, it can be difficult to weight the importance of human intervention in the conservation of small populations. Separate long-term studies of two mammals, the North American bison (*Bison bison*) and the white-nosed coati (*Nasua narica*), and a bird, the Acorn Woodpecker (*Melanerpes formicivorus*), demonstrate differential extinction of genetic lineages. Irrespective of the mechanisms affecting population structure, which may range from stochastic environmental events to such behavioral phenomena as poor intrasexual competitive abilities, our results show that lineages can be lost at rapid rates from natural populations. A survey of comparable studies from the literature indicates that the loss of matriline over the course of the study varies from 3% to 87% in wild mammals and from 30% to 80% in birds, with several small mammals losing approximately 20% of matriline per year of study. These lineage extinctions were not an artifact of the length of the study or the generation time of the species. Such rapid losses of lineages in less than 20-year periods in natural populations suggest that efforts to maintain maximal genetic diversity within populations may not always reflect processes that occur in the wild. Conservation biologists need to give further thought to the extent to which parity among genetic lines should be a primary goal of management of captive and small wild populations.

460: -.107

This study evaluated the genetic consequences of a reintroduction of the endangered annual plant *Cordylanthus maritimus* ssp. *maritimus* to Sweetwater Marsh (San Diego County, California). A survey of 21 enzyme loci in natural populations revealed that genetic diversity is very low and is primarily found as rare alleles at a few loci, making this species especially susceptible to the loss of alleles and heterozygosity through genetic drift. The reintroduction was performed in 1991 and 1992 by sowing seeds (collected from Tijuana Estuary) in numerous small patches of suitable habitat. For this study, leaf tissue was collected from all plants in all patches during flowering in 1995 and surveyed for genotype at the three enzyme loci that are polymorphic at Tijuana Estuary. Rare alleles were absent in 27 out of 30 patches for Pgm-1, in 17 out of 30 patches for Pgm-2, and in 10 out of 11 patches for Mdh-1. In all, half of the patches lacked any rare allele. Rare alleles tended to occur in patches with few individuals. Overall rare allele frequency was lower than in the colonies from which seeds were collected at two of the three loci, and heterozygosity was reduced. The Sweetwater Marsh population is at risk of losing most of its genetic variation at enzyme loci through the extinction of patches with few individuals. Future reintroduction attempts should attempt to create contiguous sets of patches or to periodically reseed existing patches to reduce the loss of genetic variation.

To identify populations with the ability to accumulate heavy metals, approximately 30 accessions pertaining to 30 plant species were grown for 4 wk in a hydroponic media that approximated the

nutrient and heavy metal composition of a soil contaminated with moderate levels of cadmium (Cd), copper (Cu), and zinc (Zn). The results indicated that several Brassica spp. exhibited moderately enhanced Zn and Cd accumulation. Selected accessions of Brassica juncea (L.) Czern., B. napus L., and B. rapa L. were then grown in pots with heavy metal-contaminated soil to compare the Zn and Cd phytoextraction by these species to that of Thlaspi caerulescens J. & C. Presl, a known Zn and Cd hyperaccumulator, and two grass species, Agrostis capillaris L. and Festuca rubra L. The three Brassica spp. were the most effective in removing Zn from the contaminated soil, primarily because they produced more than 10 times the shoot biomass produced by T. caerulescens. When the soil was amended with Gro-Power, a commercial soil amendment that improves soil structure and fertility, removal of Zn by plant shoots doubled to more than 30 000 mg Zn pot⁻¹ (4.5 kg). The results suggest that for phytoremediation of metal-polluted soils to be successful, a strategy should be considered that combines rapid screening of plant species possessing the ability to tolerate and accumulate heavy metals with agronomic practices that enhance shoot biomass production and/or increase metal bioavailability in the rhizosphere.

463: +.120

Captive-born mountain gazelles were reintroduced to Hawtah Reserve in central Saudi Arabia from 1991 to 1995. This study describes the survival, reproduction and changing number of gazelles within the population during the first four years of the programme. The mortality rate was highest during the first month after release, but 69-73% of gazelles survived for greater than or equal to 1 year and 58-59% survived for greater than or equal to 2 years. Weaned gazelles <2 years-of-age had the highest survival rate during the first year after release. The mean annual survival rate for gazelles which survived their first month of freedom was 78%. Predation was a major mortality factor and older gazelles were particularly vulnerable. Rainfall was seasonal, but calves were born throughout the year, with peaks in the number of births during spring and autumn. Females often produced two calves annually. All calves were singletons. The exponential rate of increase (r) of a subpopulation during two years after the last release was 0.275 on a yearly basis. In a wadi protected from domestic livestock, the density of gazelles remained constant after reaching ca. 15 gazelles km⁻². By the end of 1994, the estimated number of gazelles in the reserve was 165, more than twice the number released during the previous four years. An important lesson for all reintroductions is that predators can be a major problem even when uncommon. Recommendations are given for selecting gazelles for release during future reintroductions. The status of Yellow-footed Rock-wallabies (*Petrogale xanthopus*) and Black-footed Rock-wallabies (*P. lateralis*) in South Australia was assessed by comparing recent survey and census data with previously collated information about the distribution and relative abundance of each taxon. *Petrogale xanthopus* has maintained most of its known geographic range within the state; however its relative abundance has declined significantly and 35 (or 15%) of a total of 229 recorded colonies have become extinct since European settlement. Eight of these colony extinctions have occurred over the past 25 years; three of them since 1981. As this species is continuing to decline it should be regarded as threatened within the state. *Petrogale lateralis* has at least two sub-species which occur in South Australia. *Petrogale lateralis pearsoni* is endemic to the state and occurs on offshore islands. Since 1960 its natural occurrence of about 3-500 individuals on North Pearson Island has been expanded to four other islands through translocations and the total population is now about 700-1100 animals. This subspecies, while not occurring in large

numbers, is nonetheless relatively secure due to the additional populations established and the fact that these are on islands isolated from most mainland threats. The mainland subspecies, *Petrogale lateralis* MacDonnell Ranges race, by comparison has suffered a drastic reduction in both geographic range and abundance to the point where it is South Australia's most critically endangered vertebrate taxon. It has declined from being a very common species in the state's far northwest to only two known, widely separated, colonies which total less than 100 animals between them. Management and research recommendations are provided.

In 1989, 13 Sugar Gliders *Petaurus breviceps* were introduced into the Organ Pipes National Park, a re-afforested valley, 26 km north-west of Melbourne, Victoria. These Sugar Gliders were relocated from a nearby (20 km) State Forest at Pyrete Range, Toolern Vale. This initial release was followed up in 1990 with the release of a further 24 animals. Due to the absence of natural tree hollows, 24 nesting boxes were installed prior to the release, spread over a 10 ha area. Introduced glider population densities varied from 0.8 ha⁻¹ to 5 ha⁻¹ from February 1989 to October 1992. In June 1993, 43 Sugar Gliders were trapped and nesting boxes were installed over a wider area. By May 1995, 31 Sugar Gliders were trapped, marked with 'electronic chips' and some were found nesting in boxes specifically designed for bats. Although there had been a number of reintroductions at other locations in Victoria, namely Tower Hill, Blackburn Lake and Coolart, this was the first time wild Sugar Gliders had been trapped and relocated. Due to senescence amongst Black Wattles *Acacia mearnsii* at Organ Pipes National Park, food sources may have reduced during the study period. Despite this, the data indicate that the population may have been successfully established.

The Hawaiian goose or nene (*Branta sandvicensis*) restoration program, initiated in 1949, and with the release of about 2,150 captive-bred birds, has not resulted in a self-sustaining wild population. Results from a capture-recapture analysis indicate that 3 factors affected mortality rates: the year of release, age-class and method of release. Estimated annual mortality ranged from 0 to 87%. Comparisons between sites revealed the unsuitability of some upland sanctuaries as release sites. Hawaiian geese released in the 1960s survived at levels comparable to other wild, healthy goose populations (i.e., between 5 and 16% mortality) until the drought years 1976-83. During this period the majority of captive-reared and released Hawaiian geese (about 1,200) perished. Previously released adults generally survived better than newly released goslings. Birds made temporarily flightless initially to contain them in release pens survived less well than those released before fledging. The upland Hawaiian geese that did survive, did so at areas other than their release site; if they emigrated they survived better, especially during drought years. In all cases movement was away from habitats with dry upper montane-volcanic scrubland to areas with managed grasslands, managed ranch land, or supplemental feed and water. More movements occurred in drought years. Once the geese moved they rarely returned to their release sites. The lowest mortality and highest nest success rates were achieved by geese living at Hawaii Volcanoes and Haleakala National Parks. Hawaiian geese in these areas survived at levels similar to other nonhunted goose populations.

468: +.210

Gray wolf (*Canis lupus*) recovery in the Rocky Mountains of the U.S. is proceeding by both natural recolonization and managed reintroduction. We used DNA microsatellite analysis of

wolves transplanted from Canada to two reintroduction sites in the U.S. to study population structure in native and reintroduced wolf populations. Gene flow due to migration between regions in Canada is substantial, and all three recovery populations in the U.S. had high genetic variation. The reintroduced founders were moderately genetically divergent from the naturally colonizing U.S. population. These findings corroborate that the reintroduction more than meets generally accepted genetic guidelines. Maintaining this variation, however, will depend on ample reproduction in the first few generations. In the long term genetic variation will best be retained if migration occurs among the recolonizing and the two transplanted populations. Evidence from field observation and genetic studies shows extensive dispersal by wolves, and we conclude that exchange among these groups due to natural dispersal is likely if public tolerance and legal protection are adequate outside lands designated for wolf recovery.

469: +.093

the endangered Mauna Kea silversword (*Argyroxiphium sandwicense* ssp. *sandwicense*) has experienced a severe decline in distribution and abundance because of predation by alien ungulates. By the late 1970s only a small remnant natural population persisted on the Mauna Kea volcano on the Island of Hawaii. The Hawaii Department of Land and Natural Resources, Division of Forestry and Wildlife, initiated an outplanting program in the 1970s to promote recovery of *A. sandwicense* ssp. *sandwicense*. Intermittent outplanting since 1973 has generated an outplanted population of over 450 plants on Mauna Kea, but the program has unintentionally resulted in a major population bottleneck. All plants in the outplanted population appear to be first- or subsequent-generation offspring of only two maternal founders from the natural population. Genetic variation in the natural and outplanted populations was assessed for 90 random amplified polymorphic DNA loci. Eleven loci were detectably polymorphic in the natural population, whereas only three loci were detectably polymorphic in the outplanted population. Thus, the population bottleneck has been accompanied by a 73% reduction in the level of detectable polymorphism. In addition, for eight loci, the population bottleneck has resulted in the loss of the marker allele in the outplanted population. A management strategy involving manual pollen transfer has recently been implemented to incorporate additional founders from the natural population into the outplanting program. As a supplement to the outplanting program, the strategy also includes a program promoting direct seedling establishment following manual pollen transfer. Incorporating additional founders may serve to overcome the legacy of the population bottleneck, especially if founder representation can be equalized.

470: +.241

The demography of red squirrels *Sciurus vulgaris* removed from three different source areas and reintroduced between February 1987 and January 1988 in an urban park near Antwerp, Belgium was monitored for six years. Animals that were used to human presence had a higher initial survival than those not accustomed to human disturbance. Contrary to our predictions, woodland structure at the removal site did not affect a squirrel's settlement success, and post-release survival of subadults was not higher than that of adults. Only three (33%) introduced males, and five (50%) females survived to produce offspring. Reproductive rate was density-dependent and tended to increase with food abundance (tree seed crop of beech and oak). Consequently, population growth was high the first three years (low density) and decreased after 1990 (high density), when both adult and post-breeding densities (0.8-0.9 squirrels/ha) remained stable, suggesting the reintroduced population had reached its equilibrium density. We discuss some guidelines to increase the success of red squirrel reintroduction projects. (C) 1997 Elsevier Science Ltd.

471: -.002

Fire history and stand structure was examined in twelve virgin forest stands situated within forest reserves in northern Sweden. The selected stands represented fire refuges as well as different successional stages after fire. Six of the stands were dominated by Norway spruce (*Picea abies* L. Karst.), three were dominated by Scots pine (*Pinus sylvestris* L.), and three were dominated by hairy birch (*Betula pubescens* Ehrh.) or aspen (*Populus tremula* L.). In 3 of the southernmost stands, the average fire interval was 34 to 65 years during the late 1600s to late 1800s, but since 1888 no fires had occurred in any of the stands. The absence of fire disturbance since 1888 is probably caused by the fire suppression in the overall landscape. The standing volume of living trees ranged between 87 and 511 m³ ha⁻¹ while the volume of dead trees, including both snags and logs, ranged between 27 and 201 m³ ha⁻¹. The volume of dead trees constituted ca. 30% of the total stem volume. In the conifer dominated stands, there was a statistically significant relationship between total stem volume, including both living and dead trees, and site productivity. A comparison between the amount of dead and living trees indicated substantial changes in tree species composition in several stands. It is suggested that data on the amount of dead trees, especially logs, and its distribution over decay classes could be used to examine the continuity of certain tree species. All stands had a multi-sized tree diameter distribution, which in most cases was similar to a reversed J-shaped distribution. In general spruce was numerous in the seedling cohort and in small diameter classes, indicating that its proportion in the stands was stable, or was increasing at the expense of pioneer tree species such as pine, aspen and silver birch (*Betula pendula* Roth.). The most numerous species in the seedling cohort, rowan (*Sorbus aucuparia* L.), was almost totally missing in the tree layer, indicating a high browsing pressure preventing rowan seedlings from growing into trees. The general increase of spruce and the sparse regeneration of pioneer species, in the stands previously affected by fire, are discussed in relation to natural disturbance regimes, biological diversity and nature conservation policies. It is proposed that reintroduction of fire disturbance is a necessity for future management plans of forest reserves. Other management practices to increase species diversity within forest reserves are also discussed. (C) 1997 Elsevier Science B.V.

472: +.318

There is a great need for developing new approaches to monitoring and recovering rare plants. We have only begun to adopt or invent the perspectives, tools, and institutions to provide better data for making management decisions regarding populations in the wild. Monitoring approaches and tools are best applied when they provide clear answers to specific, management-oriented questions. Recovery of rare plants through reintroduction or enhancement of populations is an experiment, supported by ex situ conservation techniques and informed by the results of modeling the dynamics of surrogate populations. There is a larger role for botanical gardens and arboreta to play in conservation. That larger role must extend into the realm of offsite projects, resource management, and other applied aspects of plant conservation. By combining ex situ and in situ approaches, botanic gardens will thus develop expertise in managing wild-lands as potential habitat for rare and endangered species. However, creating and managing plant populations in the wild is but one facet of restoration ecology, a fledgling science in need of an institutional home that promotes a full exchange between theory and practice.

473: +.000

Euphorbia clivicola R.A. Dyer, an endangered Northern Province endemic, is restricted to only two known populations, both of which are threatened with extinction. The area between and

surrounding the known populations, totalling 8874 km², was therefore searched for sites where either unknown populations could exist, or which could represent a suitable habitat for the introduction of a new population. A raster-based Geographical Information Systems package, IDRISI for Windows, was utilized to manipulate two point vector files, representing rainfall and altitude of the searched area, digitized within the TOSCANELLI system. The INTERPOL module produced two digital elevation models, from which the SURFACE module created slope and aspect images representative of the searched area. RECLASS and OVERLAY modules were finally utilized to identify 12 potential sites, covering only 1.4% of the total searched area. Ground-truthing is now needed to determine the presence or absence of further populations and to assess habitat suitability. This study emphasizes an additional application of GIS techniques to investigations with relevance to the biological sciences, specifically to problems of rare and threatened species. GIS represents a cost-effective alternative method for addressing these problems by focusing ground searching activities to only a small number of potential sites.

474: +.136

In the 1980s, Little Spotted Kiwi (*Apteryx owenii*) were transferred to Long, Red Mercury and Hen Islands to establish new populations beyond their strong hold on Kapiti Island. Recent surveys indicate that all three populations are increasing at between 4% and 8% per annum. Recently, a fifth population has been established successfully on Tiritiri Matangi Island in the Hauraki Gulf, and has grown at a rate of about 11% per annum. Little Spotted Kiwi now appear to be secure with five viable populations on predator-free islands. Aerial poisoning of rats using brodifacoum baits does not appear to have had any long-term adverse effect on the populations of Little Spotted Kiwi on Red Mercury and Tiritiri Matangi Islands.

475: +.161

One of the oldest forms of tillage in the world is the digging of subterranean organs of wild plants for food and other purposes. Many areas were managed for increased densities and abundances of wild plants with edible corms, bulbs, tubers, and rhizomes. The horticultural techniques of digging, replanting, and sparing, in conjunction with larger-scale habitat management, created ecological effects at the species, population, community, and landscape levels. California provides a vivid example of an area where tillage was an important element in a comprehensive land management system that was in place for millennia. It is hypothesized that native California tillage activities mimicked natural disturbances with which plants coevolved, and played an ecological role that is now vacant in many wildlands, where Native Americans can no longer harvest and manage plants. Their land management system needs to be studied, described, interpreted, and experimentally mimicked to better understand indigenous disturbance regimes. It is suggested that some wildland areas would benefit from the reintroduction of management and harvesting regimes that authentically mimic indigenous techniques.

476: +.024

We conducted a trail survey of De Brazza's monkey (*Cercopithecus neglectus*) on Mt. Elgon and the Cherangani Hills between October 1994 and February 1995. The objectives were to assess the status and distribution of the species and its habitats and to formulate recommendations on its conservation. We counted a total of 49 monkeys: 3 groups and 6 lone individuals near Kimothon River (Mt. Elgon) and 4 groups and 6 lone individuals at Kapolet Forest Reserve and its environs (Cherangani Hills). The mean group size is 6.6. Wanton habitat destruction was evident in all the forest habitats. The species now inhabits unprotected remnant strips of riverine forest.

Furthermore, the Kapolet Forest Reserve offers little or no protection to De Brazza's monkeys or their habitat. Translocation of the monkeys from unprotected areas to a protected habitat is recommended as an urgent conservation measure to save the De Brazza's population in Mt. Elgon and the Cherangani areas of Kenya.

477: -.025

African wild dogs (*Lycaon pictus*) are a seriously endangered species with only around 5000 individuals left. We examined the factors likely to be affecting the distribution and density of wild dogs living in the Kruger National Park, South Africa. We collected data, by traditional and satellite radio-tracking, on diet selection, sizes of packs, dispersion and sizes of territories, and patterns of habitat selection for eight packs of wild dogs. In Kruger wild dogs specialize on impala (*Aepyceros melampus*) and kudu (*Tragelaphus strepsiceros*). They live in packs averaging about nine dogs and inhabit territories of 350-950 km². Neighboring territories overlap to some extent but packs meet very rarely. The dispersion pattern of food plays only a minor role in determining the density and distribution of dogs in the Kruger; dogs exist at their lowest density where their food is most abundant. This apparent paradox comes about because the dogs seem to avoid areas that, although prey-rich, are heavily used by lions. This is a sensible strategy because lions are a major cause of dog mortality, accounting for some 39% of natural pup deaths and at least 43% of natural adult deaths. Wild dogs may be conserved most successfully in areas with moderate to low densities of lions and spotted hyenas, and management strategies should be careful not to promote these species to the detriment of wild dogs and other carnivores. The densities of lions and spotted hyenas should be important criteria when considering an area for the reintroduction of wild dogs and other similar sized carnivores.

478: +.313

The natterjack toad (*Bufo calamita*) is an endangered species in Britain and has been legally protected since 1975. This amphibian suffered a major decline during the first half of the twentieth century, due partly to habitat destruction but mostly to successional changes in its specialized biotopes and anthropogenic acidification of breeding sites. In addition to site and species protection, extensive autecological research over the past 25 years has provided the foundations for an intensive, 3-year species recovery program funded by the statutory nature conservation organizations (English Nature and the countryside Council for Wales). This program was based on habitat management and reintroductions to restored sites and followed similar but less intensive efforts. Management of heath and dune habitats focused on restoration and maintenance of early stages of seral succession, initially through physical clearance of invasive scrub and woodland vegetation and later by the reestablishment of grazing regimes similar to those prevalent in earlier centuries. In some cases extra breeding pools were provided to either increase or stabilize natterjack toad populations that had become reliant on one or very few pools at small sites or to promote range expansion within large habitat areas. By 1995 proactive conservation work had been carried out at 29 (69%) of the 39 sites with extant native populations, including 8 during the recovery program. Twenty reintroductions also had been attempted, including nine during the program. At least six reintroductions resulted in the foundation of expanding new populations, and an additional eight have shown initial signs of success. Conservation methods developed for *Bufo calamita* should provide a useful precedent for long-term conservation of early successional habitats and species.

479: +.364

This work was directed to the repopulation of the pearl oyster *Pteria sterna* through artificial seeding techniques. Four different seeding conditions were tested on 658 young cultured pearl oysters: protected substrate, unprotected substrate, natural substrate, and artificial substrate. Two other bioecological variables were tested: depth and specimen size. We assessed survival, settlement speed, acid strength, and the in situ growth of specimens. With the best results obtained, we attempted to define the optimum depth, size, and seeding materials to be used for further extensive repopulation actions. Protection was a very important factor for the survival of individuals; all oysters seeded on unprotected substrates were killed in few days. Natural substrates enhanced settlement speed and the strength and growth of individuals, whereas artificial substrates did not. A depth of 9 m and small-medium sizes gave the best results in terms of survival, settlement speed, and strength, and growth.

480: -.146

The Pall mynah (*Leucopsar rothschildi*) is an endangered bird endemic to the island of Pall, Indonesia. The wild population of approximately 17 birds is confined to West Ball National Park (Taman Nasional Ball Barat). The species was intensively collected for the bird trade in the 1960s and 1970s, and poaching for the internal trade in Indonesia remains the primary threat to the wild population. We conducted an experimental release of one captive-bred and five confiscated, wild origin Ball mynahs on the small offshore island Pulau Menjangan. Released birds readily developed flight and foraging skills. Of the six, radio-tagged birds released, one was stolen, three were likely killed by a raptor, and two were returned successfully to the wild. Many challenges remain for the conservation of this species, including poaching in the national park, disease in the captive population, predation by raptors on newly released birds, and destruction of essential habitat. Results suggest that the Pall mynah is a suitable species for an expanded propagation and release program, provided that poaching is curtailed and disease in birds intended for release can be eliminated. (C) 1998 Wiley-Liss, Inc.

482: +.153

In their biogeography model, MacArthur and Wilson (1967) assumed that populations occurring in isolated patches of suitable habitat differ in that some of them, called continental, are large and persistent, whereas the others, called insular, are small and submitted to periodic extinction and thus making some patches vacant. The former populations are the source of immigrants which colonise patches in which local populations have become extinct. The constant process of extinction and colonisation is called turnover. Another attempt of describing multi-population system was metapopulation model proposed by Levins (1970). Each population here, its size notwithstanding, has equal chances of becoming extinct or turning into the source of emigrants colonising vacant patches of habitat. Pulliam (1988) was the first to incorporate habitat quality in multi-population models. Assuming that populations occupy a mosaic of habitats that vary in quality, he divided them into two types: sink habitats, where reproduction fails to balance mortality, and very productive source habitats, where reproduction exceeds mortality. Decisions about species conservation made without distinguishing between sink and source populations, may lead to undesirable results. If the number of specimens is the only criterion taken into account, which is often the case, large sink populations may be protected, despite the fact that they may be strictly dependent upon small but very productive source populations which are far more worth protecting (Pulliam 1988). If non-protected source habitat is destroyed, extinction of the whole metapopulation may occur. Attempts to restore species by reintroductions should be carried out into former source habitat, i.e. into the core of the former range, rather than into sink ones, i.e. periphery of the former range (Lawton 1993). There is a considerable deal of discussion about the

ways of distinguishing sink and source populations in practice. A comparison of demographic parameters in populations occurring in different habitats was primarily suggested as yielding the strongest evidence for sinks and sources (Bergerud 1988, Pulliam 1988, Pulliam and Danielson 1991). The studies required are long and estimation of immigration and emigration is particularly difficult (Jarvinen and Vaisanen 1984). Questioning the previous criteria of distinguishing sources and sinks, Watkinson and Sutherland (1995) defined "pseudo-sink" populations: viable as sources, yet appearing as sinks due to intensive dispersal into them. According to the authors, not only simple comparison of demographic parameters between populations, but also determination of the nature of density-dependence acting upon them is necessary to identify sources and sinks. These methods are in practice impossible for most organisms.

486: +.131

Vast literature, was analysed and data bank on rare and vanishing plants of the Russian flora has been compiled on this basis. It allows to compile a list of rare and vanishing plant species in their habitats, one of the main limiting factor for which is pasture of farm animals. Recommendations for investigation, conservation and possible restoration of rare and vanishing plants on the territory of Russia, growing in wild nature as well as introduced in botanical gardens, are given.

487: -.072

In 1992 and 1993, 411 live reindeer were shipped by air from Hagemester Island to the Anchorage area, Alaska. Reindeer were either rounded up by helicopter and then corralled or captured by net-gun fired from a helicopter. Outcome of both capture events showed that helicopter corraling of reindeer was more successful than catching them with a net-gun and that post-rut rounding up was more successful than rounding up during the rut itself.

488: +.152

The Noisy Scrub-bird is a small, semi-flightless insectivore which forages in leaf litter and the lower stratum of dense vegetation. More widespread when discovered last century the species declined rapidly after European settlement of Western Australia due to habitat clearing and large scale, uncontrolled wildfires. A small, remnant population survived in dense low forest and thickets on Mt Gardner at Two Peoples Bay. Exclusion of fire from scrub-bird habitat allowed the population at Two Peoples Bay to increase through natural breeding. Translocations to new sites, where successful, have provided more habitat for the scrub-bird resulting in seven sub-populations in the area between Oyster Harbour and Cheyne Beach east of Albany. Rapid increases in numbers have occurred in the Mt Manypeaks area in recent years. The whole population has now increased to 10.5 times its size at rediscovery. This paper reviews Noisy Scrub-bird conservation efforts during the 35 years since its rediscovery and focuses on recent progress, population trends, and the current status of the species. Successful conservation management has been based on research into the scrub-bird's biology and ecology and has involved habitat reservation and protection, fire management, population monitoring, and translocation. Scrub-bird conservation has also provided benefits for other threatened species.

489: +.172

The Pampas deer (*Ozotoceros bezoarticus* L. 1758) is the most endangered neotropical cervid, and in the past occupied a wide range of open habitats including grassland, pampas, savanna, and cerrado (Brazil) from 5 degrees to 41 degrees S. To better understand the effect of habitat

fragmentation on gene flow and genetic variation, and to uncover genetic units for conservation, we examined DNA sequences from the mitochondrial control region of 54 individuals from six localities distributed throughout the present geographical range of the Pampas deer. Our results suggest that the control region of the Pampas deer is one of the most polymorphic of any mammal. This remarkably high variability probably reflects large historic population sizes of millions of individuals in contrast to numbers of fewer than 80 000 today. Gene flow between populations is generally close to one migrant per generation and, with the exception of two populations from Argentina, all populations are significantly differentiated. The degree of gene flow was correlated with geographical distance between populations, a result consistent with limited dispersal being the primary determinant of genetic differentiation between populations. The molecular genetic results provide a mandate for habitat restoration and reintroduction of Pampas deer so that levels of genetic variation can be preserved and historic patterns of abundance can be reconstructed. However, the source of individuals for reintroduction generally should be from populations geographically closest to those now in danger of extinction.

490: +.100

The Asp viper (*Vipera aspis*) went extinct at several localities in northwestern Switzerland during the past decades. The present study shows that localities where the species went extinct are overgrown by forest, whereas localities where *V. aspis* still occurs are free of forest. The genetic variability of the extant viper populations in the study area does not follow any geographic pattern. This suggests that gene flow may have occurred until recently within a large area of the snake's distribution area. The present study also shows that small populations have a smaller genetic variability than large ones. To preserve the genetic variability it is important to protect not only the small, but also the large populations. Translocations of vipers from large into small populations are accompanied by many problems, e.g. the introduction of pathogens or locally maladaptive animals. Therefore, it is better to maintain the habitat suitable for the viper by regularly cutting the new-growing bushes and trees. Large populations can be promoted by enlarging the area of their habitat and connecting them with neighbouring populations.

491: -.097

Fourteen radio-tagged red squirrels were released in pine woodland containing grey squirrels. Movements of the squirrels were related to the tree species of the donor site. Survival after release was lower than for the grey squirrels: of 11 red squirrels that survived at least a week, only three survived more than three months and none for four months. More than half were eaten or cached by predators, mainly foxes; an experiment with grey squirrel carcasses indicated that they had been killed, not scavenged after death. Hypertrophied adrenals, disease and loss of weight indicated stress as another factor in the deaths. Data on overlap of core ranges, and reluctance of red squirrels to enter traps used by grey squirrels in the mixed population, indicated interference competition between the two species, with grey squirrels possibly dominant. We recommend: (i) that care should be taken to release translocated animals in similar habitat to their origin; (ii) that grey squirrels should be excluded from future release areas until red squirrels have settled and, before biodiversity is reduced by landscape management for red squirrels; (iii) more research to determine whether interactions with grey squirrels or differential predation will ultimately displace red squirrels in conifers.

492: +.154

The responses of ruffe (*Gymnocephalus cernuus* (L.)) abundance to eutrophication were studied in

the brackish water of the Baltic Sea off Helsinki. The productivity gradients in the area permitted an analysis of the dependence of ruffe catches taken with gill nets in 1969 to 1972 on spatial differences in eutrophication level. There appeared to be a relationship between the level of primary productivity and the catch per unit effort of ruffe. The gill net catches showed that ruffe were more abundant in eutrophic than oligotrophic areas but less abundant in the most eutrophic areas. Due to the better purification of municipal sewage and the relocation of effluent discharge sites, primary production has declined in the most eutrophicated inner bays during recent decades. The responses of ruffe reproduction to these changes were studied on the basis of catches taken with small bench seines in 1982 to 1996. The number of zero-catches of 0+ ruffe increased significantly after oligotrophication, but decreased again in 1996 after the accidental reintroduction of waste waters.

Since 1989 the orang-utan *Pongo pygmaeus* has been a protected species in Taiwan. Between July 1995 and September 1996 a survey was carried out of 16 facilities maintaining orangutans in Taiwan. Data on the management, age, sex and life history were collected for 72 orangutans housed at three public zoos, nine private parks, two animal breeding farms, one rescue centre and a temple. Information on animals registered as privately owned was also examined. This paper presents data on the status of orangutans maintained in Taiwan and gives recommendations for their future management. Reintroduction strategies, developed at a workshop organized by the Pingtung Rescue Center for Endangered Wild Animals, are also presented.

494: +.047

Effective live-trapping of beaver (*Castor* spp.) has been and will continue to be necessary for introductions, re-introductions, translocation for the preservation of populations, removal of nuisance beaver, and to obtain animals for fur breeding, zoological gardens and research. The aim of this study was therefore to review the existing knowledge about live-trapping through a literature study, contact with individuals involved in live-trapping, and personal experience. Before starting live-trapping, the area used by the beaver should be determined by careful reconnaissance. Beaver are usually captured either in unbaited traps placed at sites frequently visited by beaver, or in traps baited with castoreum or an aspen twig. Human scent on traps and around the trap site may be reduced by adding mud, water or scent. Usually Bailey or Hancock traps are used for live-trapping beaver. The Hancock trap is preferable because of its greater catch efficiency and versatility. Other traps reviewed are the Breathe Easy trap, Scheffer-Couch trap and different types of cage traps. Other methods used for live-trapping of beaver are snares (often considered highly effective), the Byelorussian trapping method, nets and seines, landing nets, pits and enclosures. Capture methods involving the destruction of lodges/dens and dams have often been employed in the past. Such methods require special permission in most countries and are usually not to be recommended. The Eurasian beaver (*C. fiber* Linnaeus, 1758) is reportedly more difficult to live-trap than its North American counterpart (*C. canadensis* Kuhl, 1820). New, effective methods for live-trapping of beaver also need to be developed.

495: +.087

Black-footed ferrets *Mustela nigripes* are considered one of the world's most endangered mammals. The last known wild population was found in Meeteetse, Wyoming, and it collapsed due to an epizootic of canine distemper, but 18 free-ranging ferrets were successfully captured to initiate a breeding programme. Captive propagation has been successful and, throughout the last

12 years, more than 2,600 kits have been born in captivity. Reintroduction began in 1991. Since then, ferrets have been released in Wyoming, Montana, South Dakota, and Arizona, USA. In 1995, reintroduction efforts were discontinued in Wyoming due to an epizootic of sylvatic plague. Montana and South Dakota first received ferrets in 1994. Reproduction in the wild was consistently successful and by 1998 there were approximately 100 wild-born young between both sites. Expectations are high that a viable wild population can be established in one or both of these states. Reintroduction began in Arizona in 1996 and current efforts are aimed at developing on-site breeding techniques in outdoor naturalistic enclosures. A new reintroduction/on-site breeding area was established in the Colorado-Utah border area in 1998. The ferret programme has been using scientific research as a tool to direct recovery efforts. Experimental work has demonstrated that a naturalistic captive environment helps "precondition" black-footed ferrets for life in the wild and significantly increases survival after release. Results from captive and field research have been critical in shaping current recovery efforts.

498: -.035

Created in 1934 in Eastern Rwanda, the Akagera National Park (ANP) has been the scene of two introductions and one reintroduction of large ungulates. Two male and four female black rhinoceros, a species which never lived before in the ANP but was present in Tanzania, beyond the river Akagera matching approximately the international border and working as a biogeographical barrier, were introduced in 1957 ; these animals reproduced and spread over the whole savanna. Their real number was never accurately known as they were regularly poached by Rwandees and Tanzanians. About ten specimens were still living before the Rwandese war and at least four at the end of 1996. The last elephants living in the ANP were noticed in 1960-61 before the species was reintroduced in 1975. The government had decided to eradicate a population of some 150 individuals causing trouble to peasants in the Bugesera ; all large, aged animals were shot whereas 25 young ones were transferred into the ANP, where they settled in the lakes border zone. There were 45 individuals before the war and these seem to have escaped from damages. The giraffe is considered a species never living for historical times in the area presently known as ANP. A personal deal between the president of Kenya and the former president of Rwanda resulted in the introduction in 1986 of six young animals - two males and four females - in order to improve the park diversity and attractiveness. Scientists were reluctant. The animals reproduced, extended their home range, and their numbers grew up ; they resisted the war and some 20 individuals were still living in December 1997. The reintroduction in the ANP of the elephant from a Rwandese population was legitimate. The introduction of the black rhinoceros was questionable. The introduction of giraffes had no biological justification and was opposed by scientists : they were sure that the operation would be a wreckage. Paradoxically, it is thanks to the presence of giraffes that the new governmental authorities decided it was worth preserving 100 000 ha of the park, considering that the giraffe investment had to be saved. Non-scientific arguments succeeded where biological ones had not...

499: -.010

The disappearance of the Otter, linked with anthropological factors, is also due to contamination of its food by PCB and heavy metals (cadmium, mercury, lead). With a view to reintroducing or strengthening a population, it was suitable to determine which rivers in the Rhone-Alpes area could offer feeding possibilities of satisfactorily quality. Seven rivers were selected as they all offered favourable possibilities for otters to settle and as more or less old observations had been made on their courses. The Allier river, which still shelters important otter populations, was chosen as reference. The PCB and heavy metals accumulate in the fats in different ways

according to the species and diet, so that five species of fish (Gudgeon -*Gobio gobio*-, Trout -*Salmo trutta*-, Barbel -*Barbus barbus*, Bladjeon -*Leuciscus souffia*-, Chub -*Leuciscus cephalus*-) among the most abundant were chosen. The analyses for PCB show generalized contamination. The Bladjeons of the Isere river are definitely more contaminated than those of the Drome or the Buech rivers. The Chub of the Rhone and Guiers Rivers are less contaminated than those of the lower part of the Rhone, where human and industrial concentration is important. The Gudgeon and Barbel have relatively weak amounts, whereas the Trout of the Arve river have average ones. The Buech, the Drome, and the Allier are the least polluted rivers, while the most polluted by PCB are the Arve, the Isere and the lower Rhone. Lead was not traceable in any of the samples. The highest rates of cadmium and mercury are to be found in the upper Rhone; but they are relatively low and the concentrations in heavy metals do not seem to be an essential limiting factor. At present, a reintroduction on the Drac, the Isere, the Arve, and the lower Rhone cannot be contemplated. The Ain and the upper Rhone are in an intermediate position. The Drome and the Buech are comparatively favourable.

500: +.164

The pollination of flowering plants by animals represents a critical ecosystem service of great value to humanity, both monetary and otherwise. However, the need for active conservation of pollination interactions is only now being appreciated. Pollination systems are under increasing threat from anthropogenic sources, including fragmentation of habitat, changes in land use, modern agricultural practices, use of chemicals such as pesticides and herbicides, and invasions of non-native plants and animals. Honeybees, which themselves are non-native pollinators on most continents, and which may harm native bees and other pollinators, are nonetheless critically important for crop pollination. Recent declines in honeybee numbers in the United States and Europe bring home the importance of healthy pollination systems, and the need to further develop native bees and other animals as crop pollinators. The "pollination crisis" that is evident in declines of honeybees and native bees, and in damage to webs of plant-pollinator interaction, may be ameliorated not only by cultivation of a diversity of crop pollinators, but also by changes in habitat use and agricultural practices, species reintroductions and removals, and other means. In addition, ecologists must redouble efforts to study basic aspects of plant-pollinator interactions if optimal management decisions are to be made for conservation of these interactions in natural and agricultural ecosystems.

501: +.022

The Lake Eacham rainbowfish (*Melanotaenia eachamensis*) was declared extinct in the wild in the late 1980s after it disappeared from its only known locality, an isolated crater lake in northeast Queensland. Doubts have been raised about whether this taxon is distinct from surrounding populations of the eastern rainbowfish (*Melanotaenia splendida splendida*). We examined the evolutionary distinctiveness of *M. eachamensis*, obtained from captive stocks, relative to *M. s. splendida* through analysis of variation in mtDNA sequences, nuclear microsatellites, and morphometric characters. Captive *M. eachamensis* had mtDNAs that were highly divergent from those in most populations of *M. s. splendida*. A broader geographic survey using RFLPs revealed some populations initially identified as *M. s. splendida*, that carried *eachamensis* mtDNA, whereas some others had mixtures of *eachamensis* and *splendida* mtDNA. The presence of *eachamensis*-like mtDNA in these populations could in principle be due to (1) sorting of ancestral polymorphisms, (2) introgression of *M. eachamensis* mtDNA into *M. s. splendida*, or (3) incorrect species boundaries, such that some populations currently assigned to *M. s. splendida* are *M. eachamensis* or are mixtures of the two species. These alternative hypotheses were evaluated

through comparisons of four nuclear microsatellite loci and morphometrics and meristics. In analyses of both data sets, populations of *M. s. splendida* with eachamensis mtDNA were more similar to captive *M. eachamensis* than to *M. s. splendida* with splendida mtDNA, supporting hypothesis 3. These results are significant for the management of *M. eachamensis* in several respects. First the combined molecular and morphological evidence indicates that *M. eachamensis* is a distinct species and a discrete evolutionarily significant unit worthy of conservation effort. Second it appears that the species boundary between *M. eachamensis* and *M. s. splendida* has been misdiagnosed such that there are extant populations on the Atherton Tableland as well as areas where both forms coexist. Accordingly we suggest that *M. eachamensis* be listed as vulnerable, rather than critical (or extinct in the wild). Third, the discovery of extant but genetically divergent populations of *M. eachamensis* on the Atherton Tableland broadens the options for future reintroductions to Lake Eacham.

502: +.331

Following reports of dramatic declines in managed and feral honey bees from nearly every region of North America, scientists and resource managers from the U.S., Mexico, and Canada come together to review the quality of the evidence that honey bees as well as other pollinators are in long-term decline and to consider the potential consequences of these losses on the conservation of biodiversity and the stability of the yield of food crops. These experts in pollination ecology confirmed that the last 5 years of losses of honeybee colonies in North America leaves us with fewer managed pollinators than at any time in the last 50 years and that the management and protection of wild pollinators is an issue of paramount importance to our food supply system. Although there are conclusive data that indicate 1200 wild vertebrate pollination may be at risk, data on the status of most invertebrate species that act as pollination agents is lacking. The recommendations from a working group of over 20 field scientists, presented here, have been endorsed by 14 conservation and sustainable agriculture organizations, research institutes, and professional societies including the Society for Conservation Biology. Among the most critical priorities for future research and conservation of pollinator species are (1) increased attention to invertebrate systematics, monitoring, and reintroduction as part of critical habitat management and restoration plans; (2) multi-year assessments of the lethal and sublethal effects of pesticides, herbicides, and habitat fragmentation on the wild pollinator populations in and near croplands; (3) inclusion of the monitoring of seed and fruit set and floral visitation rates in endangered plant management and recovery plans; (4) inclusion of habitat needs for critically-important pollinators in the critical habitat designations for endangered plants; (5) identification and protection of floral reserves near roost sites along the "nectar corridors" of threatened migratory pollinators; and (6) investment in the restoration and management of a diversity of pollinators and their habitats adjacent to croplands in order to stabilize or improve crop yields. The work group encourages increased education and training to ensure that both the lay, public and resource managers understand that pollination is one of the most important ecological services provided to agriculture through the responsible management and protection of wildland habitats and their populations of pollen-vectoring animals and nectar-producing plants.

503: +.061

Due to over-hunting c. 1200 Eurasian beavers *Castor fiber* survived in eight relict populations in Europe and Asia at the beginning of the 20th century. Following hunting restrictions and translocation programmes in IS countries, the Eurasian beaver became re-established over much of its former range, and presently numbers c. 430 000. The translocated populations often consist of a mixture of geographical forms. Preservation of the original, unmixed populations has therefore top

priority. all five in Europe have reached the assumed minimum viable population size of c. 1880 animals each, but the three in Asia are still endangered. Their protection should be carried out at the level of river catchments. Nowadays the main threats for beavers are habitat destruction and introduced North American beavers *Castor canadensis*. On the other hand, growing beaver populations cause increasing conflicts with man, and population and/or damage control may therefore be required. In view of these two very different problems, we conclude that the conservation of beavers is best served by preservation and restoration of riparian woods with intact natural water regimes. (C) 1998 Elsevier Science Ltd.

504: +.031

The lycaenid butterfly, *Maculinea rebeli*, and its specialist parasitoid, *Ichneumon eumerus*, live in small, closed populations. Given the threatened status of the butterfly, it is reasonable to assume that its specialist parasitoid is even more vulnerable to local extinction than the butterfly host. Based on a mechanistic model recently developed for the tightly-woven community surrounding *M. rebeli* at a site in the Spanish Pyrenees, we investigate how the removal of habitat, and more particularly, specific habitat promoting the persistence of the butterfly, affects the population persistence of the parasitoid. Because of the relatively small impact of the parasitoid on the butterfly population in the Spanish Pyrenees, guidelines for conserving the parasitoid are only slightly more restrictive than those for its host. It is argued that at sites of more marginal quality for the butterfly than the reference site, achieving the dual aims of conserving both species will be more problematic.

505: +.040

Details of a reintroduction of *Maculinea teleius* (scarce large blue butterfly) and *Maculinea nausithous* (dusky large blue butterfly) into a nature reserve in the Netherlands are given. The introduced population of *M. teleius* expanded during the first three years. In contrast, the newly established population of *M. nausithous* declined in the year after the reintroduction but expanded later. After a considerable increase in numbers, this species can nowadays be seen in two subpopulations: one in and one outside the nature reserve. Although the results are quite positive with respect to the numbers of butterflies, some alarming features have also been found. Both species, but especially *M. teleius*, have a very low mean minimal lifetime, which makes them more susceptible to stochastic catastrophes. While the area populated by *M. nausithous* is still expanding, *M. teleius* can only be found on the meadow where it was released and has not dispersed at all. The possible consequences of reintroductions are discussed.

506: +.103

1, Reintroduction of plants and animals has become a common practice in the attempt to establish, re-establish or augment endangered populations. The fate of these translocation programmes is likely to depend, on the one hand, on several ecological attributes of the introduced species, on the other hand on introduction effort.² In a recent paper, Veltman, Nee & Crawley (1996) reported the correlates of introduction success of exotic birds released by humans in New Zealand before 1907. introduction effort (minimum number of release events and minimum number of released propagules) accounted for most of the variance in introduction success.³ One of the factors potentially affecting the establishment of new populations concerns the intensity of sexual selection. Sexually selected species may be more vulnerable to extinction risks for several reasons (they may be more sensitive to both environmental and demographic stochasticity) and therefore have lower introduction success when compared to nonsexually selected species.⁴ In the present

study the data set reported by Veltman et al. (1996) was used to address the particular issue concerning sexual selection and introduction success. Each bird species was scored as monochromatic or dichromatic; plumage dichromatism is supposed to have evolved under sexual selection pressures. These scores were then correlated to the fate of introduction.⁵ Plumage dichromatism was found to be, as expected, a significant predictor of introduction success, after removing the potential confounding effect of introduction effort. Dichromatic species had lower introduction success than monochromatic species. This pattern holds true for nonpasserines and passerines, although the correlation between plumage dichromatism and introduction success was not significant for the latter.⁶ These results indicate that dichromatic species may experience reduced chances of establishing new populations when compared to monochromatic species. The presumed mechanisms involved in this phenomenon range from a reduced ability to adapt to a novel environment, to an increase in the risks of extinction through environmental and demographic stochasticity.

507: -.018

A literature search on hazel grouse, *Bonasa bonasia*, biotopes has shown that this bird most often frequented "heterogeneous" woodlands, i.e. those in which it will find high trees, understoreys and edges. A satellite image (LANDSAT August 1991) was analyzed to detect habitats potentially suitable for a theoretical reintroduction of the hazel grouse in the Cevennes National Park (40,000 ha). A preliminary treatment of the image allowed to locate wooded habitats and to identify the heterogeneous sectors. Then, based on a selection in the field of biotopes that are "favourable" to the species, a classification of the vegetation cover, called "supervised classification", was made for the whole park to locate favourable sectors, which were arranged hierarchically. The method was validated by a survey among the agents of the "Office National des Forets", and by several field trips. On condition that the selected criteria are the most relevant ones and that biases are minimized, an analysis of the image thus carried out has proven to be significant. In the Cevennes National Park, 30% of the woodlands would be favourable for a reintroduction of the hazel grouse. However, because of the dispersion of these favourable sectors, a "viable" population could only be established in the Aigoual sector. The less extensive, more broken up but not isolated sectors of Bouges, Monts Lozere and Goulet, could be used in case of a hypothetical expansion of the population of Aigoual.

508: +.378

Long-overdue concerns about the genetic effects of releases of hatchery-reared progeny on wild populations have been increasingly addressed during the past 20 yrs. Because of an extensive history of translocation and culture, much attention in both of these categories has focused on salmonid species. Native salmonids have been indirectly affected by translocations through such activities as induced overharvest in stock mixtures, disease introductions, and displacements resulting in fragmented populations with reduced numbers and, commonly, localized extinctions. Direct genetic effects through introgressive hybridizations of translocated salmonids have resulted in replacement of many native populations by hybrid swarms. Genetic effects from salmonid culture have led to losses of variability, both within the cultured populations and between the total cultured and wild populations, and to adaptive divergences distinguishing cultured and wild populations. Examples are provided that show that the overall salmonid experience is directly relevant to marine culture as well, although special considerations deal with the lower among-population diversity and greater fecundity often found in marine species. As marine enhancement programs inevitably expand identifying and preserving natural populations are concerns common to harvest, management, and conservation interests. Coordinated rather than polarized approaches

to these concerns best serve all parties as well as the irreplaceable resources.

509: +.176

Capercaillie (*Tetrao urogallus*) populations are declining in western parts of their range, including Scotland. It has been proposed that their numbers, and the extent of their range in Scotland be increased to reduce the risk of a second extinction in the UK. The feasibility of a reintroduction of capercaillie to coniferous plantations in southern Scotland was assessed by undertaking a population viability analysis. Following a review of capercaillie ecology and habitat requirements, VORTEX population simulation software was used to identify a minimum viable population (MVP). From this the minimum dynamic area of suitable habitat required in order to support such a MVP was then calculated. It was estimated that a minimum of 60 individuals would be required in approximately 5000 ha of habitat in order for the population to have a >0.95 probability of surviving for 50 years. Supplementation of populations with two unrelated individuals every five years reduced the MVP to ten individuals. Further simulations were run in order to establish the sensitivity of the model to changes in three key parameters. Assessment of areas of suitable habitat identified two potential release sites, Wauchope and Newcastleton forests, in southern Scotland. Some practical considerations relating to management of a release population are outlined. It was concluded that an appropriately planned and resourced reintroduction was feasible.

514: +.145

The Yellow-shouldered Amazon (*Amazona barbadensis*) is one of the most endangered species of parrots in Venezuela. An integrated conservation program has focused on reversing the causes of parrot population decline on the Macanao Peninsula in Margarita Island. As a result, the parrot population on the island has increased to about 1900 individuals in 1996 from an estimated population of 750 in 1989, when the project started. Cooperation from national and local authorities and the project's community outreach have resulted in several confiscated chicks. Whereas most confiscated chicks were successfully reintroduced in a cross-fostering nest program, some had to be kept in captivity for later release. We hand-reared 14 *A. barbadensis* and housed them for a year in a large outdoor aviary. Before release the birds were screened to determine their general health. Four parrots were fitted with radio transmitters and monitored for a minimum of 11 months. All 4 birds with radio transmitters survived and adapted successfully to their natural environment, 10 of the 12 released parrots survived at least 1 year, and 1 was seen alive 34 months after release. Integration into wild groups varied from 5 to 9 months, with the two youngest parrots showing a slower integration process. None of the parrots reproduced the first year after release. Later three were seen scouting nesting holes with their partners, and one of the parrots was confirmed attending a nest with three eggs 28 months after release. Two chicks fledged from this nest. A substantial portion of the success of this program rests on 5 years of previous work on environmental education, public awareness, and studies on the parrot's biology. To provide some guidance on the costs of reintroduction projects, we estimated an overall expenditure of about U.S. \$2800 per parrot. Previous attempts to reintroduce captive-raised parrots are introduced to an area with a resident population. Although reintroduction can significantly reduce the chances of extinction, it also involves some risks. The long-term solution against extinction of *A. barbadensis* will be a combination of scientific understanding of their biology and habitat, awareness by local human communities, reduction in the wild bird trade, and continued commitment by conservation enforcement agencies.

516: +.193

. Species richness in calcareous grassland is discussed against the background of historical dispersal processes associated with traditional land-use management such as grazing, but also the artificial establishment by hayseed. Important vectors in the traditionally man-made landscape were sheep and cattle or other livestock such as goats. Calcareous grasslands were not only connected to each other but also to other habitats such as villages, forests, arable fields and heathlands by these vectors which could cover large distances (e.g. transhumance shepherding), which is not the case in the current man-made landscape. Species richness after restoration management of abandoned and afforested calcareous grasslands was predicted by using characters of dispersability in space and time. These were the persistence of the species in the vegetation and the diaspore bank after abandonment or afforestation and the dispersal capacity through wind and sheep. The results reveal that reintroduction of sheep grazing is necessary to reestablish the original species richness. The first validation of the prediction of the succession on clear-cut sites and a comparison with data of species composition in abandoned quarries and the surroundings made it obvious that a species' own dispersal capacity in space is very low except for some well wind-dispersed species. Therefore, it is recommended to include and to simulate dispersal processes in future management to be able to restore the original species richness.

517: -.012

. Rare vascular plant species are endangered worldwide. Population losses are most commonly caused by human-related factors. Conservation management seeks to halt this adverse trend and if possible, to enhance long-lasting self-sustainable populations. In general, rare species are poorly recruited from seed banks, or disperse themselves very poorly. It may be a management option to translocate such plants by seeds and/or transplants. This paper asks which problems may be faced. It is argued that translocation is only acceptable if it is based on knowledge of species biology and ecology and the size and structure of its geographic range through time. Such knowledge of rare species is often lacking. The finite management goal can only be achieved if conservationists closely cooperate with both ecologists and geneticists.

518: +.232

The natterjack toad *Bufo calamita* is rare in Britain, which is at the northwestern edge of its biogeographical range. We investigated the level of genetic differentiation amongst almost all (34 out of 38) of the surviving British populations of this species, and among six new populations established by translocations during the 1980s. For eight microsatellite loci, allele sizes and frequencies were analysed using samples from each of these populations. The populations clustered into three robustly differentiated groups, each of which corresponded with a geographical region (east/southeast England, Merseyside and Cumbria). The Cumbrian populations showed a further weak geographical substructuring into northern and southern clades. The populations in south Cumbria were genetically more diverse than those in any of the other regions, as judged by the mean numbers of alleles per locus and the mean heterozygosity estimates. The translocated populations clustered close to their founders and, with one exception, did not differ significantly with respect to mean allele numbers, heterozygosity or polymorphism level. However, significant genetic differentiation (as measured by unbiased R_{ST}) was found between all but one of the founder-translocation pairs. The implications of this phylogeographic study for the future conservation of *B. calamita* in Britain are discussed.

519: +.202

Historically documented founder events provide opportunities to assess the effects of population

size reductions on genetic variation, but the actual magnitude of genetic change can be measured only when direct comparisons can be made to the source or ancestral population. We assayed variation at nine microsatellite loci in the translocated population of the Laysan finch (*Telespiza cantans*) at Pearl and Hermes reef (PHR), and compared the level of variation to that in the source population on Laysan Island. Heterogeneity in allele frequencies was highly significant at eight of the nine loci, primarily as a result of fluctuations in allele frequencies in the three PHR populations. Intra- and interpopulational measures of genetic diversity generally matched predictions based on the well-documented history of three islet populations at PHR: significantly lower numbers of alleles and polymorphic loci, as well as higher pairwise F_{ST} values and genetic distance, were observed for the two populations that underwent severe size reductions. Changes in heterozygosity at single loci were unpredictable, as both significant increases and decreases were observed in founder populations. A significant excess of heterozygotes was found in two populations and was highly significant over all four finch populations ($P < 0.003$). Estimates of effective population size from temporal changes in heterozygosity and allele frequencies were very small ($N(e)$ less than or equal to 30) as a result of the founding events and the constraints of islet area on population numbers. We concluded that the PHR population is not adequate as a secondary genetic reserve for *T. cantans*, and an alternative refuge needs to be established.

520: -.016

Sandhill Cranes are large, gray birds that are widely distributed in North America. Although Sandhills usually nest in water, they spend most of their time in uplands. Most Sandhill Cranes are migratory, but Florida has a substantial population of resident cranes. Because Sandhills are common in some areas, sick or injured individuals are frequently brought to rehabilitators. This article summarizes the species' distribution and biology, and treatment of its most important health problems. In addition, we describe techniques for raising chicks and strategies for releasing chicks or adults then back to the wild.

521: +.069

During a recent land drainage scheme, a population of the Freshwater Pearl Mussel *Margaritifera margaritifera* (L., 1758) was discovered in a small stream in north-west Wales. The dredging operations effectively destroyed the population which was estimated to have been as high as 5000 individuals. The presence of juvenile shells under 20 mm in the spoil tips suggests this was a viable, recruiting population. An attempt to translocate the remaining mussels to an unaffected downstream site was unsuccessful. The loss of this nationally important population demonstrates the urgent need for comprehensive distributional data upon which an effective conservation policy can be based.

522: +.345

Discovery of populations of the marsh snail *Vertigo moulinsiana* near and within the route of a new road in southern England whilst site clearance was in progress, caused the urgent development of a strategy to protect the animals. The snail's inclusion on Annex II of the European Habitats & Species Directive made it vital for appropriate action to be implemented to protect the snail along the proposed road. As it was not feasible to change the route it was decided to translocate the wetland habitat supporting the *Vertigo moulinsiana* populations to places off-route. As a further safeguard, new marsh habitat was created to provide the opportunity for *V. moulinsiana* colonisation. The methods of translocation and the subsequent monitoring

programme are described. Early results indicate that the translocation of snail rich vegetation has been successful and that the snails are breeding.

524: +.220

All species of howlers are at risk due to habitat destruction. I review the three most serious threats to howler survival-agricultural disturbance, logging disturbance, and hunting-both in a general context and in species accounts. Withal, the adaptability of howlers has allowed them to be a widespread genus throughout Central and South America. *Alouatta* is especially adaptable due to its generalized folivorous diet. I discuss how this adaptability relates to survival in situations of habitat destruction. In addition, I examine howler preference for riverine habitats and their ability to capitalize on secondary forests and secondary growth. I take a practical approach, suggesting some solutions for species survival, which include habitat management and reintroductions. Successful conservation models highlighted are the Community Baboon Sanctuary in Belize, in which villagers manage their lands for the benefit of the black howler and for their own economic benefit from ecotourism, and a village-sustainable logging system in Quintana Roo, Mexico, which has reduced levels of deforestation while benefiting both villagers and howlers, as well as other wildlife. A successful translocation of black howlers in Belize in order to reestablish a viable population is also described. The paper concludes with further suggestions to encourage howler conservation.

525: -.087

As assessed by the IUCN Mace-Lande system, seven (35%) of the 20 *Alouatta* species and subspecies with adequate data are classified as "threatened," i.e., critically endangered, endangered, or vulnerable (Rylands et al, 1995). This percentage is much lower than the 75 to 100% threatened taxa for, the other large-bodied genera: *Ateles*, *Lagothrix*, and *Brachyteles*. Only 5 of the 16 Neotropical genera have lower percentages of threatened taxa than that of *Alouatta*: *Cebuella*, *Pithecia*, *Saguinus*, *Saimiri*, and *Cebus*. The threatened howler taxa occupy small distributions in areas of forest fragmentation. In general, populations are most affected by major habitat disturbance, such as total deforestation and flooding from dam construction, and by human hunters. Facilitated by their ability to exploit folivorous diets in small home ranges, howlers can tolerate considerable habitat fragmentation but not the increased exposure to hunting that may accompany it. Howlers seem particularly vulnerable to yellow fever and bot fly parasitism. Although the former threat may decrease by increasing fragmentation of the habitat, other sorts of parasitism may ino ease in disturbed habitats. The Low genetic variability of the Central American howlers suggests a resistance to inbreeding depression potentially experienced during population

bottlenecks. Greater between-population variability may still exist. Although howlers are not readily bred in captivity, they respond well to translocation. Translocation has been successfully achieved for greater than or equal to 4 howler species and is a viable option for introducing new genetic variability into population fragments and repopulating areas from which howlers are extinct. Their pattern of bisexual dispersal facilitates colonization of regenerating habitats, and in suitable, protected habitats they have shown the capacity for strong population recovery.

526: +.097

There is considerable interest in restoring stocks of Atlantic sturgeon (*Acipenser oxyrinchus*), one of only two dozen extant sturgeons worldwide. Populations of its two subspecies are found in large rivers along the North American coasts of the Atlantic (*A. o. oxyrinchus*) and the Gulf of Mexico (*A. o. desotoi*). Although these populations were severely reduced because of overfishing and, in some instances, blockage of spawning runs, their present statuses, vary from those that still support limited fisheries (St. John River, New Brunswick), to a large but apparently declining population (Hudson River), to relict-sized (Delaware River, Mobile River), to apparently extirpated (Maryland tributaries of Chesapeake Bay; St. Johns, river, Florida). There are two primary alternatives for restoring these populations: (1) eliminating harvest and allowing natural recolonization and increase and (2) hatchery-based stocking (reintroduction or supplementation). We performed genetic analyses aimed at guiding restoration efforts. Mitochondrial DNA analysis revealed strong stock structure along both coasts at the regional and, in some instances, population levels. Estimates of gene flow rates were low and suggested slow natural recolonization rates. Thus, the first alternative avoids the genetic risks of interstock transfer and inbreeding depression that may result from hatchery-based programs, but given the low intrinsic rates of increases and recolonization of Atlantic sturgeon, recovery may take decades to centuries, if it occurs at all. Therefore, it is imperative that the restoration approach be tailored to the particular circumstances and demographics of each population; however, the characteristics of this species and poor funding prospects make this information difficult to obtain. It appears likely that initial Atlantic sturgeon stocking efforts will target systems where they are extinct, as recently occurred in the Nanticoke River of Chesapeake Bay.

527: -.026

In parts of the world such as the Pacific Islands, Australia, and New Zealand, introduced vertebrate predators have caused the demise of indigenous mammal and bird species. A number of releases for reestablishment of these mammal species in mainland Australia have failed because predators extirpated the new populations. The nature of the decline of both extant populations and reintroduced colonies provides information on the dynamics of predation. Predator-prey theory suggests that the effects of predation are usually inversely dependent on density (depensatory) when the prey are not the primary food supply of exotic predators. Thus, such predators can cause extinction of endemic prey species. Three types of evidence can be deduced from the predator-prey interactions that allow predictions for conservation: (1) whether per capita rates of change for prey increase or decrease with declining prey densities, (2) whether predation is depensatory or density-dependent, and (3) the overall magnitude of predation. If this magnitude is too high for coexistence, then the degree of predator removal required can be predicted. If the magnitude of predation is sufficiently low, then the threshold density of prey that management must achieve to allow predator and prey to coexist can also be predicted. We analyzed published reports of both declining populations and reintroduced colonies of endangered marsupial populations in Australia. The observed predation curves conformed to the predictions of predator-prey theory. Some, such as the black-footed rock-wallaby (*Petrogale lateralis*), were classic alternate prey and were

vulnerable below a threshold population size. Others, such as the brush-tailed bettong (*Bettongia penicillata*), have a refuge at low numbers and thus offer the best chance for reintroduction. Our predictions suggest a protocol for an experimental management program for the conservation of sensitive prey species: (1) determination of net rates of change of prey with declining population, (2) improvement of survivorship through habitat manipulation, (3) improvement of survivorship through predator removal, (4) determination of the threshold density above which reintroductions can succeed, and (5) manipulations to change interactions from Type II to Type III. The task in the future is to determine how to change the vulnerability of the prey so that they can have a refuge at low numbers.

528: +.109

A Recovery Team oversaw implementation of a Recovery Plan for the woylie (*Bettongia penicillata ogilbyi* (Waterhouse 1841)) from 1990 to 1995, and then reviewed its conservation status. Using the 1994 IUCN Red List criteria, the team showed that the species had been recovered from Vulnerable to Lower Risk (Conservation Dependent). Furthermore, it no longer met the requirements for listing as a threatened species under Western Australian or Commonwealth legislation and all but one of the specific targets of the Recovery Plan had been achieved. The exception, at least 7.5 percent trap success in a new population at Julimar Conservation Park, had not been met at that time because translocation to Julimar had been delayed. However, a population had been established and was increasing. Criteria for listing threatened species under Western Australian and Commonwealth legislation are based on the subject's status nationally. South Australian legislation requires consideration of its status within the State. The Recovery Team recommended that the authorities responsible for advising the Western Australian and Commonwealth conservation Ministers should convey to them the Recovery Team's conclusions. The woylie has since been removed from categories of threatened taxa established under those jurisdictions. The team recommended to the South Australian authorities that they should review its status within that State. The review is an unpublished report addressed to those authorities who would have to progress the Recovery Team's recommendations. However, as it was the first to use the 1994 IUCN criteria to assess the outcome of an Australian Recovery Plan, the issues encountered by the recovery team provide a useful case study for other people preparing Recovery Plans and reviewing the outcomes. Therefore it is published here.

529: +.081

Since 1960 107 translocations of wild-caught Weka (genus *Gallirallus*) have occurred in New Zealand. Only four of these Weka liberations resulted in a population that persisted for more than 10 years and only one was successful on the North Island (the resultant population is now believed extinct). The reason for these failures was not known. In 1991 members of the Royal Forest and Bird Protection Society commenced breeding North Island Weka *Gallirallus australis greyi* in captivity for another liberation. Between 1992 and 1996 101 weka were released. We used radio telemetry to follow the fates of the first 17 Weka released in the Karangahake Gorge, near Paeroa, North Island, New Zealand to determine possible outcomes of the liberation. Only one of the 17 birds released survived until 242 days post release. Most newly released Weka were killed by predators, mainly dogs. Future Weka and flightless rail introductions should occur only in areas where predators are being removed to allow survival of released birds and production of young to exceed mortality.

530: +.052

The National Commission for Wildlife Conservation and Development was established in 1986 to oversee all wildlife conservation programmes in Saudi Arabia. The Arabian oryx *Oryx leucoryx* is one of the flagship species of the Saudi Arabian reintroduction policy. It has been captive-bred since 1986 at the National Wildlife Research Center near Taif. With the creation of a network of protected areas in the former distribution range of the species, attention has shifted to the release of captive-bred oryx into Mahazat as-Sayd and 'Uruq Bani Ma' arid reserves. Similar programmes carried out in other countries of the Arabian Peninsula underline the need for regional co-operation and pan-Arabic public awareness programmes, in addition to captive-breeding and reintroduction projects.

531: +.231

Tidal marshes have been actively restored in Connecticut for nearly 20 years, but evaluations of these projects are typically based solely on observations of vegetation change. A formerly impounded valley marsh at the Barn Island Wildlife Management Area is a notable exception; previous research at this site has also included assessments of primary productivity, macroinvertebrates, and use by fishes. To determine the effects of marsh restoration on higher trophic levels, we monitored bird use at five sites within the Barn Island complex, including both restoration and reference marshes. Use by summer bird populations within fixed plots was monitored over two years at all sites. Our principal focus was Impoundment One, a previously impounded valley marsh reopened to full tidal exchange in 1982. This restoration site supported a greater abundance of wetland birds than our other sites, indicating that it is at least equivalent to reference marshes within the same system for this ecological function. Moreover, the species richness of birds and their frequency of occurrence at impoundment One was greater than at 11 other estuarine marshes in southeastern Connecticut surveyed in a related investigation. A second marsh, under restoration for approximately ten years, appears to be developing in a similar fashion. These results complement previous studies on vegetation, macroinvertebrates, and fish use in this system to show that, over time, the reintroduction of tidal flooding can effectively restore important ecological functions to previously impounded tidal marshes.

532: +.281

The Sword-grass Brown Butterfly Project (SBBP) is a community driven project initiated by the Knox Environment Society. We are planting habitat at sites between known populations of the butterflies in the hope of increasing their numbers. Project activities include revegetation and propagation, community art, monitoring and translocation. SBBP is also raising public awareness of the needs of Sword-grass Brown Butterfly and other butterfly species within The Basin-Boronia area.

533: -.268

Reintroductions of the endangered razorback sucker *Xyrauchen texanus* and Colorado squawfish *Ptychocheilus lucius* into the Verde River, Arizona, have failed to establish self-sustaining populations. The failure of these reintroductions is often attributed to predation and competition by normative fishes and habitat loss, but parasite infestations (particularly a copepod, *Lernaea cyprinacea*) also have been implicated. We assessed the relationships among fish health, eukaryotic parasites, and bacterial and viral infections of these endangered fishes collected from two locations (Perkinsville and Childs) on the Verde River, Arizona, during February and June 1996. We also examined surrogate nonendangered native fishes (Sonora sucker *Catostomus insignis*, desert sucker *Catostomus clarki*, and roundtail chub *Gila robusta*) and normative species

(common carp *Cyprinus carpio* and smallmouth bass *Micropterus dolomieu*) to determine if there were any systemwide patterns in parasite infestation and health of fishes. All tests for viruses were negative. We identified 19 bacteria (7 known fish pathogens) and 14 parasites from examined fishes. Six of the seven dominant (>10% prevalence) parasite taxa were more prevalent at Perkinsville than at Childs; *Lernaea* occurrence was not related to site. Time of year did not have a consistent effect on parasite prevalence across fish species, and *Lernaea* occurrence was not related to time of year. *Lernaea cyprinacea* were present on 17.3% of the 313 fish examined; 67% of the parasitized fish were infected with a single *L. cyprinacea*. Regression analyses on the calculated health assessment index, hematocrit, and leukocrit indicated that month, site, *Trichodina*, *Ichthyophthirius* (*ich*), *Ornithodiplostomum* and *Posthodiplostomum* (white grubs), and the cestode *Isoglaridacris hexacotyle* affected the health of fishes. However, all fishes examined were considered "healthy," suggesting that parasites were not seriously affecting Verde River fishes. A suite of factors is likely responsible for the failure of these endangered species to reestablish.

534: +.019

The results of two reintroduction programmes of Badgers are discussed, one with repeated releases of a few individuals at time, and the other with a more or less simultaneous release of eight animals. It turned out that the latter attempt was much more successful. In the former attempt more animals left the study area and especially (but not always) the last introduced animal was chased away by Badgers that had already settled. Most of the straying animals became victim of traffic or drowned in a sheetpiled watercourse. As mustelids can disperse over rather long distances, reintroduction is only relevant if artificial barriers can be removed and the habitat quality is restored. Reintroduction to overcome natural barriers is quite out of the question.

535: +.028

1. We examined the effects of phosphorus, an important pollutant in fresh waters, on mussels *Anodonta anatina* and embryos of European bitterling *Rhodeus sericeus amarus*. These species are involved in an unusual symbiosis, with the fish depositing eggs inside the mussels' gills, where the embryos develop for 3-6 weeks until the larvae leave the mussel.² High concentrations of phosphate (500 $\mu\text{g L}^{-1}$) and higher caused a significant increase in the rate of premature expulsion and emergence of bitterling embryos from the mussels, with a concomitant increase in fish mortality.³ At concentrations of 750 $\mu\text{g L}^{-1}$) and higher, mussels reduced their frequency of ventilation and movements through the substratum.⁴ These results have implications for understanding the nature of the symbiosis between the fish and their mussel hosts, showing that mussels have control over bitterling developing in their gills. The premature expulsion of bitterling embryos at high phosphate levels is detrimental to the fish that they harbour.⁵ Recommendations for the conservation of bitterling and species of mussels, which are threatened or endangered over parts of their ranges, include reductions in levels of phosphorus in natural habitats and the need for low levels in reintroduction sites for the fish and their mussel hosts.

536: +.302

As effective population size (N_e) decreases, genetic factors may become relatively important to a population's or species' persistence. Conservation biologists should be aware of anything that can potentially cause a sudden reduction in N_e . I used simple models to illustrate how certain types of female mating preferences combined with certain types of male traits may lead to a sudden and substantial decrease in N_e . Specifically, if and when there is a sudden 'downward' shift in the

expression of condition-dependent male traits, females using fixed-threshold mate choice criteria might find fewer acceptable males. While mechanisms of female choice remain elusive, a variety of sexually selected traits may be condition dependent. Because the expression of condition-dependent traits is likely to be impacted by natural or human-induced environmental changes, behavioral and conservation biologists should pay special attention to them around the mating season. Armed with knowledge of condition-dependent male traits, it may be possible to minimize the impact on condition-dependent traits while planning translocations or reintroductions.

537: -.203

The present status and distribution of Cape buffalo *Syncerus caffer caffer* in southern Africa is reviewed. The present estimate of southern Africa's buffalo populations are Botswana 29 300 (+/-9000), Zimbabwe 48 200 (+/-21000), Namibia 2 800 (+/-1000) and South Africa 31 500 (+/-10000). Buffalo numbers for Mozambique are incomplete, but a decline is estimated at 79% in the buffalo population in the Marromeu Complex. The total number of buffalo in the six largest excluding Mozambique, has decreased by more than 50% between 1991 and 1996. The main factor influencing buffalo numbers and distribution in the sub-region is the development of the cattle industry, followed by drought and disease. Only South Africa and Zimbabwe activity produce surplus buffalo for translocation or sale. However, the cumulative loss of genetic diversity in these small, isolated populations may have potentially serious consequences.

538: +.091

Reintroduction programs are a high-risk conservation strategy for restoring populations of endangered species. The success of these programs often depends on the ability to identify suitable habitat within the species' former range. Bioclimatic analysis offers an empirical, explicit, robust, and repeatable method to analyze large areas rapidly using a small number of locality records, and in turn predicting (and/or reconstructing) its potential distribution limits. This approach therefore can estimate the broad limits of the distribution of a taxon, using data that may be inadequate for standard forms of statistical analysis. We illustrate the potential value of bioclimatic modeling for reintroduction biology using a case study of the highly endangered Helmeted Honeyeater (*Lichenostomus melanops cassidix*) from Victoria, southeastern Australia. The results of our analyses assisted us to both predict the former range limits of the Helmeted Honeyeater and determine the broad limits of those areas that may contain potentially suitable sites for future reintroduction programs for the subspecies. The analysis predicted that the range of the Helmeted Honeyeater extends from the Yarra River district east of Melbourne, south to the Western Port Bay and east as far as the Morwell area of Victoria. The climatic characteristics of habitat occupied by the extant population of the Helmeted Honeyeater were found to be unique within its predicted range. We recommend that reintroduction efforts therefore be concentrated within this small area, as has occurred to date.

539: +.003

This review of Iowa's mammal fauna at the close of the 20th century summarizes changes in distributional patterns following Euroamerican settlement in the early 1800s. Data from historical records, museum specimens, and presettlement late Holocene fossils indicate presence of 69 resident mammals at that time. Hunting pressures and the conversion of prairie and forest to agricultural fields reduced the populations and ranges of many state mammals, and 14 species were extirpated by 1900. An additional 15 species are either uncommon or rare today, and the Iowa Department of Natural Resources lists four species as endangered, three as threatened and

one as of special concern. Species dependent upon either forest or prairie have suffered most; forest-edge species generally have thrived and even increased. River otters and a captive bison herd were reintroduced recently, and several (like the spotted skunk and the bobcat) have benefitted from setaside acreage, flood-plain and wetland reclamation, and roadside management initiatives. Species distribution and relative abundance vary slightly among the state's five geographic regions.

540: +.143

Repeated liming of Hovvatn during the 1981-1995 period assured successful reintroduction of lake spawning brown trout, *Salmo trutta*. Poor natural recruitment to the population was associated with low survival during early life stages (before hatching) as shown by the 0.5, 3.5, 0.9 and 1.0% of live embryos found in natural redds during the 1992-1995 period, respectively. The low survival was most likely caused by the combination of shallow spawning areas (<2.0 m) and acidic runoff (pH 4.0-4.8) which overlaid the limed part of the water body during the ice covered period. It is therefore concluded that this type of episodic acidification poses a major threat to lake spawning salmonids, and that it can retard or inhibit biotic recovery towards preacidified conditions expected as a result of liming. Addition of limestone gravel (8-32 mm) onto spawning grounds was an efficient alternative liming strategy as 33-36% live embryos were found in this substrate. Conversely, the trout actively avoided additions of shellsand, a behaviour most likely caused by the small particle size of shellsand (3-7 mm) relative to natural spawning gravel.

541: +.124

Flying foxes (*Pteropus* spp.) are important pollinators and seed dispersers in many island ecosystems. Populations of flying foxes have declined markedly on most islands in the South Pacific since the 1940's. One potential conservation strategy is to reintroduce bats on islands where they historically occurred. In this manner, the risk of species extinction due to local catastrophic events can be reduced. Ideally the source population for such reintroductions must be robust. One such population might be in the Kingdom of Tonga, where flying foxes have been protected by local custom for a long time. However, virtually nothing has been published on the numbers, locations, and reproductive biology of *Pteropus tonganus* in Tonga. I therefore censused flying fox populations on as many islands as possible from 28 June to 26 July 1995. I found seven major roosts containing a total of 3,582 bats on Tongatapu, one roost with 30 bats in the Ha'apai group, and 27 roosts with a total of 5,925 bats on 14 islands within the Vava'u group. Thus, the flying fox population in Tonga seems robust and dispersed on many islands and is therefore a valuable potential source population.

542: +.111

The Zanzibar red colobus *Procolobus kirkii* is one of Africa's most endangered primates, with only c. 1500-2000 individuals remaining in the wild. The authors made preliminary surveys of three areas where this monkey was translocated or introduced in the 1970s and 1980s. It appears that only one of these releases was successful. A total of 67 animals were caught and translocated or introduced (including four that died during the process). Thirteen to 20 years later, 62-70 red colobus were located at the three sites; i.e. there had been a net gain in colobus numbers as a result of the translocations and introduction. One attempt apparently failed because of insufficient habitat, and another perhaps because of insufficient numbers of colobus or an imbalance in the age and sex composition of animals released. The one successful translocation involved moving a fairly large number of monkeys (36) into a forest with a relatively high diversity of tree species. In

light of these findings, the authors recommend that far more attention be given to protecting the monkeys and their habitat where they currently exist, rather than spend time and money on translocations that are as likely to fail as to succeed.

543: +.165

Captive propagation has become increasingly important in preventing extinction in many avian species, including the Hawaiian crow (*Corvus hawaiiensis*) and Mariana crow (*C. kubaryi*). We used 3 surrogate species, common raven (*C. corax*), American crow (*C. brachyrhynchus*), and black-billed magpie (*Pica pica*), to develop captive-rearing protocols for endangered corvids. Here we compare the health, growth, and survival among nestlings hand-reared on 14 feeding regimes. Frequency of feeding chicks for the first 2 weeks after hatch varied from once every 30 min to once every 2 hr. From 2 weeks until near fledging age, frequency of feeding varied from once every hour to once every 3 hr. Initial amounts of food fed varied from unlimited (*ad libitum*) to a restricted amount (a total of 15, 25, or 40% of a chick's body mass). Combinations of frequent feeding and large amounts of food produced fast-growing, heavy birds with few fault bars in their feathers, but all hand-reared nestlings grew more slowly than wild-reared chicks. Initial amount of food offered to day-old chicks affected growth and survival more than frequency of feeding in very large passerines (e.g., common ravens). In small- to medium-sized passerines (e.g., black-billed magpies, American crows), frequency of feeding affected growth and survival more than initial amount of food.

544: +.075

Methods for trawl-acoustic surveys were developed and used on the basis of visual registration of the state of acoustic recording with simultaneous recording of the size of catches, using *T. chalcogramma* as an example. Five surveys of the resources of the species were carried out near western Kamchatka during the prespawning and spawning periods in February-April 1996. Main concentrations of the wall-eye pollock were shown as were their appearance, translocations and disappearance. A wave of winter spawning predominated. The second spawning wave taking place in spring was observed in southern areas. The total potential catch was evaluated on the basis of the results of a series of surveys. Five groups were identified based on the sizes of individuals, and the location and time of spawning; spawning in two of the groups took place in spring. These groups regardless of their smaller size have higher commercial value and require further investigations and immediate protection measures.

547: -.147

Eight of 11 native forest bird species on Guam were extirpated by the introduction of the Brown Tree Snake *Boiga irregularis*. Emergency measures necessary to rescue the Guam subspecies of Micronesian Kingfisher *Halcyon cinnamomina cinnamomina* from extinction involved translocation and captive breeding in American mainland zoos. Soon after the establishment of a captive breeding population, the kingfisher demonstrated a high degree of susceptibility to avian tuberculosis (ATB), a disease that proved to be a major threat to the preservation of the species. The cause of ATB is *Mycobacterium avium* which produces a prolonged course of infection in kingfishers and other birds. Kingfishers infected with *M. avium* are difficult to detect until late in the course of the disease, thereby potentially posing a risk of transmitting ATB to the Guam captive population of Guam Rails *Gallirallus owstoni*, if kingfishers are repatriated. *M. avium* is considered to be ubiquitous in nature. However, there are no reported mortalities due to ATB in any bird species on Guam. In this study, six of twenty-one cultures yielded *Mycobacterium* spp.,

two of which were further identified as *M. avium*. Since this study demonstrates that *M. avium* already exists on Guam, repatriating kingfishers to Guam poses no threat of introducing a new pathological agent to the island's ecosystem. Strict quarantine procedures along with rigorous animal husbandry protocols should minimize risks of repatriating infected kingfishers to Guam, and prevent transmission of ATB to the captive population of Guam Rails and other bird populations on Guam.

548: +.060

Ecologically sound efforts to manage or reintroduce populations of rare species require detailed knowledge of species habitat requirements. However, the fact that such species are rare implies that the data needed for habitat characterization are sparse and that species might well be absent from favorable sites due to chance aspects of dispersal or mortality. We use four rare plant species endemic to southern Appalachian high-elevation rock outcrops, to illustrate how nonparametric and parametric logistic regression can yield predictive models of the probability that a species will occur, given certain site conditions. Models were constructed for each species at two scales: 100-m² plots and 1-m² subplots. At the 100-m² plot scale, absences beyond the current geographic range were excluded. At the 1-m² subplot scale, absences from subplots were only included if the species occurred elsewhere on the 100-m² plot. Six significant models resulted; no significant model could be constructed for *Solidago spithamea* or *Calamagrostis cainii* on 1-m² subplots. For 100-m² plots, the most valuable predictors were potential solar radiation, a soils gradient related to available soil iron, boron, and copper, and coarse-scale rock surface texture, although *Geum radiatum* occurrences were difficult to predict at this scale. For 1-m² subplots the best predictors were available soil cations, potential solar radiation, the proportion of exposed bedrock, and vegetation height. Along individual gradients response curves were often similar, but no two species were predicted by identical sets of site parameters. Beyond current range limits, existence of suitable habitat on 100-m² plots was demonstrated for *Solidago spithamea*, supporting a view that the range limits of this species are not necessarily set by availability of suitable habitat. Habitat-based models have numerous management applications (such as to guide restoration and reintroduction efforts as well as to direct searches for additional populations) and provide a framework for future work on species-specific physiological requirements.

549: +.203

We use the phylogenetically based statistical method of independent contrasts to reanalyze the Wolf, C.M., Griffith, B., Reed, C., Temple, S.A. (1996). Avian and mammalian translocations: update and reanalysis of 1987 survey data. *Conservation Biology* 10, 1142-1154). translocation data set for 181 programs involving 17 mammalian and 28 avian species. Although still novel in conservation and wildlife biology, the incorporation of phylogenetic information into analyses of interspecific comparative data is widely accepted and routinely used in several fields. To facilitate application of independent contrasts, we converted the dichotomous (success/failure) dependent variable (Wolf et al., 1996; Griffith, B., Scott, J.M. Carpenter, J.W., Reed, C., 1989. Translocations as a species conservation tool: status and strategy. *Science* 245, 477-480) into a more descriptive, continuous variable with the incorporation of persistence of the translocated population beyond the last release year, relative to the species' longevity. For comparison, we present three models: nonphylogenetic multiple logistic regression with the dichotomous dependent variable (the method used by Wolf et al. 1996 and Griffith et al. 1989), nonphylogenetic multiple regression with the continuous dependent variable, and multiple regression using phylogenetically independent contrasts with the continuous dependent variable. Results of the phylogenetically

based multiple regression analysis indicate statistical significance of three independent variables: habitat quality of the release area, range of the release site relative to the historical distribution of the translocated species, and number of individuals released. Evidence that omnivorous species are more successful than either herbivores or carnivores is also presented. The results of our reanalysis support several of the more important conclusions of the Wolf et al. (1996) and Griffith et al. (1989) studies and increase our confidence that the foregoing variables should be considered carefully when designing a translocation program. However, the phylogenetically based analysis does not support either the Wolf et al. (1996) or Griffith et al. (1989) findings with respect to the statistical significance of taxonomic class (bird vs mammal) and status (game vs threatened, endangered, or sensitive), or the Griffith et al. (1989) findings with respect to the significance of reproductive potential of the species and program length. (C) 1998 Elsevier Science Ltd. All rights reserved.

550: +.080

This study assesses the impact of Pacific Rat *Rattus exulans* predation on the endangered Ouvea Parakeet *Eunymphicus cornutus uvaensis* and investigates the feasibility of translocating this bird to the island of Lifou (despite the presence of Ship Rat *R. rattus*). A rat trapping campaign, conducted from July 1995 to October 1996 in the forest of Ouvea and Lifou (Loyalty Islands, New Caledonia, South-west Pacific), confirmed the presence of Pacific Rats in Ouvea and both Pacific and Ship Rats in Lifou. Population dynamics, sex ratio, age structure and diet of both rats were investigated. An experiment, using quail eggs in natural tree holes during the main bird breeding season, in Ouvea in 1994 and in Ouvea and Lifou in 1996, compares the nest predation rate between these islands. Mayfield's estimator for a 21 day theoretical incubation period gives a survival rate of 0.80 and 0.99 in the two experiments in Ouvea but only 0.22 in Lifou. Most of the difference in egg survival observed between the islands appears to be related to the presence of Ship Rat in Lifou, while the difference in the two experiments in Ouvea may estimate the effects of trapping. The study shows that Lifou is not a suitable place for translocating Ouvea Parakeets, unless active habitat management is carried out to protect this bird against Ship Rats. The value of low intensity rat control in Ouvea immediately prior to the parakeet breeding period is also suggested.

551: +.047

I used VORTEX to make a prior evaluation of the planned reintroduction project of the endangered bearded vulture (*Gypaetus barbatus*) in the mountains of southern Spain. The minimum size of a captive population needed to ensure the release of two bearded vulture fledglings per year is 30 individuals. If breeding success was improved, this minimum captive population could be reduced to 10 individuals. As the cost of the project is proportional to the size of the captive population, some research effort should be devoted to improving breeding success in captivity. The current size of the captive population - four individuals - is not enough to start the releases, even if the vultures were already breeding. The first step for the project should be to increase the size of the captive population. If on average one individual per year was added to the captive population, it would take 15 years to reach 30 individuals. If breeding in captivity was improved, it would take only three to seven years to reach the minimum captive population of 10 individuals. Once releases were started, the project would need on average 20 years to reach a goal of 15 adult pairs in the Cazorla mountains. Both the success of the project and the time necessary to reach this stated goal are very sensitive to the mortality rates in the wild. There is little known about these rates, and better estimates are urgently needed to improve the predictions of the models.

552: +.147

Recent reintroduction of the black-footed ferret (*Mustela nigripes*) in west-central South Dakota has focused new attention on black-railed prairie dogs (*Cynomys ludovicianus*), because prairie dog colonies provide essential habitat for ferrets. Currently, management agencies are assessing prairie dog populations by counting active burrows, a technique that is attracting criticism. We correlated active and total burrow counts with prairie dog mark-recapture population estimates from 12 colonies located in Badlands National Park and adjacent Buffalo Gap National Grassland. We also correlated visual counts of prairie dogs and counts of mounds from aerial photographs with mark-recapture estimates to assess an alternative method to index populations. We found no significant relationships ($P > 0.05$) with any form of active burrow or total burrow counts (ground or aerial) using the linear model $Y = a + bX$. However, visual counts of prairie dogs, using maximum rather than mean values, on 4-ha plots were significantly related ($P < 0.0138$). The best model was $Y = 3.04 + 0.40X$, where Y is the maximum visual count and X is the estimated population density. The inverse of this equation $X = (Y - 3.04)/(0.40)$, could be used to index numbers of black-tailed prairie dogs from visual counts under conditions similar to those encountered in this study. An 8-point protocol for making visual counts is provided.

554: +.030

Riparian plants have been classified as "drought avoiders" due to their access to an abundant subsurface water supply. Recent water-relations research that tracks water sources of riparian plants using the stable isotopes of water suggests that many plants of the riparian zone use ground water rather than stream water and not all riparian plants are obligate phreatophytes (dependent on ground water as a moisture source) but may occasionally be dependent on unsaturated soil moisture sources. A more thorough understanding of riparian plant-water relations must include water-source dynamics and how those dynamics vary over both space and time. Many rivers in the desert Southwest have been invaded by the exotic shrub *Tamarix ramosissima* (saltcedar). Our studies of *Tamarix* invasion into habitats formerly dominated by native riparian forests of primarily *Populus* and *Salix* have shown that *Tamarix* successfully invades these habitats because of its (1) greater tolerance to water stress and salinity, (2) status as a facultative, rather than obligate, phreatophyte and, therefore, its ability to recover from droughts and periods of ground-water drawdown, and (3) superior regrowth after fire. Analysis of water-loss rates indicate that *Tamarix*-dominated stands can have extremely high evapotranspiration rates when water tables are high but not necessarily when water tables are lower. *Tamarix* has leaf-level transpiration rates that are comparable to native species, whereas sap-flow rates per unit sapwood area are higher than in natives, suggesting that *Tamarix* maintains higher leaf area than can natives, probably due to its greater water stress tolerance. *Tamarix* desiccates rind salinizes floodplains, due to its salt exudation and high transpiration rates, and may also accelerate fire cycles, thus predisposing these ecosystems to further loss of native taxa. Riparian species on regulated rivers can be exposed to seasonal water stress due to depression of floodplain water tables and elimination of annual hoods. This can potentially result in a community shift toward more stress-tolerant taxa, such as *Tamarix*, due to the inability of other riparian species, to germinate and establish in the desiccated floodplain environment. Management efforts aimed at maintaining native forests on regulated rivers and slowing the spread of *Tamarix* invasion must include at least partial reintroduction of historical flow regimes, which favor the recruitment of native riparian species and reverse long-term desiccation of desert floodplain environments.

555: +.178

The development of ex situ conservation work for Orthoptera is demonstrated by examples of two captive-breeding programmes at the Zoological Society of London. The field cricket *Gryllus campestris* and wart-biter bush cricket *Decticus verrucivorus* are both species that have been bred in captivity and reintroduced to field sites in attempts to strengthen dwindling wild populations. Despite a similar approach to both programmes, we have encountered significant differences in the practical applications of the captive management process for the two species. By reviewing these breeding programmes, we examine some of the practical considerations associated with ex situ orthopteran programmes and compare some of the different elements that can influence programme success.

556: +.113

Up to 30 species of fish were generally found in medium-sized rainforest streams in Sabah, Malaysia. However, depauperate fish communities were found in two streams above large (>8 m) waterfalls (five and nine species) and in two very small streams located in deep forest (five and six species). A fifth stream with small cascades and waterfalls had a faunal list of 12 species. Species resident above waterfalls were predominantly herbivores while fishes in the two forest streams were from a variety of trophic groups. Abundance and biomass of fishes above waterfalls were significantly lower than all other sites. A translocation experiment was performed in one stream to distinguish between the hypotheses that fish communities above waterfalls were determined solely by colonization ability and were unsaturated with species or that they were limited by habitat quality or food. Seven species (775 individuals) were translocated into one isolated section and four species (570 individuals) into another. Species that were translocated included trophic groups that were not represented by resident species. Twelve months after translocation, only four and one translocated species were collected in the two sections, all at greatly reduced densities. After 20 months, the number of species were three and two, respectively. One translocated species, *Rasbora sumatrana*, had increased in abundance from 12 months and juveniles were present in the population. Individuals of other translocated species appeared to be remnants of stocked populations. Abundance and biomass of resident species fluctuated widely between years. Interpretation of results was complicated by a large flood which substantially changed habitat conditions about a month after translocations were performed. It is suggested that two different factors were responsible for depauperate communities: movement barriers for waterfall sites and physico-chemical conditions and/or habitat availability at other sites. (C) 1998 The Fisheries Society of the British Isles.

557: +.073

The effects of deer hunting by humans on deer population dynamics and behavior may indirectly affect the population dynamics and behavior of deer predators. We present data on the effects of hunting on the behavior of white-tailed deer (*Odocoileus virginianus*) on the Osceola National Forest, a potential reintroduction site for the endangered Florida panther (*Felis concolor coryi*). We then use this information to formulate and recommend testable hypotheses to investigate whether these changes in deer behavior influence panther movements, mortality, and hunting success. We monitored 14 radio-collared deer from June 1990 through July 1991 to compare movement activity, and habitat-use patterns between the hunting and non-hunting seasons. Mean distance of deer to the nearest road, mean distance of activity centers of diel home ranges to the nearest road, and mean nocturnal rate of activity were greater during the hunting than the nonhunting seasons. During the hunting season, deer avoided clearcuts, young pine plantations (4-10 years old), and other open habitats and preferred sub- and mature pine forests, both of which provided cover. These results suggest that deer responded to hunter disturbance by moving away

from roads and increasing nocturnal activity. Although recreational deer hunting may reduce the prey base for panthers, the changes we observed in deer behavior during the hunting season may benefit panthers in the following ways: (1) an increase in nocturnal activity and movement away from roads by deer into areas frequented by panthers may increase prey availability for panthers; (2) the movement of deer away from roads may in turn draw panthers away from roads, which may decrease the chance of panthers being killed by vehicular traffic or poachers.

The single surviving wild population of Campbell Island Teal, restricted to Dent Island in the New Zealand subantarctic, is unlikely to exceed 25 pairs. Twelve Campbell Island Teal were released in 1999 onto Codfish Island in southern New Zealand to establish, temporarily, a second wild population. These birds originated from a captive breeding programme that has produced 40 fledglings during 1994 - 1998 from an initial wild-caught stock of 11 birds. Wild-raised and wild-acclimatised teal from Codfish Island are intended as the source for eventual re-establishment on Campbell Island. Planning for the removal of Norway rats, the sole remaining alien mammal there, has commenced.

559: -.214

The Siberian Crane is the third rarest of the world's 15 species of cranes and considered by the International Crane Foundation to be the most endangered. Field surveys suggest that only 2900-3000 birds in three populations remain. While potentially encouraging, these numbers can be misleading due to the significant threats faced by this species.

560: +.091

Dipodomys merriami parvus was listed as endangered by the U. S. Fish and Wildlife Service (USFWS) in September 1998 following its emergency listing of January 1998. A Biological Opinion issued by USFWS on a sand and gravel mining within Cajon Wash, an area of critical habitat, included translocation as a minimization measure. Preliminary to translocation, a salvage trapping effort was initiated in May 1998 to remove animals from a 32.5-ha site scheduled for mining operations. Fifteen *D. m. parvus* (11 males and 4 females) were captured and released on a re-vegetated reclamation site that contained a complement of native rodents including three resident *D. m. parvus*. All translocated animals were reproductively active. Translocation success was assessed in August 1998. Thirty-three percent of the original resident *D. m. parvus* and 30% of the translocated individuals were still present on the site. In contrast, among resident animals of other species, 57.1% of *Dipodomys simulans* and 15.4% of *Peromyscus maniculatus* remained on the site. Three juvenile *D. m. parvus*, apparently offspring from released animals, were captured in the release area. All adult *D. m. parvus* captured in August showed signs of reproductive activity, including evidence of a second litter in progress. Continued monitoring will verify the apparent short-term success of the translocation and suggest refinements for future efforts.

562: -.010

We question the rationale and methodology behind two recent amphibian translocations into west-central Illinois. In both cases, species were translocated outside their native ranges and no rigorous criteria for gauging success were utilized. We are concerned that translocations such as these will give the mistaken impression that new populations of amphibians can be easily established, even

in marginal habitats, and that any translocation effort will result in successful amphibian conservation.

563: -.082

Although river otters (*Lutra canadensis*) were common in Illinois during early European settlement, habitat degradation and unregulated harvests caused populations to decline dramatically by the mid-1800s. Otters were considered rare in the state by the early 1900s, and were listed as a state endangered species in 1989. Recovery strategies developed by the Illinois Department of Natural Resources included reintroducing otters in suitable but unoccupied habitats. Wild otters obtained from Louisiana were released in the Wabash (n = 137), Kaskaskia (n = 72) and Illinois (n = 137) River basins from January 1994 through March 1997. Dead otters recovered from 1994 through 1997 included more males (n = 20) than females (n = 9). Losses were attributed to hoop nets (n = 8), vehicles (n = 7), traps (n = 7), stress (n = 6), and domestic dogs (n = 1). Surveys and sightings indicated that otters were persisting and reproducing in release areas. Reports from outside of release areas suggested that native populations along the Mississippi and Cache Rivers were increasing and expanding their ranges. Otters had colonized the Central Mississippi Landscape Management Unit, probably as the result of releases in Missouri during the 1980s. Criteria for changing this species' status from endangered to threatened have been met.

564: +.043

Reports suggest: that there is widespread reproductive failure in *Linnaea borealis* in Britain, Scandinavia, and North America. Our investigations of Scottish populations of this clonal dwarf shrub indicate that, although visited by a number of different insects, pollen transfer in this species is highly effective and principally occurs by small flies (Muscidae). However, natural levels of fruit set varied between populations (from 0% to 25.1%) and reproductive failure was most severe in populations which were composed of single clones. Microscopic examination of stigmas showed that there is no barrier to pollen flow since at least 85% of stigmas have sufficient germinating pollen to effect seed set. fluorescence microscopy of germinating pollen grains indicates high levels of pollen rejection in the style and only a small proportion of the pollen tubes were able to reach the ovary. It was concluded that lack of xenogamous pollination limits fruit formation in populations of *L. borealis*. Reproductive success in an isolated population with extreme reproductive failure was restored by experimental hand pollination with viable pollen imported from plants from another population. In Scotland, *L. borealis* occurs in small, isolated populations and restoration of reproduction can be achieved by the reintroduction of compatible mating partners. This is an important consideration for the conservation management of isolated populations since their long-term recovery may only be possible by translocation of different genotypes from elsewhere into the population. Habitat fragmentation in any part of the species range may impose a potential reproductive bottleneck by causing loss of population diversity and this could explain the low levels of seed set recorded for this species in other parts of its range.

565: +.227

In 1989 an experiment was started at the Bukhara Breeding Centre, Kyzylkum Desert, Uzbekistan, to discover whether zoo-bred Przewalski's horses *Equus przewalskii* could adapt to semi-wild desert conditions. One stallion and four mares of different ages were released into a 5126-ha fenced area and monitored over a period of 17 years. This paper presents the information gained from the studies concerning home ranges, interactions with other ungulate species, adaptation to new food resources and comparative changes in daily activity. The results of breeding and changes

in the structure of the group are also presented. The horses appeared to adapt well to the new conditions and there appeared to be no negative effects of interspecific interaction with introduced kulans *Equus hemionus kulan* in the release area.

566: -.086

The recovery of dead animals and incidental captures of live animals (= without looking for the animals) are reliable proofs of presence which may be collected on a large scale and at low cost when studying the distribution of rare and secretive species of large carnivores. We used the number of data collected per five-year period to study the long term population trend of re-introduced lynx (*Lynx lynx*) populations in France. Causes of death and sex-ratio of the juveniles and adults-subadults found dead in the wild were also examined. From 1974 to 1998, 52 lynx were found dead or were wounded in France and 5 lynx were caught incidentally. In the Jura mountains, the number of data collected by five-year period increased regularly, from one in 1974-1978 to 20 in 1994-1998. This trend confirmed the settlement of the lynx in the Jura mountains concurrently with the geographical expansion of the species. In the Alps, a maximum of two data were collected per period. The last data was collected in 1990, which suggests that there is no well-established population. In the Vosges mountains, two to four data were collected per five-year period since the first re-introductions of lynx in 1983. This may well reflect the onset of colonisation. In the Pyrenees, the absence of data for decades is linked with the extinction of the species. Causes of death were undetermined in six cases. Mortality was man-related, either directly or indirectly, in 83 % of the cases (n = 38). Mortality factors were road or train traffic (n = 26), illegal killing (n = 10) or secondary poisoning by anticoagulants (n = 2). Natural mortality factors (rabies, starving, etc.) were at the origin of 17 % of the cases (n = 8). The juvenile (less than or equal to 12 months) to adult-subadult (> 12 months) ratio varied with the causes of death and captures. Juveniles were more frequent (75 %) than adults-subadults in the cases of natural mortality. Adults-subadults were more frequent (60.5 %) in cases of man-related mortality. The sex-ratio did not vary with the causes of death and captures and did not differ from 1 : 1 despite a trend in an over-representation of females (28 : 20).

567: -.060

Trout stocking in the mid-1960s eliminated the calanoid copepod *Hesperodiaptomus arcticus* and other large-bodied crustaceans such as *Gammarus lacustris*, *Daphnia middendorffiana*, and *Daphnia pulex* from many alpine lakes in the Rocky Mountain Parks of Canada. *H. arcticus* frequently dominates the plankton communities of fishless lakes, preying on rotifers and nauplius larvae. Following the extirpation of *H. arcticus*, rotifers and small-bodied cyclopoid copepods dominate the zooplankton assemblages of alpine lakes. We studied the zooplankton community of Snowflake Lake, Banff National Park, from 1966 to 1995. *H. arcticus* was eliminated following stocking of the lake with trout in the 1960s. It failed to become reestablished after the disappearance of the fish population in the mid-1980s. Several species of rotifers and small-bodied crustaceans, species originally rare or absent from the plankton, became abundant following fish stocking and remained so after the fish population declined. In 1992, we reintroduced *H. arcticus* to Snowflake Lake. The *H. arcticus* population grew exponentially for 4 yr, but had not reached stable densities typical of unmanipulated alpine lakes by 1995. By 1994, however, even the small population of *Hesperodiaptomus* was beginning to suppress populations of rotifers, copepod nauplii, and large diatoms. Because *H. arcticus* is omnivorous, a simple model of cascading trophic interactions did not predict the outcome of trophic manipulations in this alpine lake.

568: +.089

Translocation of nuisance raccoons (*Procyon lotor*) is a common practice, but the fates of translocated animals after release are not known. We monitored postrelease survival rates and dispersal of radiocollared raccoons that were trapped as nuisance wildlife in suburban Chicago and translocated to a rural forest preserve (translocated urban), trapped in another wooded area and translocated to the forest preserve (translocated rural), and trapped and released in the forest preserve that served as the release site for the translocations (resident). Thirty-one raccoons were radiotracked in autumn 1993, and 45 were radiotracked in autumn 1994. We detected no differences in survival rates among the 3 treatment groups ($P > 0.05$). Resident raccoons tended to remain in the vicinity of the release site, whereas translocated raccoons left the release site within hours to days and dispersed into the surrounding area. Dispersing raccoons had high daily movement rates for the first 2 weeks postrelease but then seemed to establish new home ranges. Translocated raccoons frequently denned near human residences and in agricultural fields, whereas resident raccoons denned primarily in the forest preserve. Because translocated raccoons survived well, translocation could be an effective way to supplement depleted or reestablish extirpated populations of this species. However, translocating large numbers of raccoons for animal damage control could cause problems for other wildlife and human residents near release sites, and translocated animals could serve as vectors for wildlife diseases during zoonotic outbreaks.

569: +.066

The cervids represent a complex assemblage of taxa characterized by extreme diversity in morphology, physiology, ecology and geographical distribution. Farmed species (for example red deer and fallow deer) are usually the common larger-bodied, gregarious and monotonous species that express marked reproductive seasonality in their temperate environment. Their commercial importance has facilitated considerable research into reproductive physiology and the development of assisted reproductive technologies (ART). In contrast, the remaining species, including many of tropical origin, show wide diversity in reproductive patterns, have generally received little scientific scrutiny, and include a number of endangered taxa that are reliant on ex situ conservation efforts (such as captive breeding) to ensure their survival. Domestication and ex situ management programmes have been associated with widespread translocation of various cervid species around the world, often placing the animals in environments that are not compatible with their evolved reproductive patterns. For example, the summer calving/lactation pattern of red deer, attuned to northern continental climatic patterns, is frequently misaligned with seasonal changes in feed availability in the Australasian pastoral environment. Similarly, seasonal or aseasonal calving patterns of tropical species translocated to temperate regions are usually associated with increased perinatal mortality of calves born in cool seasons. Conversely, temperate species in tropical zones may exhibit aberrant reproductive patterns in the absence of biologically significant photoperiod fluctuations. ARTs, which presently include artificial insemination, embryo transfer and in vitro embryo production, have potential application to the genetic management and population growth of various cervid species. Although application to some farmed cervid species is widespread, these technologies are rarely directly transferable from farmed to endangered species. Even within species, ART protocols developed successfully for one genotype (i.e. subspecies) may be ineffective in another (for example superovulation of red deer and wapiti). Therefore, application to genetic management of endangered species necessitates prior research into their reproductive patterns. This is often difficult because of the rarity of the animals, a lack of suitable handling facilities for the particular species, and the timid nature of the deer. More recently, however, non-invasive reproductive profiling, based on remote collection and monitoring of excreted steroid metabolites, has facilitated such research.

570: +.088

The cervids represent a complex assemblage of taxa characterized by extreme diversity in morphology, physiology, ecology and geographical distribution. Farmed species (for example red deer and fallow deer) are usually the common larger-bodied, gregarious and monogamous species that express marked reproductive seasonality in their temperate environment. Their commercial importance has facilitated considerable research into reproductive physiology and the development of assisted reproductive technologies (ART). In contrast, the remaining species, including many of tropical origin, show wide diversity in reproductive patterns, have generally received little scientific scrutiny, and include a number of endangered taxa that are reliant on ex situ conservation efforts (such as captive breeding) to ensure their survival. Domestication and ex situ management programmes have been associated with widespread translocation of various cervid species around the world, often placing the animals in environments that are not compatible with their evolved reproductive patterns. The setting of conservation priorities within species requires explicit goals and identification of the appropriate targets for conservation. I suggest that the conservation goal should be to conserve ecological and evolutionary processes; rather than to preserve specific phenotypic variants - the products of those processes. From this perspective, we should seek to conserve historically isolated, and thus independently evolving, sets of populations (i.e., Evolutionarily Significant Units, ESU). This can require manipulation of the component Management Units (MUs), some of which may be phenotypically distinct. Here I explore the application of this approach to the design of translocations for conservation management. A process-oriented approach suggests that individuals should not be translocated between ESUs, but under some circumstances it is appropriate to mix individuals from different MUs within an ESU. These circumstances include augmentation of remnant populations that are showing signs of inbreeding depression or increased fragmentation and the use of mixed stocks for reintroductions into modified or changing environments or for introductions into novel environments. These actions are consistent with the goal of maintaining processes, but the extent to which differences in adaptation or coadaptation constrain the viability of populations subject to translocation needs further exploration. Both theory and limited experimental evidence suggests that these constraints can be overcome if sufficient genetic variation is present and evolutionary processes can operate without substantially reducing population viability. One remaining question is the extent to which genetic coadaptation, and the resulting outbreeding depression, develops along environmental gradients and how this

compares to the build-up of genetic incompatibility between historically isolated populations.

572: +.089

Three new microsatellite loci were isolated and characterized in the Alpine marmot (*Marmota marmota*). Using these markers together with the previously published L-I microsatellite locus eight populations from Austria, Switzerland and Spain were analysed. In the autochthonous populations the expected heterozygosity values (H-c) are rather similar (from 23.1 to 30.2), whereas the introduced populations show a much broader range (from 3.4 to 60.1). Only two of the introduced populations from Austria appear to be genetically deprived. Some of the introduced populations are even highly variable, e.g., the populations from the Pyrenees and from Turracher Hohe. The allele frequencies and the occurrence of particular alleles allow for the estimation of the origins of the introduced populations. The three primer pairs designed for *M. marmota* proved to be also applicable for cross species amplification of the microsatellites in the North American species *Marmota flaviventris*. For the study of this highly endangered species, hair samples were used for DNA-extraction and microsatellite analysis. The results obtained for the three loci reveal a severe reduction of genetic variability.

573: +.090

Five microsites in shallow dystrophic waters were selected for the introduction of a critically endangered aquatic carnivorous plant *Aldrovanda vesiculosa* in the Trebon region in S Bohemia, the Czech Republic. The selected sites were fen pools close to two hypertrophic fishponds, Ptaci blato (four microsites) and Domaninsky tone microsite). In June 1995, 30 plants from an allochthonous population in E Poland were introduced in each of the microsites. Water chemistry and plant growth dynamics were investigated at the microsites throughout the 1995-1996 seasons, and the maximum size of the subpopulations were estimated during the 1997-1999 seasons. The selected waters may be characterized as oligo-mesotrophic. The warm and dry 1995 season resulted in a low water level (ca. 10 cm below average) and plant propagation was poor at all but one microsite. However, the rainy and colder 1996 season resulted in a high water level, and thus rapid plant propagation occurred at all four microsites at the Ptaci blato fishpond and between 841 and 2669 turions were formed. Here, the doubling time of the apices was between 13.5-19.3 days in the summer. At the Domaninsky fishpond, however, the growth was relatively poor in 1996. The overwintering rate of turions (19-100%) was found as being high enough to keep the introduced plant populations stable. At each of the four microsites at Ptaci blato, the maximum numbers of shoot apices were estimated to be between 1,000-20,000 in the 1997-1999 seasons. Depth of free water appears to be the crucial factor for the rapid growth of *Aldrovanda* at some selected sites; water depth below 5 cm is unfavourable. Overall, *Aldrovanda* was successfully established in an intensively agricultural landscape in the Trebon region.

The Norwegian Directorate for nature management has begun planning a management strategy for the large freshwater mussels in Norway. The present paper reviews the biology of the freshwater pearl mussel *Margaritifera margaritifera* (L., 1758). This is a contribution to increase the knowledge of this species in Norway. The freshwater pearl mussel is an interesting species with a particular biology. It is long-lived (150-200 years), has a parasitic larval stage on fish, is an efficient filterer and stores environmental information in the shell. Despite mussel has not been subject to indepth studies in Norway. The populations of the mussel have shown a steady decrease over a long period. In many localities the populations have become extinct or the recruitment has

stopped resulting in populations totally dominated by old individuals. The explanation for the decrease earlier could be overexploitation in search of pearls in certain localities. More importantly today, however, are environmental disturbances and destruction of biotopes through acidification, extinction of fish, hydroelectric activity, eutrofication, pollution, construction of canals and closing of streams, drainage of mires, erosion and clear-cutting of forest. The net result of this influence is that the freshwater pearl mussel is listed as threatened in the Norwegian red list. Surveys of the freshwater pearl mussel have shown that the species has declined dramatically in occurrence and distribution within its zoogeographic range since the turn of the century. It has been indicated that the population has decreased by 95% in central Europe, and absence of young individuals has been observed in most of the European populations. In many cases the recruitment stopped 50-60 years ago, and the mussel may become extinct in many areas. In Sweden the mussel has been found all over its geographic range, but individual populations have declined and the species has disappeared from one third of all watercourses where it was recorded early this century. Such data are not available for Norway, but we believe the situation is very much the same only in approximately one third of the watercourses where the mussel still can be found, and the remaining populations have become fragmented. Healthy populations are only found in watercourses which are relatively undisturbed by human activity. The normal length of the freshwater pearl mussel is 10-13 cm with a maximum size of 15-16 cm. The species is normally dioecious with male and female individuals. Sperm and eggs mature in the gonads normally in summer. Sperm is released into the water by the males and reach the females' gills with the water current. The eggs migrate from the gonad to the gills where they are fertilised. After fertilisation the zygotes develop into glochidia which are stored by the female in all the four demibranchs. They develop into sessile mussels only after an obligatory parasitic larval stage on the gills of a suitable fish (salmon or trout). The water temperature determines the length of the parasitic stage, which normally lasts 8-11 months. The glochidia grow during this period (from 0.05 to 0.45-0.50 mm), and go through a metamorphosis. After the glochidia have left the fish they live submerged in the gravel the first 4-5 years after which they emerge. They can live until they reach an age of 70-150 years. A freshwater pearl mussel can filter 50 litres of water over the gills within 24 hours. Food particles are filtered out, while organic compounds are released into the environment and fall to the bottom. In this way the mussel may filter out 92-100% of the particles in the water, and act as very important natural water cleansers. This is important for may contribute to maintain large populations of freshwater fish. Since the shell of the mussel is compact, chemical compounds may be stored in the shell and may be traced even after the mussel is dead. The shell may therefore be used as an environmental archive, and element analyses may describe a watercourse over a timespan of more than a hundred years. Swedish scientists have, by this method, found radioactive isotopes from nuclear tests, mercury from industry, lead from combustion engines, pollution from mining, development of eutrofication and the industrialisation as well as acid rain. The freshwater pearl mussel lives mainly in running water and is normally found at the depth of 0.5-2.0 m, but occasionally occurs in deeper stretches. The mussel is normally present at water velocities of 0.1-0.8 m/s, but it tolerates up to 2 m/s. The number of young mussels decreases with increasing water velocity, and at 0.3 m/s the number of young mussels is close to zero. The mussel has a relatively wide temperature tolerance, and survives in temperatures close to zero as long as it does not freeze, and may tolerate up to 20°C for shorter periods. The freshwater pearl mussel is considered to be stenohaline and can only be found in waters with < 0.5 ‰ salt content. It avoids localities with high turbidity, and tends not to thrive in areas with high levels of humus. In adult mussels there is a clear connection between survival and pH; when pH falls below 5 a negative effect is manifest. Young individuals are even more sensitive to acidification than mussel occurs naturally in areas with low calcium content in the soil, but it may also occur in more calcareous areas. In acidified areas where liming has been carried out, positive changes has been observed with an increase in recruitment and improved growth. Added contents of phosphor and nitrogen,

as well as organic compounds, lead to poorer water quality due to an increase in eutrofication. This results in an increase in sedimentation, as well as increased oxygen consumption in the sediment. This may be detrimental to young mussels in the first few years when they live submerged in the sediment. The freshwater pearl mussel has been found to survive in water containing 4.5-14.0 mg O₂/l, but it has an optimum growth at 5.5-8.5 mg O₂/l. Young mussels have higher oxygen requirements than older ones. To protect the remaining populations of pearl mussel, a ban on catching and increased knowledge about its biology alongside a management strategy is necessary. A law protecting the species is not sufficient. It has to be followed by protection of remaining habitats, as well as an identification of key factors responsible for the decline in the populations. Measures to reduce erosion and securing areas with erosion will be important. Clear-cutting, removal of riparian vegetation and various other man-made alterations along rivers and streams containing mussel should be prevented. Adding of organic compounds, phosphor and nitrogen should also be considered detrimental and therefore reduced. Other measurements to protect and mussels could include introducing adult mussels or infected fish, alongside hatching and release of young mussels in suitable localities. In acidified areas liming is important to secure remaining populations or create an environment for reintroduction of mussels.

575: +.068

Native fish stocks in the high-altitude saline Lake Issyk-kul (altitude 1608 m) in Kyrgyzstan have been subjected to predatory pressure from the introduced Sevan salmon (*Salmo ischchan gegarkuni*). Due to its oligotrophic character, the lake has low fish yields. The rapid growth in human population, development of tourism around the lake, increasing eutrophication and high demand for fish have necessitated a new assessment of the existing fishery and formulation of new fishery strategies. The best response to the current trends in the changing environment is to concentrate on the development of fish stocks to satisfy recreational fishery, while gradually reducing the commercial fishery. South of Lake Issyk-kul are the high mountains of the Pamir. Four of the existing several hundred lakes, all situated from 3220 m to 4260 m altitude, have a medium productivity. Their fish yield estimates range from 20.4 to 39.6 kg ha⁻¹. Such lakes offer good conditions for fish feeding on zooplankton, and in some lakes the northern whitefish (*Coregonus peled*) have been stocked. Few of these lakes are fished at present. It has been suggested that some of the Pamir lakes serve as sanctuaries for the preservation of coldwater fish species which are threatened in their original habitat. In the River Chu (Kyrgyzstan/Kazakhstan) damming, water diversion for irrigation and increased water salinity in its lower course as a result of the reintroduction of drainage waters from irrigation, have had a negative impact on the indigenous coldwater fish stocks. The present fish production in reservoirs and fish ponds, achieved through management efforts, produces about the same quantity as before the indigenous fish loss, but at a much higher cost.

The distribution of native and alien crayfish inhabiting the British Isles is described separately for England, Wales, Scotland, Northern Ireland, Irish Republic, and some associated islands. Distribution of the single native species, *Austropotamobius pallipes*, is largely determined by geology, water quality and human intervention. Very large populations exist in England, Wales, and the Irish Republic, but in recent years some of these have been eliminated, particularly by crayfish plague in the 1980s. Active measures are being taken to conserve the remaining stocks of this species in line with the terms of the Rio Convention and European Directives. Since the 1970s, a number of alien crayfish have been introduced into England, Wales, and Scotland. *Pacifastacus leniusculus* is cultivated in a number of extensive and semi-intensive facilities.

Astacus leptodactylus is not cultivated to any extent but those caught from the wild are used for culinary purposes. Large populations of both species now exist in the wild as a result of escapes and implants, particularly in central and southern England. The wild harvest of these two species is now probably greater than that derived from cultivation. Other alien crayfish such as *Astacus astacus*, *Procambarus clarkii*, and *Orconectes limosus* are also present in the wild in England, and *Cherax quadricarinatus* is kept by aquarists. Due to the environmental impact that wild populations of alien crayfish are having in Great Britain, stringent legislation has recently been introduced to try and stem their spread and that of crayfish plague. Northern Ireland and the Irish Republic ban the import of alien crayfish, although Great Britain does not. Reintroduction programs for *A. pallipes* are being initiated and monitoring of populations of both native and alien crayfish are being carried out at national and local level.

Conservation ecology is a new field which provides an interdisciplinary approach to the study of the problems of biodiversity and threats to biodiversity. This textbook is intended for ecological or environmental laboratory courses at the undergraduate level. The work contains fourteen laboratory exercises based on the RAMAS EcoLab software covering biodiversity, population growth, population parameters, density dependence, extinction, conservation of threatened and endangered species, sustainable harvesting, management of wildlife, reintroduction of endangered species, island biogeography, metapopulation biology, human population growth and consumption, and conservation decision making. The manual may also be used in conjunction with standard textbooks in the field. A CD-ROM containing the RAMAS EcoLab software program and an appendix containing the EcoLab software manual are included. EcoLab 2.0: SPECIFICATIONS: IBM-compatible computer with Windows 95, Windows, 98, Windows NT 4.0, or later. 16MB memory. Pentium or faster processor. 2MB hard disk space. DESCRIPTION: RAMAS EcoLab contains four main programs: Random Numbers; Population Growth; Age and Stage Structure; and Multiple Populations. The Random Numbers program gives a pair of uniform random numbers whenever a button is pushed. The Population Growth program allows a single population model to be constructed with no age or stage structure. The Age and Stage Structure program constructs a single population model with age and stage structure, such as Leslie matrix models. The Multiple Population program creates metapopulation models with spatial structure. Simulations using any of these programs may be run. Results of all simulations may be viewed, saved and printed. The software is user-friendly with on-line context-sensitive help from any screen. Technical support for RAMAS EcoLab is available at <http://www.ramas.com>; ecolab@ramas.com; and RAMAS, 100 North Country Road, Setauket, NY, 11733 USA.

We used DNA fingerprinting in order to assess 'a posteriori' the outcome of a captive breeding and reintroduction program of guans *Penelope obscura bronzina* and *P. superciliaris jacupemba*. The reintroductions started after the reforestation of part of the area that was damaged during the construction of a hydroelectric power dam in Sao Paulo, Brazil, in a region belonging to the Atlantic Forest. Our results showed that the free-living populations that became established in the reforested areas were related to the birds of the captive breeding and reintroduction programs. The segregation pattern of paternal and maternal DNA fragments of a captive family show that at least nine independent loci were detected by each of the human minisatellite multilocus probes used in the present work (33.6 and 33.15). Even though we detected a reduction in the genetic variability of these free-living populations compared to that of the captive stocks as a consequence of their

small number of founders, the birds of both species have been breeding adequately in the reforested areas. (C) 1998 Elsevier Science Ltd. All rights reserved.

Lumholtz's tree-kangaroo (*Dendrolagus lumholtzi*) and Bennett's tree-kangaroo (*Dendrolagus bennettianus*) are the two largest arboreal folivores in Australia and are both restricted to the tropical rainforests and adjacent forest communities in North Queensland. Both species display cryptic and secretive behaviour, and consequently are poorly studied. Bennett's tree-kangaroos are found within a relatively small area (similar to 2000 km²) of the Wet Tropics, however the majority of this area is within a protected 'World Heritage Area', and consequently the conservation status of this species is considered moderately safe despite its rarity. The overall distribution of Lumholtz's tree-kangaroo, which is also considered rare, covers a larger area (similar to 5500 km²), which also has considerable overlap with the 'World Heritage Area' (WHA). Despite this, the species appears to maintain its highest densities in forest outside the WHA conservation zone. Lumholtz's tree-kangaroos are more commonly found in the fragmented forests on the Atherton Tablelands, and are often associated with remnant and secondary rainforests on basalt soils. These forest communities are considered rare and are poorly represented in existing reserves. This paper considers the conservation issues for both of these species, but focuses particularly on Lumholtz's tree-kangaroos for which more data is available. Issues discussed include the loss of habitat outside the World Heritage Area, road deaths of animals, predation by canids, traditional hunting, and fecundity and recruitment. Measures for the conservation of these species are suggested, including measures for the retention-of habitat on private land, public education, translocation and captive breeding. The applicability of-research on Australian tree-kangaroos to the conservation of the eight species of tree-kangaroos in Papua New Guinea is also considered. Reproduction of *Megalonias nervosa* (Rafinesque, 1820) has not been documented for over 20 y in much of the Cumberland River, where water temperatures have decreased and flow regimes have been greatly altered by hypolimnetic discharges from impoundments. Studies in other streams have implicated low temperatures or changes in discharge patterns as causative factors inhibiting reproduction, *Megalonias nervosa* were collected from the Cumberland River, translocated to the Tennessee River, and held in an embayment of Kentucky Lake. After the first and second y samples of *M. nervosa* were taken from the Cumberland River, an existing population in Kentucky Lake, and the translocated group. Histological examination indicated that translocated mussels had a high incidence of hermaphroditism, and like mussels originating in Kentucky Lake, had undergone an otherwise normal reproductive development. Individuals functioning successfully as females from the translocated group had mature glochidia in their marsupia. Females from the Kentucky Lake sample also had mature glochidia present. In contrast, there was no indication of reproductive activity in gonads or marsupia of individuals collected from the Cumberland River. Our results indicate that a return to a more natural temperature regime in the Cumberland River would reinstate a normal reproductive cycle. We suspect that the altered temperature regime is also disrupting the gametogenic cycle of all mussels, including at least six federally listed endangered species occurring in the Cumberland River. These relic populations will disappear unless they are translocated or the thermal regime returned to normal.

The adjustment of captive-reared and developmentally deprived ringtailed lemurs (*Lemur catta*) to supported release on St. Catherine's Island, Georgia, was studied over 7 years to examine if these animals developed behavior comparable to wild populations. Initial changes after release included decreased obesity and increased agility as well as foraging for appropriate novel plants. Ranging, daily behavior cycles, and vocalizations developed more slowly over 1-3 years, but eventually the behavior resembled that of wild groups. Group composition and social structure changed through conflict to resemble wild and captive troops in social organization, including the emergence of matrilineal dominance and male emigration. Since behavior eventually resembled that seen in the wild, some resilience of species-typical wild behavior in captivity is supported. (C) 1999 Wiley-Liss, Inc.

586: +.094

The introduction of rare and threatened species on new or previously occupied sites was examined. Results point to both the success (*Gentiana pneumonanthe*, *Littorella uniflora*, *Polygonum bistorta*, *Senecio aquaticus*), uncertainty (*Pedicularis palustris*) and failure (*Alopecurus bulbosus*) of establishment. Population dynamics, niche requirements and life properties of species are sensitive indicators of ecological prerequisites of several communities e.g. site conditions and management practices. Rarity and limiting dispersal of target species require the systematic (re-) introduction by man to preserve local populations even under improved environmental conditions.

587: +.114

Mitochondrial DNA (mtDNA) control region sequences were analysed to determine the geographical genetic structure of *Hippotragus niger* (sable antelope) and *H. equinus* (roan antelope). Analyses by AMOVA, minimum evolution networks, parsimony, neighbour joining and maximum likelihood show that the roan antelope populations are geographically partitioned and that their phylogeography corresponds well with subspecific boundaries. In sharp contrast,

however, our sequence data group all the sable antelope into two well-delineated maternal clades. One comprising specimens from the strictly east African *H.n. roosevelti*, and a second geographically diverse group which includes *H.n. niger* (South Africa, Zimbabwe), *H.n. variani* (Angola), and *H.n. kirkii* (Zambia, Malawi). The differences in the genetic population structure suggest that distinct extrinsic and intrinsic factors have shaped the phylogeography of these two closely related antelope species. In the absence of obvious extrinsic barriers to gene flow, we suggest that behavioural differences may be responsible, at least in part, for the contrasting spatial patterns detected among geographical localities. Although our data reflect only the maternal phylogeny of these important game species, they nonetheless suggest that different management strategies should be applied. We recommend that roan antelope be translocated only within the currently defined subspecies boundaries, while in the case of sable antelope, conservation measures should focus on preserving the genetic integrity of the east African and southern African sable populations. Implicit in this is that translocations of animals between populations comprising these two distinct maternal genetic clades should be actively discouraged.

588: +.187

Reintroduction of animals is becoming increasingly popular as a means of restoring populations of threatened species. Sometimes depletion of wild populations leaves only captive populations from which reintroduction projects can obtain founders for releases. The World Conservation Union guidelines on reintroductions recommend that the individuals to be reintroduced should be of the same subspecies as those that were extirpated. In some cases, however, a subspecies may have become extinct in the wild and in captivity. A substitute form may then be chosen for possible release. Such substitutions are actually a form of benign introduction. Considerations include assessment of the value of a substitution project and the selection of a suitable substitute. Species substitutions increase biodiversity, conserve related forms, improve public awareness of conservation issues, educate the public, and may be implemented for aesthetic or economic reasons. Selection of a suitable substitute should focus on extant subspecies and consider genetic relatedness, phenotype, ecological compatibility, and conservation value of potential candidates. An example of a substitution project is the reintroduction of the North African Red-necked Ostrich (*Struthio camelus camelus*) into areas once occupied by the now extinct Arabian Ostrich (*Struthio camelus syriacus*). *S. c. camelus* was chosen as a substitute because of its geographic proximity, phenotypic similarity, and conservation value. The World Conservation Union's reintroduction guidelines should be consulted before a project is begun.

589: +.196

An early motivation for this study was the problem of relocation of scarce or endangered species of animals for breeding and/or reintroduction to establish new populations in the wild. In this paper, we introduce single and multiple objective optimization models which are designed to comprehend a wide variety of objectives which are of interest to conservation and wildlife managers. We present the models in a general way and point out special features relative to ecology as they arise. Thus, the models may be used for relocation decisions analysis in diverse fields, not only in conservation and ecology. After presentation of the model in such a general way, we reformulate the models to make use of the special structure present. Such reformulation reduces the number of decision variables and constraints and, in general, makes solutions easy to obtain. By easy to obtain, we mean that tools from linear and mixed-integer programming together with elementary sorting procedures provide the basis for solving the models. In order to illustrate the capabilities of the models and solution techniques developed, we present the results of their application to the real-life relocation problem arising while analyzing restoration of the globally

590: +.112

Understanding the evolutionary role of gene flow is pivotal to the conservation of endangered populations. Gene flow can be enhanced through population translocations that are conducted to maintain genetic variation and combat the negative consequences of inbreeding depression (two of the major concerns in the conservation of subdivided or isolated populations). While researchers have given extensive consideration to the idea that gene flow can act as a creative evolutionary force by maintaining genetic variation or spreading adaptive gene complexes, the focus of this paper is to investigate gene flow as a force that constrains local adaptation. I briefly review the theoretical basis of and summarize empirical studies that indicate gene flow can constrain local adaptation, and may thereby lower short-term population fitness. This review suggests that knowledge of gene flow rates and understanding ecological differences among populations is necessary before embarking on a program to artificially enhance gene flow. 591: +.032

The range of the tammar wallaby (*Macropus eugenii*) has decreased substantially in Australia in recent times. Because two introduced populations in New Zealand may have descended from a now-extinct Australian population(s), we investigated their origins using a novel approach. We combined data from seven highly polymorphic microsatellite markers with simulation modelling to infer the history and conservation value of the New Zealand populations. The microsatellite alleles in one New Zealand population (Rotorua) are merely a subset of those in the other (Kawau Is.), suggesting Rotorua had no immigrants from an independent source. However, in the Kawau Is. population (sample size 33-37), 37 alleles were absent that were present in the Kangaroo Is. (South Australia) population at frequencies ranging from 1-40%. The probability of those alleles being lost during a founding event from Kangaroo Is. was investigated using a program that simulates the genetic consequences of population size bottlenecks. Use of realistic bottleneck parameters resulted in probabilities approaching zero that the observed allele deficiencies in the Kawau population could have occurred randomly, identifying the New Zealand tammar wallabies as descendants of a distinct taxon that is no longer extant in Australia.

592: +.136

Habitat characteristics of wetlands that contain the federally endangered sedge, *Scirpus ancistrochaetus*, were investigated in a one-point-in-time held survey. Sixteen adjacent seasonal ponds, four of which supported populations of *S. ancistrochaetus*, were sampled for 26 habitat variables. Using only five of these variables, we were able to separate ponds with and without *S. ancistrochaetus* in a linear discriminant analysis. These five variables are wetland area, percent cover of overlying forest canopy, soil percent organic matter, soil exchangeable [Na], and water [H-]. Ponds containing *S. ancistrochaetus* had higher soil organic matter content, higher soil [Na], greater area, lower water [H+], and lower percent forest canopy cover compared to ponds that did not support this species. This information can be used toward understanding factors that control the distribution of this species and also toward evaluating possible habitat for reintroduction of this endangered species.

593: +.176

Fifty-three captive-bred New Zealand Shore Plover (*Thinornis novaeseelandiae*) were released on Motuora Island in the Hauraki Gulf, New Zealand in an attempt to establish a second population of this endangered shorebird in the wild. The birds were liberated in four releases between September 1994 and February 1997. In September 1997, eight (15%) of the released birds were still resident on Motuora Island. Dispersal to the mainland was the principal known cause of loss of birds from the island, with predation being the next most important cause. Differences were found between the use of adult and juvenile birds for release but there did not seem to be any difference between using hand- or parent-reared birds. Possible seasonal patterns of disappearance may become clearer once more birds have been released on the island. Recommendations for future management and research include continuing the transfer programme to Motuora Island with intensive monitoring during the first month after release, inclusion of more adult birds in releases, release of both hand- and parent-reared captive birds and conducting more research into Morepork predation of Shore Plover.

594: -.011

The return of the Arabian oryx *Oryx leucoryx* to Oman symbolized the success of a new approach to species conservation and established reintroduction as a conservation tool. Ten years after the species had been exterminated in the wild by poaching, the first 10 founder oryx, descendants of the 'World Herd', were reintroduced to the desert, in central Oman in January 1982. A second release followed in 1984 and the population grew slowly through a 3-year drought that was broken by rain in June 1986. Further years of good rainfall and more founders meant that by April 1990 there were over 100 oryx in the wild, independent of supplementary feed and water, and using a range of over 11,000 sq km. At that time a new monitoring programme was implemented that allowed the transition from individual- to population-based monitoring and management. The population continued to grow and by October 1995 numbered approximately 280 in the wild (of which 22 were surviving founders) and used over 16,000 sq km of the Arabian Oryx Sanctuary. However; in February 1996 poaching resumed and oryx were captured for sale as live animals outside the country. Despite the poaching the population continued to increase and by October 1996 was estimated to be just over 400. However, poaching intensified and continued through late 1996 and 1997. By September 1998 it had reduced the wild population to an estimated 138 animals, of which just 28 were females. The wild population was no longer considered viable and action was taken to rescue some of the remaining animals from the wild to form a captive herd.

595: -.267

The Chinese alligator *Alligator sinensis* is one of the world's most endangered reptiles. At one-time widespread throughout much of the lower Yangzi River basin, the remaining wild individuals are now restricted to a small area in Southern Anhui Province and perhaps in adjacent Zhejiang Province. Population estimates conducted in the 1980s suggested that only 500-735 wild individuals remained at that time. Current figures suggest that the wild population is c. 400 individuals and continues to decline. The principal factor contributing to historic population decline has been habitat loss, but deliberate killing of alligators and the heavy use of pesticides have also had significant negative effects; The current conservation programme in Anhui Province is based on captive breeding and the establishment of a reserve for small groups of wild alligators. However, the inferred recent decline in the size of the wild population suggests that the reserve design is inadequate for the long-term survival of alligators. Programmes to survey the status of the remaining wild populations and evaluate the feasibility of establishing new wild populations by reintroducing captive-bred animals are currently being developed.

596: +.022

African wild dogs *Lycaon pictus* have been extirpated across most of West and central Africa, and greatly depleted in eastern and southern Africa. Given an urgent need for population recovery, especially in West and central Africa, this paper discusses the possibilities for using reintroduction to re-establish wild dog populations. Reintroduction is probably now technically possible, as long as release groups include wild-caught animals; several past attempts failed because captive-reared animals lacked skills needed to survive in the wild. However, reintroduction has only a limited role to play in wild dog conservation. Ideally, it should involve animals of the appropriate local genotype. Limited genetic data indicate that wild dogs from West and central Africa may be distinct from those in eastern and southern Africa. Because there are no wild dogs with West or central African genotypes in captivity, and no wild populations in the region large enough to be harvested for translocation, future reintroductions might have to use animals with non-native genotypes. In addition, there appear to be no suitable sites for wild dog reintroduction in West or central Africa, and few in eastern and southern Africa. Releases currently planned in the Republic of South Africa will be locally valuable, but will not establish a population likely to remain viable without intensive management in perpetuity. For these reasons, protecting remaining wild dog populations currently represents a better investment than any attempt at reintroduction.

597: -.003

Before-and-after surveys at several southern California sites indicated that populations of endangered tidewater goby *Eucyclogobius newberryi* persisted through heavy flooding in 1995. This was contrary to our expectations that flooding might have led to extirpation in some smaller wetlands. There was also no significant change in tidewater goby density before and after the flooding. Several apparent recolonization events coincided with the flood, suggesting that flooding may be important for the long-term persistence of the species.

598: +.103

Sophora toromiro was endemic to the Pacific island of Papa Nui (Easter Island) and is extinct in the wild. The species has survived in private and botanic gardens. The species is the subject of an international study to support its conservation ex situ and eventual reintroduction. As a contribution to this study the genetic diversity of the surviving stocks and herbarium samples has been assessed by means of random amplified polymorphic DNA (RAPD) and inter-simple sequence repeat (inter-SSR) analysis. The analysis indicated low levels of genetic diversity suggesting a very small number of founders. In addition, misidentified trees were identified allowing their removal from the conservation project.

599: -.132

Metapopulation structure of species in fragmented landscapes is ultimately the result of spatial variability in demographic processes. While specific information on demographic parameters is desirable, a more practical approach to studying metapopulations in fragmented landscapes may begin with analyses of species' occurrence in relation to large-scale habitat variability. Here, we analyzed occurrence of stream-living bull trout (*Salvelinus confluentus*) in relation to physical, biotic, and geometrical characteristics of habitats. Bull trout occurrence was analyzed at several spatial (10(chi) m) scales. Data were from nested sampling of 720 sites (10 m), 179 reaches (10(2) m), and 81 patches (greater than or equal to 10(3) m) of stream habitats within the Boise River basin of central Idaho. Based on previous findings, patches were defined as stream catchments

with suitable conditions for spawning and rearing of bull trout (>1600 m elevation). Patch-scale bull trout occurrence was significantly related to patch area and isolation (stream distance between occupied patches). Lack of spatial autocorrelation between patches indicated that isolation effects were more likely the result of limited interaction among habitats (such as dispersal), rather than of correlated environmental conditions. A third factor, human disturbance in the form of roads, was associated with reduced bull trout occurrence at the patch-scale. Analyses of occurrence among reaches within occupied patches showed bull trout may select larger (>2 m width) stream habitats. Occurrence of bull trout was not associated with nonnative brook trout (*Salvelinus fontinalis*) at large (patch), intermediate (reach), or small (site) spatial scales. Definition of a metapopulation structure for bull trout in the Boise River basin was complicated by uncertainties in the frequency and magnitude of dispersal. From the distribution of patch sizes and isolation among occupied patches, we suggest that the metapopulation is a complex mosaic of several elements found in conceptual models. This complexity poses a challenge to empirical and theoretical attempts to study stream-living bull trout. Future work to define the structure of bull trout metapopulations must relate temporal and spatial patterns of patch occupancy with complex patterns of dispersal that likely interact with habitat spatial structure, life history variability, and the historical context of regional climate changes. Results of this work suggest that conservation of bull trout should involve protection of larger, less isolated, and less disturbed (as indexed by road densities) habitats that may serve as important refugia or sources of recolonization. Bull trout populations in smaller, isolated, and more disturbed habitats may be at risk of extinction. Finally, metapopulation structure implies the existence of suitable, but presently unoccupied habitat, which should be managed carefully to facilitate potential natural recolonization or reintroductions of bull trout.

600: +.159

Indigenous populations of the North America river otter (*Lontra canadensis*) were extirpated from Indiana by 1942. To initiate a statewide restoration program, 25 otters (15M:10F) from Louisiana were released at Muscatatuck National Wildlife Refuge in southern Indiana. We evaluated their post-release survival, movements, and reproductive activity using radiotelemetry with 15 animals (9M:6F), field surveys, and observations for >1 year. Cause of death for 4 radiotransmitted otters (2M:2F) and 1 non-radiotransmitted male included collisions with vehicles (n=3), research-related factors (n=1), and unknown causes (n=1). Survival for radiotransmitted otters was 71% during the first year following release. We monitored 14 otters (8M:6F) for 235.1±112.9 days and obtained 1,218 radio locations (\bar{x} over bar=87.0/otter; range 24-144). Adaptive kernel home ranges averaged 35.1 (SD=26.4), 10.9 (SD=8.0), and 3.0 (SD=2.6) km² for the 95%, 75%, and 50% utilization distributions, respectively. Otters dispersed an average of 2.8±1.5 km, but distance traveled did not differ between sexes. Twelve of 15 otters known to have survived >100 days established 50% core areas on the refuge or adjacent waterways. Extensive intrasexual (\bar{x} over bar=59% between males; \bar{x} over bar=36% between females) and intersexual overlap (\bar{x} over bar=48%) of these areas, sightings of otter groups, and concurrent use of common den sites suggest a high degree of post-release interaction among radiotransmitted animals. Recruitment was not confirmed in the first year, but 3 litters were documented in the second reproductive season after release. Data obtained since this study indicate that otters persist in the release area and have expanded to adjacent portions of the watershed.

602: +.162

A genetic map was constructed from an F-2 population of 76 individuals for the purpose of comparing the arrangement of loci in the A and E *Solanum* genomes. This progeny was derived from an interspecific cross between the species *Solanum palustre* x *Solanum tuberosum*, both of

which are E-genome species. Two hundred and eighty one probes previously mapped in tomato and potato (A-genome, as postulated for diploid cultivated potato species by Matsubayashi 1991) disclosed 109 segregating loci in this population. Of these, 80 loci were linked in 19 linkage groups covering a total of 720.4 cM, with an average of 9 cM between markers. Although the genetic map of the E-genome showed conservation for most linkage groups with those of tomato and the A-genome, various translocations and possible inversions and transpositions were detected. It is evident that the accumulation of these structural changes in the E-genome is sufficient to cause the observed hybrid sterility. The major rearrangements in the E-genome included multiple translocations involving mostly linkage groups 2 and 8. Also a transposition was detected on group 9, with the same group-10 inversion distinguishing potato from tomato. Definitely groups 2, 8, 9 and 10, and possibly groups 1, 4 and 12, in the E-genome are structurally different from their homologues in the A-genome. In general, recombination values were larger in the E- than in the A-genome. The extensive structural differentiation of the E-genome with respect to that of potato and tomato justifies its present designation as a different genome, which is supported by previous chromosome-pairing studies. The difficult introgression of desirable traits from the *Etuberosum* species into potato can be explained by these structural differences.

603: +.081

The Mariana crow (*Corvus kubaryi*) is an endangered species that is restricted to the islands of Guam and Rota in the Mariana archipelago. Predation by the introduced brown tree snake (*Boiga irregularis*) has decimated bird populations on Guam, and the crow population there is the last wild remnant of the endemic forest avifauna. The population on Guam is critically endangered and, despite intensive management, the population has continued to decline. Additional management options include intermixing the Guam and Rota populations, but such options are best evaluated within a population genetics framework. We used three types of molecular markers to assay genetic variation in the Mariana crow: mitochondrial DNA (mtDNA) sequences, minisatellites and microsatellites. The two populations could be differentiated by mtDNA sequencing and they differed in allele frequencies at nuclear markers. Thus, the populations could be designated as evolutionarily significant units. However, the Guam population is genetically more diverse than the Rota population, and its survival probability if managed separately is very low. All markers did indicate that the two populations are closely related and separated by a shallow genealogical division. Intermixing the populations is justified by two rationales. First, the apparent population differences may result from recent human activities. Second, a greater amount of genetic information may be preserved by joint management. The translocation of birds from Rota to Guam has begun, but strategies that will ensure maintenance of the variation in the Guam population warrant further exploration.

604: +.123

Behavioral theories, insights, and techniques are too frequently ignored by conservation biologists. Yet an animal's survival and reproductive success clearly depend on its behavior. Using examples from marine, freshwater, and terrestrial realms, I assert that behavioral information is invaluable in five conservation areas: (1) managing wild species (e.g., designing marine reserves; reducing animal-human conflicts; understanding and managing species' responses to human-induced environmental stress such as fishing, introduced species, and chemical, visual, and acoustic pollution); (2) actively reversing the decline of imperiled wild species (e.g., reducing by catch by improving selectivity of fishing gear; re-establishing breeding populations and boosting reproduction); (3) assessing biodiversity (e.g., modeling population viability; censusing and

monitoring populations and species); (4) captive breeding and reintroduction programs (e.g., minimizing loss of valuable phenotypes; teaching or maintaining valuable survival skills); and (5) changing human behavior in resource exploitation (e.g., using principles from social psychology). Both realized and potential applications to fishes are stressed. Finally, behavioral diversity, a valuable but neglected element of biodiversity, needs to be explicitly conserved to maintain diverse populations. Arguments are presented that the conservation of species diversity and genetic diversity alone does not necessarily protect important behavioral diversity. The maintenance of both individual and population variability may be essential for the preservation of a species.

605: +.114

Understanding the ecology and behavior of endangered species, such as the tidewater goby, *Eucyclogobius newberryi*, is important for identifying problems and formulating solutions for species recovery. The tidewater goby forms isolated populations in California's coastal lagoons, creeks, and marshes. Rapid declines in the number of populations led to its listing as an endangered species in 1994. This benthic fish prefers stillwater habitats and feeds on small invertebrates. It is an annual species with an extended breeding season. Fish are larger in marsh habitats than in lagoon or creek habitats. The male digs a spawning burrow, preferably in sand, where he provides care for a single clutch. The tidewater goby is sex-role reversed: females compete more intensely than males for access to mates. The tidewater goby is a species at risk, in part due to narrow habitat: preferences, isolation of populations, short lifespan, lack of marine dispersal, and vulnerability to introduced predatory fishes. Attributes that favor its recovery include euryhaline tolerances, rapid reproductive rate, its potential for opportunistic feeding, and the possibility of natural recolonization under certain circumstances. Potential conservation measures include protecting coastal marshes that adjoin creeks and lagoons, maintaining natural hydrologic regimes, preventing artificial breaching of the sandbar at the estuary's mouth, and preventing introductions of predatory fishes. Captive breeding and reintroduction of tidewater gobies are potential tools for recovery, provided that underlying problems of habitat availability and suitability and issues of genetic integrity and disease transmission are addressed. Further research into the tidewater goby's utilization of marsh habitats, dispersal mechanisms, response to artificial breaching events, and metapopulation genetics would provide additional information for management.

606: +.167

Species recovery efforts generally focus on in situ actions such as habitat protection. However, captive breeding can also provide critical life history information, as well as helping supplement existing or restoring extirpated populations. We have successfully propagated nine species in captivity, including blackside dace, spotfin chubs, bloodfin darters, and boulder darters. Threatened blackside dace, *Phoxinus cumberlandensis*, were induced to spawn in laboratory aquaria by exposing them to milt from a reproductively mature male stoneroller, *Campostoma anomalum* or river chub, *Nocomis micropogon*. The latter are nest-building minnows, with which *Phoxinus* may spawn in nature. Eggs are broadcast among gravel and pebbles. Blackside dace individuals reared in captivity were used for translocation. Threatened spotfin chubs, *Cyprinella monacha*, fractional crevice spawners, deposited eggs in laboratory aquaria in the spaces created between stacks of ceramic tiles. Captively produced spotfin chubs were used as part of a larger stream restoration and fish reintroduction project in the Great Smoky Mountains National Park. The bloodfin darter, *Etheostoma sanguifluum*, was first used as a surrogate to develop techniques for spawning a closely related species, the endangered boulder darter, *E. wapiti*. Both darter

species mated in a wedge created between two ceramic tiles. Our efforts have had variable but generally high success, with survival rates of 50-90% of eggs deposited. Captive production of nongame fishes can aid recovery of rare species or populations, aid in watershed restoration, and can help to refine water quality standards. In addition, captive breeding allows discovery of important behavioral or life history characteristics that may constrain reproduction of rare species in altered natural habitats.

607: -.058

Captive propagation and reintroduction programs for rare and endangered species rarely include testing of techniques prior to initiation of recovery efforts. To experimentally test the effects of rearing social altricial birds with or without a conspecific parental model (a puppet), we used Common Ravens (*Corvus corax*) in southwestern Idaho as surrogates for the endangered Hawaiian Crow (*Corvus hawaiiensis*) and Mariana Crow (*Corvus kubaryi*). A puppet is believed to reduce sexual and filial imprinting on human caretakers. We raised 49 ravens without a puppet and 25 ravens with a puppet. We initiated puppet-rearing when birds were 7 days of age and continued until 60 days of age when nestlings could fend well on their own. The influence of puppet-rearing was tested as part of a factorial design that also tested for the effects of conspecific tutoring and age at release. Rearing ravens with a puppet did not affect social behaviors prior to release, dispersal from the release area, or integration with wild birds after release. Ravens raised with a puppet, however, were more fearful of caretakers and more vigilant prior to release, characteristics that may have improved their chances for survival after release. It is important for researchers to consider the species and the desired pre- and post-release behaviors to determine if rearing with a puppet is appropriate for their recovery efforts. These considerations can be taken into account by using a surrogate species prior to recovery efforts and creative management approaches in the initial phases of an endangered species recovery program.

608: +.189

Zieria prostrata (Rutaceae) is known from only four headlands within a 3-km stretch of coastline in New South Wales, Australia. The species was presumed to have occurred at a headland 24 km south of its present range. We used random amplified polymorphic DNA analysis to assess patterns of genetic variation within and among the extant populations. The analysis also included an individual reputedly rescued from the now extinct population. A high level of population divergence was revealed by principal coordinate analysis and an analysis of molecular variance (AMOVA; 37% among populations). Our genetic findings provide implications for the conservation management of the species. First, the loss of any one population would lead to a severe loss of genetic variation. Second, an adequate ex situ collection must sample the full range of genetic diversity from all populations. Third, the consequences of mixing populations may be an important conservation consideration if further translocations proceed. Fourth, the individual apparently sampled prior to its population extinction is genetically similar to individuals from one of the extant sites. This degree of similarity was unexpected and, after further investigation, led to the conclusion that prior existence of the species at the site is doubtful. Subsequently, a planned reintroduction program was abandoned. So far, of these four management implications, only the last has had a direct management outcome. These implications that failed to lead to practical management outcomes did so because the same management recommendations could be obtained without genetic research. Clearly, the challenge for more effective conservation managers. This may be best achieved by assessing the outcomes of genetic studies already conducted.

610: +.105

We evaluated translocation as a technique for restoring the Florida scrub-jay (*Aphelocoma coerulescens*) to unoccupied portions of its historic range. Prior to the breeding seasons of 1989, 1990, and 1995, we translocated 20 jays (14 nonbreeders, 3 breeding pairs) from Archbold Biological Station in Highlands County to suitable but unoccupied habitat at Rookery Bay National Estuarine Research Reserve in Collier County. Nine of the 20 jays disappeared within the first 8 weeks following translocation; 11 jays settled at Rookery Bay. Successful nesting first occurred at Rookery Bay in 1989, and from 1991 through 1997 the population remained relatively stable with 6-10 individuals and 1-3 breeding pairs. Nesting success, juvenile survival, and adult survival of jays in the reintroduced population were all comparable to those of jays at Archbold Biological Station. The sex ratio of the reintroduced population was biased toward males, apparently because of high rates of mortality or emigration by females fledged at Rookery Bay. Overall, our results suggest translocation is a useful management technique for the Florida scrub-jay. However, because of the scarcity of properly managed translocation sites, the initially high rates at which jays emigrate or die following translocation, and the potential effect of translocation on source populations, translocation should not be viewed as an acceptable substitute for the management of existing populations of this threatened species.

611: +.084

The effects of demographic isolation may be particularly severe in small, isolated populations of the endangered red-cockaded woodpecker (*Picoides borealis*). Augmentation of single adult woodpeckers with subadult birds of the opposite sex allows managers to stabilize small, isolated populations but does not provide a means to significantly increase populations. The reintroduction of pairs of subadult red-cockaded woodpeckers into unoccupied habitat provides a technique to bolster small populations. We report the results of such efforts to increase a small, isolated red-cockaded woodpecker population in eastern Texas, and we describe postrelease movements of translocated red-cockaded woodpeckers. Seventeen red-cockaded woodpeckers (9 M, 8 F) were translocated to the Sabine National Forest in eastern Texas between December 1994 and March 1995. Prior to translocations, this forest contained 13 groups of red-cockaded woodpeckers. Five pairs, consisting of a subadult male and female, were released to attempt to establish new breeding pairs. Seven additional subadult woodpeckers were translocated to provide mates to solitary individuals. Nine previously unoccupied sites were occupied. Of the 17 woodpeckers translocated, 12 (71% 6 M, 6 F) were established in territories following the 1995 or 1996 breeding seasons. The remaining 5 woodpeckers were unaccounted for. Of the 12 woodpeckers resighted, 3 (18%) established territories at their release sites. Woodpeckers that dispersed from their release site were relocated in sites an average of 2.8 km (range = 0.5-9.6 km) away. One (20%) of the 5 pairs released remained together into the 1995 breeding season. Eight (89%) of the 9 new pairs found during 1995 and 1996 included at least 1 translocated red-cockaded woodpecker and bred during 1995 or 1996. Our results demonstrate that the direct reintroduction of multiple pairs is an effective technique for reestablishing breeding units in formerly vacant habitat. Our results also suggest the reintroduction of pairs in a spatial array dense enough to allow social contact between adjacent pairs and with preexisting clusters substantially increases the formation of new pairs.

612: -.064

Ecology of the endangered Gila topminnow is reviewed, described, and reconstructed; natural conditions are placed in perspective with human-altered habitats of today. In the natural state of waxing and waning of habitat size as a function of precipitation patterns and, catastrophic events such as severe winter cold, the species in the past likely underwent dramatic expansions and contractions in population size and geographic range. Today, population expansions are unlikely

because of constraints imposed by human activities. The original patterns of dispersal from refugia in "good" times and retreat in "bad" times, if they are to occur, must be re-created through human translocation. Further, most refugia now are destroyed, or inaccessible to recolonization, so remnant, natural populations, along with established, transplanted stocks of appropriate size and genetic quality need protection. Populations also must be established and maintained in artificial refugia. Last, even if connectedness were to be reestablished and refugia provided, intervening habitats harbor introduced piscivores such as western mosquitofish that: interdict and eat dispersing topminnows and their progeny. Elimination, exclusion, or management against such offending species is mandatory to prevent topminnow extinction and achieve recovery.

613: +.049

Social system variability in a population of reintroduced Arabian oryx *Oryx leucoryx* in Oman was investigated from 1982 to 1989 by comparing two time periods on either side of June 1986, when widespread rain ended a prolonged period of drought and supplemental feeding. Variation in three social subsystems of resource exploitation, mating, and calf-rearing were observed. From the first release of 10 oryx in 1982 until June 1986, median herd size increased over time, while average group size increased as forage conditions deteriorated after rain. In addition, within each herd subordinate adult males were tolerated by dominant males, only a few dominant males sired the majority of calves, and the proportion of mother/calf pairs involving older, weaned calves progressively increased. After June 1986 until the end of the study period in December 1989, these trends reversed. Median herd size decreased over time, and average group size decreased as forage conditions deteriorated after rain. Subordinate adult males were no longer tolerated within herds, but instead existed as solitary males. The concurrent increase in solitary males and the number of herds resulted in more breeding opportunities for the expanding adult male population. The mating system became more dynamic, and involved the emergence of previously unrecorded territorial behaviors. In addition, the proportion of mother/calf pairs including weaned calves decreased. As the transition from captivity to the wild may present special difficulties in the development of social systems specifically suited to local conditions, species with more adaptable social systems, such as the oryx, are likely better candidates for reintroduction. 614: +.293

Translocations have been widely used to conserve threatened fauna worldwide, and although the benefits of monitoring newly translocated animals are widely recognised, post-release monitoring seldom occurs. This paper reports the dispersal patterns, social organisation and survival of a newly translocated population of 26 South Island saddlebacks (*Philesturnus carunculatus carunculatus*), on Motuara Island, New Zealand. South Island saddlebacks dispersed widely through forest on Motuara Island after release and 8-10 months after release, territory sizes ranged from 1.9-8.8 ha (\bar{x} over bar = 4.21 ha, $s = 2.42$). Saddlebacks in both subadult and adult plumage attempted to breed in the first breeding season after release and an estimated 10 fledglings were produced. Maximum mortality of the translocated group was 50% 8-10 months after release. Translocations of 15-59 South Island saddlebacks have been successful in the past, suggesting the success of the transfer to Motuara Island is not jeopardised by the relatively small size of the founder group. Saddlebacks appear relatively flexible in habitat requirements and are capable of high reproductive output, enhancing the success of translocations of this species. (C) 1999 Elsevier Science Ltd. All rights reserved.

615: +.191

The Mauna Kea silversword *Argyroxiphium sandwicense* is an endangered plant endemic to the high elevation cinder deserts of Mauna Kea on the Island of Hawaii. Restoration efforts have increased the total naturally occurring population of ca. 50 adult plants by ca. 500 individuals, primarily by the outplanting of silverswords initially grown under controlled conditions. We evaluated the direct sowing of seeds into field sites as an alternative to outplanting. Gravel-covered surfaces enhanced germination and growth of seedlings and increased soil moisture. The presence of shrubs and trees was associated with increased silversword germination but decreased silversword growth and reproduction. The best environment for silverswords varied throughout the life cycle of the plant, but critical stages are pollination, seed production, germination, and seedling survival. Sowing and outplanting each have unique advantages. High elevation, moist, gravel surfaces that can be protected from ungulate browsing should be the focus of future sowing and outplanting efforts to maximize restoration success. (C) 1999 Elsevier Science Ltd. All rights reserved.

616: +.210

Lake sturgeon *Acipenser fulvescens* declined in abundance in Lake Superior's St. Louis River during the late 1800s and were eliminated from the river during the early 1900s because of the combined effects of exploitation, pollution, and habitat alteration. Since then, exploitation in the river and in Lake Superior has been reduced. Furthermore, water quality in the St. Louis River has improved, and its upper-estuary spawning habitat has remained relatively unchanged and adequate. Lake sturgeon have been stocked annually in the St. Louis River since 1983; from 1983 to 1994 stockings included 736,000 fry, 128,000 fingerlings, and 500 yearlings of the Lake Winnebago strain. Relative abundance, distribution, and growth were determined by sampling marked fish in the St. Louis River estuary and western Lake Superior with graded-mesh gill nets and bottom trawls. During 1983-1998, 644 lake sturgeon were caught in 15,486 m of gill net, and 196 were caught in 1,200 trawl tows. Lake sturgeon were sampled most frequently near channelized portions of the St. Louis River and stayed in the estuary up to 5 years before entering Lake Superior. Lake sturgeon were not captured in western Lake Superior prior to stocking, but abundance increased dramatically after 1985. Of 582 lake sturgeon sampled along the Wisconsin shore of Lake Superior from 1985 through 1998 (347,000 m of gill nets), 93% were captured in less than 30 m of water. A total of 93 lake sturgeon were reported from assessment netting conducted along the Minnesota shore of Lake Superior from 1992 through 1997. The current range of stocked lake sturgeon extends from the St. Louis River 145 km east to the Apostle Islands in Wisconsin and 110 km northeast to Little Marais in Minnesota. Increases in lake sturgeon abundance were directly attributed to the stocking program. We recommend stocking a minimum of 20 year-classes and the use of a Lake Superior egg source, if possible. Final evaluation of the project will be detection of tagged lake sturgeon successfully spawning at historical spawning areas.

617: -.080

The small population of wild dog *Lycaon pictus* ($n = 3$ to 30) in Hluhluwe-Umfolozi Park (HUP) has declined since 1992. The survival of dogs in HUP is dependent on the reintroduction of more dogs; however, wild dog reintroduction programmes are fraught with problems and many have failed. In this paper the diet and capture success of the wild dog pack in the Hluhluwe Section, and the influence of dietary considerations on the success of the future reintroduction of wild dogs in this reserve, are investigated. Diet choice was determined from scat analysis, personal observation and field staff records. Eight ungulate prey species were identified from scat analysis: nyala *Tragelaphus angasi* and impala *Aepyceros melampus* were the most abundant ungulate species in

HUP and accounted for 77% of the diet. On the whole, wild dogs included prey types in the diet consistent with a rate-maximizing foraging approach, although some prey were dearly taken opportunistically. The dogs preyed mostly on small (<25 kg) to medium-sized (40-90 kg) prey, while the young of large (> 90 kg) prey species or scavenged carcasses supplemented the diet during the dry season. Adult nyala were taken more frequently than other age classes, but wild dog preyed on juvenile impala more than expected. Female prey were taken more frequently than males but selection did not differ from prey population sex ratios. Prey capture success was similar to that of previous studies from both open and densely wooded habitats and the wild dogs successfully caught 48% of all prey species pursued. Results suggest that wild dogs are quite capable of adapting both their diet choice and foraging technique to the dense vegetation in HUP. We conclude that prey type, prey availability and habitat constraints on prey capture success, will not affect the reintroduction of more wild dogs into HUP.

618: **-.032**

Asiatic wild asses, *Equus hemionus*, were driven to extinction in Israel in the early 20th century. In 1983, a herd of these animals was re-introduced to the wild in Makhtesh Ramon, a large erosion cirque in the central Negev desert, Israel. The population has grown steadily ever since and now numbers some 100 animals. In order to determine whether the wild asses are having a significant impact on the vegetation, we have monitored the plant communities in Makhtesh Ramon since 1992, using McAuliffe's log-series survey method. Our study involves 11 pairs of plots along the length of the altitudinal gradient in Makhtesh Ramon. The altitudinal gradient results in a rainfall gradient from an average of 95 mm rain per year to an average of about 40 mm per year. Each pair of plots consists of: (1) an unfenced plot, and (2) a fenced plot that excludes wild asses but not the other large mammalian herbivore, the dorcas gazelle *Gazella dorcas*. The wild asses have not had a significant impact on vegetation cover, species richness, diversity or dominance. Three plant species showed significant increases in percentage cover in fenced plots, while one species showed a significant increase in percentage cover in unfenced plots. Furthermore, eight plant species invaded fenced plots, three species invaded unfenced plots and one species disappeared from unfenced plots during the study. Using Detrended Correspondence Analysis, we found that the major differences among plots are due to position along the altitudinal gradient. The Detrended Correspondence Analyses indicated that the wild asses have had no significant effect on vegetation community structure.

619: **-.080**

Management practices favoring conifers at the expense of deciduous tree species, and the eradication of deciduous trees, especially aspen *Populus tremula*, from managed forests have resulted in population declines in several species in Fennoscandia. In addition to species depending on decaying wood of deciduous trees, earlier evidence suggests that leaf litter, especially that of aspen, is favored by many carabid species. We ran a four-year experiment in order to compare carabid assemblages of unchanged forest floor with artificially created leaf-litter plots in central Finland. A total of 18 plots (5 m in diameter) were established in three forest stands without aspen a few kilometers apart. Each stand had 3 litter plots (litter added) and 3 control plots. Pre-treatment samples were compared with those collected after litter addition. The litter addition affected the carabid-assemblage structure by increasing the catches of some species and decreasing the catch of one species. The number of carabid species was similar in control and litter plots. The litter effect was smaller than variation among forest stands and year-to-year fluctuations. There was a strong temporal constancy among the plots: "rich" plots remained "rich" from year to year and similarly "poor" plots remained "poor". The significant influence of leaf

litter on carabid abundance can be attributable to both abiotic factors (microenvironmental conditions, especially humidity and temperature), and biotic ones (changes in niche structure, improved food supply). Leaf litter seems to have an effect on carabid distribution patterns, and deciduous trees scattered among conifers are likely to be of importance on carabid fauna in boreal forests.

620: +.020

A form of lowland, sandplain Fynbos restricted to the Cape Flats near the city of Cape Town is the South African vegetation type most threatened by urban and agricultural development. Cape Flats Fynbos remnants, totaling 4.8 km², contain 14 plant species endemic to the Cape Flats scattered through four protected areas and 11 unprotected vegetation fragments on public land. Despite their small size and management problems, the remaining protected areas are under pressure from the public and developers to function as "lifeboats," or places of safety, for attractive indigenous plant species from the unprotected areas destined for development because the popular perception is that any indigenous plant population threatened by habitat destruction should be saved by being transplanted into a protected area. The urgency for dealing with the issue of plant rescue in the Cape Town metropolitan area was the catalyst for a workshop held at the University of Cape Town in 1998 to develop protocols for Fynbos plant species translocations. We report on points raised by managers and academics at the workshop including the selection of target taxa, individuals and establishment sites, and methods for introduction, and present case histories illustrating possible solutions to the problems encountered.

622: -.026

We analysed mortality and behaviour of hihi, an endangered New Zealand honeyeater, in the first three months after translocation to 135 ha Mokoia island. Our aims were to assess: (1) whether mortality and behaviour were affected by the translocation process or post-release management, and (2) whether the fate of birds during this establishment phase affected the viability of the population. Forty hihi were translocated from the wild population on Little Barrier Island, released immediately in three different locations, and provided with sugar water feeders. Many of the birds suffered leg injuries due to the bands initially used, and up to 7 birds may have died from these injuries. Nevertheless, the mortality rate over the first three months was similar to the average rate over the first 3 years. Therefore, except for the bands used, there was no evidence of post-release mortality associated with translocation stress. Most hihi discovered the feeders quickly. However, feeder use varied greatly among birds and there was no evidence that access to feeders reduced mortality. Access to feeders also did not affect overall time spent foraging. However, birds using feeders allocated most of their foraging effort to invertebrate feeding, whereas birds not using feeders foraged mostly on flowers and fruits. Hihi dispersed quickly after release, and moved all over the island. Transmitters increased re-sighting rates over the first 3 weeks, but intensive observation during that period provided no useful information relevant to subsequent survival and reproduction. There was a slight tendency for birds to settle closer to their release sites than expected by chance, but there was no tendency for birds released together to form breeding pairs. We conclude that the viability of this population was not affected by any problems in the establishment phase. However, the population has had a consistently high mortality rate over the first 3 years, and its long-term viability appears poor. Our subsequent research is, therefore, addressing the factors that might be limiting the population in the long-term. (C) 1999 Elsevier Science Ltd. All rights reserved.

623: +.171

Lacerta schreiberi is an endemic lizard in the northwest of the Iberian Peninsula, with some isolated populations in the south. The aims of this work are to select priority areas for the conservation of the species, identify extinction risk areas, evaluate the current degree of protection and define a strategy for the conservation of this species in Portugal. We used an evaluation model of areas in a GIS environment. Conservation priority areas represent 15% of the distribution area of the species in Portugal. Populations with high risk of extinction are located primarily along the littoral strip. About 50% of the conservation priority areas are already included in the Portuguese protected areas (PPA). The conservation strategy for the species needs efficient protection of habitats, increase of PPA and creation of Regional Reserves for the littoral populations. For the isolated populations we propose five types of management actions: habitat restoration, supplementation of populations, reintroduction of individuals, captive breeding and population monitoring. (C) 1999 Elsevier Science Ltd. All rights reserved.

624: +.090

The introduction of plants into secure, managed reserves is seen as vital to the conservation of many grassland species that are now confined to small, fragmented remnants in western Victoria, Australia. The survival (> 5 yrs after planting) of reintroduction plantings conducted at three sites were assessed and success related to plant and site attributes. Of the 151 plant populations, 48 species and 10 699 plants introduced by tubestock plantings to these sites over the period 1985-1992, 48 plant populations, 19 species and 1285 plants remained at November 1997. No single plant or site attribute explained success or failure across the sites, suggesting that reintroductions will present many novel challenges to practitioners. Interestingly, threatened species proved no more difficult to establish than non-threatened species. Second generation seedling recruitment was exceedingly rare: only five species in a total of 16 populations produced successful seedling cohorts and only three species (*Acaena echinata*, *Caesia calliantha* and *Podolepis* sp. aff. *jaceoides*) are considered to be established in at least one site. Failure of most populations to recruit threatens the longterm persistence of reintroduced plantings and suggests that the conservation and management of remnant populations in situ remains crucial to the survival of these species in natural habitats. Determining the requirements for seedling recruitment of reintroduced populations presents a major challenge to ecologists. Without this knowledge, plant reintroductions in western Victorian grasslands, and their implicit role as a conservation tool, are likely to remain problematic. (C) 1999 Elsevier Science Ltd. All rights reserved.

625: +.253

In their native Australia, tammar (*Macropus eugenii*) and parma (*M. parma*) wallabies are allopatric and differ markedly in habitat use, social structure and degree of reproductive synchrony. They occur sympatrically only on Kawau Is., New Zealand, as a result of introductions last century. Reproductive data collected from wallabies on Kawau Is. in April 1996 show that *M. eugenii* maintains high reproductive synchrony while *M. parma* remains asynchronous. Both species show sexual dimorphism and differences in habitat use as seen in Australia. In addition *M. parma* is more solitary, and is frequently found in closed-canopy woodland, while *M. eugenii* tends to aggregate in open grassy clearings. Thus the species maintain broad reproductive and biological distinctions, despite enforced sympatry in a novel environment. Highly-resolving genetic (microsatellite) data reveal no evidence for hybridization. This is essential information given the known (*M. eugenii*) or likely (*M. parma*) high conservation value of New Zealand stocks. Kawau Is. is the only predator-free site with *M. parma*, a species whose persistence in Australia is threatened by fox predation. Finally, we use data on mitochondrial cytochrome b sequence divergence amongst several *Macropus* taxa to demonstrate close agreement with degree

of reproductive isolation.

626: +.315

The success of captive-breeding and release programmes is often compromised by predation of released individuals, which are naive about predators. Pre-release behavioural preparation of release candidates in the form of anti-predator training has been attempted infrequently, usually using models of predators, but success was most often measured in terms of improved behavioural responses rather than survival to breeding age after release. Here we report that post-release survival of captive-reared houbara bustards (*Chlamydotis [undulata] macqueenii*) was improved through exposure to a live predator before release: a result with possible applications for a wide range of species currently the focus of reintroduction projects. We also show that rearing houbara with minimal human contact and training with a model of a predator had no effect on post-release survival. Moreover, neither pre-release behavioural responses to a model predator nor the degree of tonic immobility were predictors of post-release survival.

627: -.000

Niuafou'ou lies very isolated in the Pacific, is well forested and not densely populated by humans. These facts as well as the lack of larger rat species make it a refuge for birds rare elsewhere in the region. This paper covers all 17 breeding species and gives breeding data for 14 of them, collected from October 1991 to December 1992. Ten species had a well-defined breeding season of 2-7 months somewhere between September and April, which often differed from other adjacent islands: Audubon's Shearwater *Puffinus lherminieri*, Pacific Black Duck *Anas superciliosa*, Banded Rail *Rallus philippensis*, Spotless Crake *Porzana tabuensis*, Purple Swamphen *Porphyrio porphyrio*, Barn Owl *Tyto alba*, Red-vented Bulbul *Pycnonotus cafer*, Polynesian Starling *Aplonis tabuensis nesiotus*, and Jungle Myna *Acridotheres fuscus*. The Blue-crowned Lorikeet *Vini australis* nested in October, November and July. It did not only breed in tree hollows, but also inside a rotten log on the ground. Other observations suggest that it visits ground holes as well, either for nesting or resting. A breeding colony of Audubon's Shearwater is the first one confirmed for Tonga. Four species nested in the wet and dry season: White-tailed Tropicbird *Phaethon lepturus*, Pacific Reef-heron *Egretta sacra*, Pacific Pigeon *Ducula pacifica* and Polynesian Megapode *Megapodius pritchardii*. Since September to March is the main breeding season for birds on Niuafou'ou, it is proposed that hunting and egg collecting, both important parts of the local tradition, are restricted to the other months of the year. In case of the endangered Polynesian Megapode we suggest a restriction of egg collecting and propose a translocation programme to another island. Additionally, we suggest that the islets in the crater lake become protected as they are free of feral cats, and some birds occur in higher densities there. Niuafou'ou also deserves attention as resting place for six vagrant and migrant species; large numbers of Wedge-tailed Shearwaters *Puffinus pacificus* are hunted when they visit between October and June.

628: +.029

The numbat has been reduced to two populations in Western Australia. To better understand the effects of range reduction on gene flow and genetic variation, and to address questions crucial for the species' management, we analysed mitochondrial DNA (mtDNA) sequences of free-ranging individuals and museum specimens. The results suggest recent connectivity between the remnant populations, although one of those may have lost significant amounts of genetic diversity during the recent population size reduction. We propose that for management purposes the remnant populations should be treated as a single historical lineage and that, subject to certain caveats,

consideration should be given to population augmentation by translocation.

629: +.238

Corn and rice genetic linkage map alignments were extended and refined by the addition of 262 new, reciprocally mapped maize cDNA loci. Twenty chromosomal rearrangements were identified in maize relative to rice and these included telomeric fusions between rice linkage groups, nested insertion of rice linkage groups, intrachromosomal inversions, and a nonreciprocal translocation. Maize genome evolution was inferred relative to other species within the Panicoideae and a progenitor maize genome with eight linkage groups was proposed. Conservation of composite linkage groups indicates that the tetrasomic state arose during maize evolution either from duplication of one progenitor corn genome (autopolyploidy) or from a cross between species that shared the composite linkages observed in modern maize (allopolyploidy). New evidence of a quadruplicated homeologous segment on maize chromosomes 2 and 10, and 3 and 4, corresponded to the internally duplicated region on rice chromosomes 11 and 12 and suggested that this duplication in the rice genome predated the divergence of the Panicoideae and Oryzoideae subfamilies. Charting of the macroevolutionary steps leading to the modern maize genome clarifies the interpretation of intercladal comparative maps and facilitates alignments and genomic cross-referencing of genes and phenotypes among grass family members.

The eight papers resulting from the Ecological Genetics session of the symposium Ecology of Stream Fish: State of the Art and Future Prospects (Luarca, Spain, April 1998) describe the use of molecular genetic markers to investigate questions of population distinctness, interbreeding, and adaptation in five salmonid species. Widely contrasting ecological distinctions described in four species indigenous to western North America [steelhead (rainbow) trout, sockeye salmon, pink salmon and bull trout] reflect past natural and human-induced activities, serving to guide future management and conservation actions through optimizing adaptive opportunities, and preventing genetic losses through localized extinctions. Studies of brown trout contrast widespread introgressions from exogenous hatchery introductions that threaten the integrity of native Spanish populations with a reduced threat based on use of indigenous fish in Portuguese hatcheries. A 9-year study of natural progeny of two genetically distinct Swedish brown trout populations introduced to a previously trout-free area identifies apparent local adaptations as a model to guide other translocations.

631: +.002

Helianthus schweinitzii (Asteraceae) is a federally endangered, endemic sunflower that only occurs in the Piedmont of North and South Carolina. This species' habitat is relegated to disturbed sites such as roadsides, utility rights-of way, edges of woods, and other open sites. We used allozyme electrophoresis to investigate the genetic variation among 25 populations throughout the range of the species. Data collected from 11 enzyme systems representing 14 loci indicated that most populations are genetically similar and that the species, as a whole, exhibits moderate variation. Genetic distances among populations were not correlated with geographic distances. This may be due to recent fragmentation of large, contiguous populations of the sunflower into isolated groups. Conservation strategies for *H. schweinitzii* should include preservation and/or creation of suitable habitat and translocation of threatened populations into protected areas. Our study suggests that mitigation programs are unlikely to disturb the genetic architecture of the species or result in outbreeding depression.

632: **-.041**

Translocation is often used as mitigation in cases where sites containing protected species are threatened by development. However, the conservation value of such exercises is unproven for many species. This paper describes a case study in which translocation was used as a mitigation measure for the slow-worm (*Anguis fragilis*) a cryptic legless lizard. At a site scheduled for development, the removal of 103 lizards over a three-month period resulted in no significant depletion of the population. At the receptor site, which had no previous slow-worm population, recaptures of translocated slow-worms declined during 2 years of subsequent monitoring; recaptured lizards were in poorer condition than those in a nearby natural population; and there was little evidence of successful reproduction. As the exercise may have prevented the inadvertent killing of a number of slow-worms, it may have been successful in terms of meeting the statutory obligations for this species. As an exercise in conserving the population in the longterm, however, the value of the translocation was questionable. (C) 1999 Elsevier Science Ltd. All rights reserved.

History and pre-history tells us that Australian mammals have fared poorly through their association with humans. First there were the Pleistocene megafauna extinctions as Aborigines colonised the continent followed later by extinction of the large marsupial carnivores after introduction of the Dingo. European colonisation first appeared to favour many native mammals but later led to declines and extinctions at an unprecedented rate. The shock waves of these massive changes are most probably still reverberating across the landscape and need consideration in our approach to species conservation. Species recovery is a new and important science. Current management efforts focus on broad scale baiting of Foxes, translocation of endangered species to offshore predator-free islands, and their protection in predator enclosures. A national and more corporate approach to species conservation has arisen from national species recovery teams. Sharing of resources, particularly technical information on threat management, is critical to effective species recovery. This is especially important in forging the desperately needed breakthrough in control of Feral Cats. History tells us that disturbance of one component of the ecosystem will often provoke changes in other areas. The current intensive focus on Foxes demands careful monitoring of the general system as an early warning of developing problems. Study of the interactions between Foxes, Dingoes, Feral Cats and Rabbits are needed to discover the likely outcomes of control programs, particularly in the more arid regions where all four species coexist. Experimental reintroduction of yet untried species occupying niches yet to be examined by this technique may expose additional but more subtle threatening processes.

634: **+.018**

At least 16 species of Australian mammals have become extinct over the past 200 years. Without islands, however, this figure would be even worse as nine species that were formerly widespread on mainland Australia were or are restricted to land-bridge islands. In addition, 13 species and subspecies of endangered and vulnerable mainland mammals that still occur on the mainland have island populations, reducing their chance of extinction. In all, 43 islands protect 29 taxa of Australian threatened mammals. Since European settlement some island mammal populations have become extinct, while many new populations, of both Australian and exotic mammals, have been established. The extinction of island native mammal populations is significantly correlated with the introduction of exotic mammals. Management of islands needs to concentrate on four areas: quarantine, monitoring (of both native mammals and possible introduction of exotics), eradication of exotics and translocations of native species. Prevention of introduction and

establishment of further exotics to important islands through quarantine procedures is vital, especially for islands with permanent or temporary human habitation. Eradication or control of existing exotics is required for many islands and eradication of further introductions, as soon after detection as possible, should be a high priority action for nature conservation agencies. Past exotic mammal eradications and needs for the future are discussed. Translocations of island mammal populations to the mainland should take place only where the species is extinct on the mainland. Translocation to islands, where translocation to or on the mainland is not feasible, is an important conservation technique. Islands with exotics can be of value for re-introduction of locally extinct mammals or introductions (marooning) of threatened species that are at risk from feral predators on the mainland once the exotics have been eliminated.

635: +.368

The high biodiversity and physical heterogeneity of the Klamath-Siskiyou Ecoregion of the Pacific Northwest (USA) suggest the need for an ambitious and multifaceted approach to conservation research and planning. We developed a process of reserve selection and design that proceeds along three parallel tracks: (1) protection of special elements, such as rare species hotspots, old-growth forests, and key watersheds; (2) representation of physical and vegetative habitat types; and (5) maintenance of viable populations of focal species (e.g., fisher, *Martes pennanti* Erxleben). Each of these complementary research tracks identified important conservation opportunities in the region. In combination they provide a basis for a reserve design and management plan that meets conservation goals better than the existing management situation established by the federal Northwest Forest Plan. Our proposed Phase I reserve design begins with protection of roadless areas on public lands that score high under the criteria of our three-track approach. A relatively small area of additional public and private land is necessary to provide habitat contiguity among roadless areas and capture remaining biological hotspots. This design would place approximately 34% of the region into the strictest category of protected areas, compared to 13% under current management, and would place an additional 19% of the region into moderate protection. A second, proposed phase of conservation would include protection of additional private lands to meet representation objectives. Also included in Phase II would be protection of linkages to other regions, necessary for long-term persistence of wide-ranging animals such as large carnivores (e.g., gray wolf, *Canis lupus* L.), which are being considered for reintroduction to the region. When implemented, Phase II would bring approximately 60-65% of the region into strict and moderate protection. Linkage design and ecological management (e.g., fire regimes) are among the critical topics for further research.

636: +.010

The elephant population of the Yala Protected Area Complex (YPC) was studied by indirect dung count method. The YPC consists of one Strict Natural Reserve, two National Parks (NP) and three sanctuaries, and occupies an area of 1,518 km². The elephant densities in different habitats were estimated using the dung pile densities in belt transects and plots. Twelve distinct habitats were recognised. The highest density occurred in grass-scrub (1.03 km⁻²) and the lowest in the riparian forest (0.08 km⁻²). No dung piles were found in the moist semi-evergreen forest, which, however formed only a small part (about 2.2% by area) of the complex. The average elephant density of the entire YPC is estimated to be 0.51 km⁻². The component reserves of the YPC had different elephant densities, the highest observed being in the Block I of the Ruhuna NP (0.80 km⁻²) and the lowest (0.31 km⁻²) in the Block IV of the Ruhuna NP, the differences being attributable to their different habitats. The recent translocation of a large group of elephants may have increased the elephant density of the YPC to 0.66 km⁻². When the habitat differences are not taken into

account, the study indicated a higher density of 0.61 km⁻² than when the particular habitats were treated separately (0.51 km⁻²).

637: +.012

Predation on endangered species by nonnative red foxes (*Vulpes vulpes*) and the resulting controversy over red fox control efforts in California prompted our investigation of the introduction and range expansion of the red fox in California. Since the late-1800s, nonnative red foxes have been introduced into California by escaping from fur farms and fox hunters, through intentional releases by pet owners and fur-farm owners and translocations of previously introduced foxes. From 1990-1993 we conducted telephone interviews of wildlife professionals to obtain observations of nonnative red foxes outside the historical range of the native Sierra Nevada red fox (*V. v. necator*). Nonnative red foxes now occur throughout lowland areas of California including the Sacramento and San Joaquin valleys, San Francisco Bay-Delta area, the southern California Coast Range and Coastal Plain and most major urban areas. Their range expansion over the last 100 y was the result of population growth from numerous points of introduction and exhibited by the exponential growth typical of invading species. Fox predation on endangered species and opposition to red fox management have been the two largest management issues associated with this range expansion.

638: +.004

Karyotypic variation in five gibbon species of the subgenus *Hylobates* ($2n = 44$) was assessed in 63 animals, 23 of them wild born. Acquisition of key specimens of *Hylobates agilis* (agile gibbon), whose karyotype had been problematic due to unresolved structural polymorphisms, led to disclosure of a compound inversion/translocation polymorphism. A polymorphic region of chromosome 8 harboring two pericentric inversions, one nested within the other, was in turn bisected by one breakpoint of a reciprocal translocation. In double-inversion + translocation heterozygotes, the theoretical meiotic pairing configuration is a double inversion loop, with four arms of a translocation quadrivalent radiating from the loop. Electronmicroscopic analysis of synaptonemal complex configurations consistently revealed translocation quadrivalents but no inversion loops. Rather, nonhomologous pairing was evident in the inverted region, a condition that should preclude crossing over and the subsequent production of duplication-deficiency gametes. This is corroborated by the existence of normal offspring of compound heterozygotes, indicating that fertility may not be reduced despite the topological complexity of this polymorphic system. The distribution of inversion and translocation morphs in these taxa suggests application of cytogenetics in identifying gibbon specimens and avoiding undesirable hybridization in captive breeding efforts. (C) 1999 Wiley-Liss, Inc.

639: +.133

The prospective for using molecular approaches in conservation and traditional biological studies is reviewed. The focus is on the methods of allozyme analysis and the polymerase chain reaction with random primers (randomly amplified polymorphisms of DNA) used to study genome polymorphism and genetic structure in the populations of *Panax ginseng* C.A. Meyer and to tag the species in the genus *Iris*. The feasibility of these approaches; is discussed, in the context of developing a strategy for conservation and the reintroduction of the rare and vanishing plant species.

640: +.189

This study addressed the initial effects of a reintroduction of Gunnison's prairie dogs (*Cynomys gunnisoni*) on resident small mammal and plant communities on the Sevilleta National Wildlife Refuge (SNWR), New Mexico. In spring 1997, 60 prairie dogs (36.8 kg live mass) were introduced onto a former prairie dog colony in a desert grassland site. Small mammals and vegetation were sampled on both a treatment (reintroduction site) and a control site (without prairie dogs) before and after the prairie dogs were reintroduced. We tested for differences in small mammal and plant community change during the 1st year of the colony's existence using repeated measures analysis of variance. Although prairie dog biomass was ca. 32 times greater than that of the resident rodent community (1.2 kg), reintroduction of prairie dogs had no significant effect on the resident small mammal and plant communities. Total biomass and abundance of rodents, and percent cover and species richness of plants did not change during the 1st year following reintroduction of prairie dogs. However, two rodent species showed significant differences in abundance between the prairie dog colony and the control site. The banner-tailed kangaroo rat (*Dipodomys spectabilis*) was significantly more abundant on the treatment site before and after reintroduction of prairie dogs. In contrast, the white-footed mouse (*Peromyscus leucopus*) was significantly more abundant on the control site following reintroduction of prairie dogs. Habitat modifications made by the former prairie dog colony may be responsible for the habitat preferences observed by *D. spectabilis* and *P. leucopus*. Although reintroduction of prairie dogs had no observable influence on the resident small mammal and plant communities in the short-term, their influences may be more evident on a long-term time scale.

641: +.153

The possibility of using molecular approaches to the problems of nature conservation and classical biology is considered. Special attention is paid to the use of allozyme analysis and polymerase chain reaction with arbitrary primers (RAPD) for the studies of genome polymorphism and genetic structure of *Panax ginseng* populations, as well as genotyping of the genus *Iris*. Expediency of such studies for the development of the policy of preservation and reintroduction of rare and disappearing plants is discussed.

642: +.197

In both conservation and biological control, translocation (the human-aided release or redistribution of individuals within a landscape) is an important management tool aimed at enhancing species persistence. Metapopulation theory, which has become a focus for understanding species' dynamics in patchy landscapes, has traditionally emphasized long-term and equilibrial dynamics rather than the consequences of a species' initial dispersion. Here, I examine a metapopulation model with stochastic catastrophes to assess the relative influence of a species' initial dispersion on metapopulation persistence times. My analyses reveal that, in contrast to the strong influences of patch number, reproductive rate, and dispersal rate, variation in initial dispersion often has minimal effects on metapopulation persistence. However, initial dispersion appears to be a more important factor in metapopulation persistence for systems facing extra threats at low density, such as Allee effects or demographic stochasticity. If proven to be more generally true, such surprisingly negligible effects of initial dispersion on metapopulation persistence times would suggest that, for some systems, the micromanagement of individuals' distributions among patches may not be a high priority.

643: -.040

Reintroductions of captive-managed animals are a vital tool for the conservation of populations

and species extinct in the wild. Because genetic diversity may impact population persistence, the genetic composition of reintroduced and captive populations is critical. For captive-managed species with known pedigrees, individual animals can be selected to create reintroduced populations with specific genetic compositions. Five genetic and demographic strategies for selecting animals were tested on four species. Selection strategies were based on criteria identified in field and theoretical studies. Simulated reintroductions of animals from captive-breeding programmes created a genetic conflict. Among the different strategies, increases in the genetic diversity of one subpopulation were negatively correlated with changes in the genetic diversity of the other subpopulation. For example, the release of genetically over-represented animals was the most beneficial strategy for a captive-breeding programme, but provided the least genetic diversity for the reintroduced population. However, gains and losses in genetic diversity between populations varied with different selection criteria and different population structures. Because captive-breeding histories vary for each species, changes in genetic composition cannot be accurately predicted and no one strategy is universally optimal. Thus, genetic trade-offs must be assessed for each population relative to specific programme goals.

644: +.252

Effective management of our National Park Service lands requires information about the social aspects or human dimensions of wildlife. Understanding attitudes aids fish and wildlife professionals to predict public responses to management strategies like species restorations. We documented visitor attitudes toward and knowledge of restored bobcats (*Lynx rufus*) on Cumberland Island National Seashore (CINS). Bobcats were restored on CINS in 1988 and 1989. During fall 1997, we compared 4 visitor user-groups (white-tailed deer [*Odocoileus virginianus*] hunters [DH], day-only [DO] visitors, developed-site [DS] campers, and back-country [BC] campers) concerning their attitudes and knowledge, using a self-administered, drop-off questionnaire distributed on return ferries and at island campsites. We contacted 1,138 individuals. Overall response rate was 82.6%. Across 4 visitor user-groups, the mean attitude-toward-restored-bobcat score was 0.8, with a range of -18 to 16. A positive score represented a positive attitude, and a negative score represented a negative attitude. Zero represented neutrality. Deer hunters had a statistically less positive mean attitude score (-0.1) than the 3 other visitor user-groups. Overall mean score for knowledge-of-bobcats was 3.8 out of a perfect score of 10.0. Deer hunters had a statistically greater mean knowledge score (5.1) than the 3 other visitor user-groups. Thus, our results indicated that visitor attitudes toward and knowledge of bobcats on CINS differed among the 4 visitor user-groups. Wildlife interpretive and education programs should be specifically targeted to address the differences in attitudes and knowledge among visitor user-groups.

645: +.103

A character-based phylogenetic species concept approach was used to examine conservation unit status for three wild populations of black and white ruffed lemurs, *Varecia vareigata variegata*, from Betampona (N = 3), Manombo (N = 6), and Ranomafana (N = 14), Madagascar. Population aggregation analysis was performed on 548 bp from the control region (D-loop) of the mitochondrial DNA (mtDNA). Twenty-one diagnostic sites were found to differentiate the Betampona (northern) population from the Manombo/Ranomafana (southern) populations. Additionally, individuals from the North American captive population (N = 11) and from Parc Ivoloina, Madagascar (N = 6) were examined for the same mtDNA fragment. The captive animals more closely resembled the southern populations and the Parc Ivoloina animals were more similar to the northern population. However, the inclusion of these ex situ animals reduced the number of diagnostic sites differentiating the northern and southern populations. Our genetic data were used

to assess the ongoing management strategy for reintroducing individuals into the Betampona population and for introducing new founders into the ex situ population. This study demonstrates the utility of combining genetic information with a consideration of conservation priorities in evaluating the implementation of management strategies.

646: +.200

A monitoring system has been established to evaluate survival rate and dispersal behaviour of reintroduced Bearded Vultures (*Gypaetus barbatus*) in Austria. In 1998 the number of observations increased by about 400 %. Nevertheless there was still a severe shortage of observations from some regions of the country even though it is likely that Bearded Vultures are present. After several years of collecting basic information we are now focussing on specific information exchange between voluntary collaborators and a central coordination. To enable individual released birds to be recognized a system of feather bleaching using hydrogen peroxide was introduced and has proved effective. An extensive network of observers has been established now. In 1996/97 the first pair of reintroduced Bearded Vultures started to breed successfully in Haute Savoie/France. Since then, additional pairs have formed in northern Italy and further pair formations may take place soon in other alpine regions. Preliminary results indicate some possible preferences in habitat selection.

647: +.198

The effects of small population size on genetic diversity and subsequent population recovery are theoretically predicted, but few empirical data are available to describe those relations. We use data from four remnant and three translocated sea otter (*Enhydra lutris*) populations to examine relations among magnitude and duration of minimum population size, population growth rates, and genetic variation. Mitochondrial (mt)DNA haplotype diversity was correlated with the number of years at minimum population size ($r(s) = -0.741, p = 0.038$) and minimum population size, ($r(s) = 0.709, p = 0.054$). We found no relation between population growth and haplotype diversity, although growth was significantly greater in translocated than in remnant populations. Haplotype diversity in populations established from two sources was higher than in a population established from a single source and was higher than in the respective source populations. Haplotype frequencies in translocated populations of founding sizes of 4 and 28 differed from expected, indicating genetic drift and differential reproduction between source populations, whereas haplotype frequencies in a translocated population with a founding size of 150 did not. Relations between population demographics and genetic characteristics suggest that genetic sampling of source and translocated populations can provide valuable inferences about translocations.

648: +.188

The Green and Golden Bell Frog *Litoria aurea* is recognized in New South Wales and nationally as a species in serious decline. We surveyed its current distribution and abundance in the Illawara region of New South Wales in order to devise a regional conservation plan for this species, based on the objective of establishing at least three isolated, viable populations. The survey was conducted during 1997-1999 across 18 sites based on historic and current records of the species, and habitat suitability. Bell frogs were detected at eight sites, four of which were on public land. The maximum number of adult frogs varied from 11 to 78 across seven sites in Port Kembla, suggesting a population of > 100 adult frogs. Breeding was poor at most sites during this study but a moderate number (ca 50) of juvenile frogs was observed at the BHP Steelworks site in January 1998 and at Coomaditchy Lagoon in February 1999. Bell frogs were recorded previously at

Shellharbour, where a large population occurred, and at Bulli. These areas are proposed as the other regional sites for bell frog conservation because they are well isolated (> 10 km away) from Port Kembla. A small number of bell frogs was present at Bulli, while none was found at Shellharbour. The apparent stability of bell frogs in the Port Kembla area suggests that the presence of multiple breeding sites within a relatively small area (2.5 km radius) is very important and the establishment of viable populations in other areas should consider this situation as a model. This will require the creation of additional breeding sites at Bulli and Shellharbour, and may require translocation to Shellharbour if no occupied sites are found in the next few years. The presence of predatory fish at nine sites demonstrates the need for the conservation strategy to include activities that improve the quality of the habitat currently available to bell frogs.

649: *-.046*

From 1995 to 1999, two species of endemic Hawaiian thrushes, 'Oma'o (*Myadestes obscurus*) and Puaiohi (*M. palmeri*), were captive-reared and re-introduced into their historic range in Hawai'i by The Peregrine Fund, in collaboration with the U.S. Geological Survey-Biological Resources Division (BRD) and the Hawai'i State Department of Land and Natural Resources. This paper describes the management techniques that were developed (collection of wild eggs, artificial incubation, hand-rearing, captive propagation, and release) with the non-endangered surrogate species, the 'Oma'o; techniques that are now being used for recovery of the endangered Puaiohi. In 1995 and 1996, 29 viable 'Oma'o eggs were collected from the wild. Of 27 chicks hatched, 25 were hand-reared and released into Pu'u Wa'awa'a Wildlife Reserve. Using the techniques developed for the 'Oma'o, a captive propagation and release program was initiated in 1996 to aid the recovery of the endangered Puaiohi. Fifteen viable Puaiohi eggs were collected from the wild (1996-1997) to establish a captive breeding flock to produce birds for re-introduction. These Puaiohi reproduced for the first time in captivity in 1998 (total Puaiohi chicks reared in captivity 1996-1998 = 41). In 1999, 14 captive-bred Puaiohi were re-introduced into the Alakdi Swamp, Kaua'i.

650: *+.129*

Twelve wild adult Colorado pikeminnow (*Ptychocheilus lucius*), captured in the tailwaters of Taylor Draw Dam on the White River, Colorado, were implanted with radio transmitters and their movement patterns monitored from 1992 to 1994. The spawning migration of these fish was extensive. In 1993, the only full year of the study, the fish migrated an average of 658 km from the White River to spawning sites in the Yampa or Green rivers and back to the White River. Eight of these fish were translocated in the river upstream of the dam in April 1993. These fish and the 4 others below the dam remained in the river until May 1993. All 12 had migrated down the White River to spawning sites in the Green and Yampa rivers by July 1993. The fish that were located above the dam successfully passed over the dam during their downstream migration. Seven fish migrated upstream toward the Yampa River Canyon spawning site and 5 migrated downstream toward the Green River Desolation/ Gray Canyon spawning site. Five of 7 Yampa River fish were found at the spawning site. The other 2 were found 5-8 km downstream of the site. One of 5 Green River fish was found at the spawning site, the other 4 between 16 and 62 km upstream of the site. All fish migrated back to the White River by August 1993 and were found near the dam by October 1993. Two fish were recaptured and translocated above the dam in September 1993. Five fish were located below the dam and 2 above the dam in April 1994. By July 1994 seven of the same fish that had migrated toward the Yampa River in 1993 were found at the Yampa Canyon spawning site. At the same time, 3 of 5 fish that migrated toward the Green River in 1993 were found at the Desolation/Gray Canyon spawning site. This included 2 fish that had been found

upstream of the site in 1993. The 12 fish traveled an average of 6 km d(-1) (range: 4-10 km d(-1)) during the migration period from May through October 1993. Generally, fish moved faster to the spawning site than back from the site to the White River. These fish moved very little within their home ranges in the White River. Six fish tagged in 1992 moved only 0.1-2.3 km in the tailwater reach below Taylor Draw Dam from September 1992 through April 1993. All fish, after their spawning runs, had moved up to or near the dam by October 1993. These fish were not tracked again until April 1994. Their movement patterns in April 1994 were similar to those observed in April 1993. The greatest amount of fish movement in the White River was displayed by the 8 fish placed above Taylor Draw Dam in April 1993 and the 2 placed in Kenney Reservoir in September 1993. They moved 1.1-40.6 km in the river before and after their spawning migration in spring and autumn 1993. These spawning migrations suggest that adult Colorado pikeminnow in the White River were recruited from both Green and Yampa river spawning populations and were presumably imprinted to these respective spawning sites. Those fish placed above Taylor Draw Dam established home ranges in habitats previously occupied by Colorado pikeminnow before the dam was completed. They remained there until they migrated downstream during the spawning period. Although we did not study fish passage, our study demonstrates that adult Colorado pikeminnow will use habitat if access is provided. Translocation of wild adult fish into historic but unoccupied habitats may be a valuable recovery option.

651: -.004

Genetic variation within and among wild Turkey, *Meleagris gallopavo*, subspecies was measured using DNA sequencing and PCR-RFLP analysis of a 655 bp portion of the mtDNA D-loop region. DNA sequencing from 25 individual Eastern, Merriam, Rio Grande and domestic Turkeys revealed 16 polymorphic sites. Parsimony and neighbor-joining analysis did not show support for the four wild Turkey subspecies studied. PCR-RFLP analysis of 118 individuals revealed 13 distinct haplotypes. Haplotype variation was detected in all wild Turkey populations, and Wright's F-statistics revealed pronounced differentiation ($F_{ST} = 0.302$) among populations. Based on these data, non-native wild Turkey populations do not appear to have suffered a genetic bottle-neck since their reintroduction.

652: -.070

Since late April 2000, a Turkey Vulture *Cathartes aura* has been observed at several sites in The Netherlands, i.e. Monster, Zwolle, Texel and Wieringen. At two such sites, it was noted that the bird did not wear rings or other artificial markings. The bird at Wieringen was seen on 13 May 2000, while foraging on a freshly dead sheep; it tried to penetrate the head through the eye sockets. At Mallnitz, in the Austrian Alps, two juvenile Bearded Vultures *Gypaetus barbatus* were released at an artificial nest in May 2000. These birds are part of a WWF-project to re-establish this species, started in 1986. Since 1997, several Bearded Vultures turned up in the lowlands of The Netherlands; these birds originated from similar reintroduction projects in the Alps and have a small chance of survival. The colonization of Austria by White-tailed Eagles *Haliaeetus albicilla* was frustrated in 2000 by poisoning incidents in winter 1999/2000 (involving three birds) and road accidents (two).

653: +.154

The first records of exotic Nile tilapia, *Oreochromis niloticus* (Linnaeus, 1758), from the Limpopo River system are reported, and differences between native Mozambique tilapia, *Oreochromis mossambicus* (Peters, 1852), and *O. niloticus* are described. Conservation implications, such as the

translocation of fish and possible hybridization with indigenous *Oreochromis*, are discussed.

655: +.168

The growing human population presents threats to the viability of many species of vertebrates through land use changes, environmental pollution, killing or disturbance, and the introduction of non-indigenous species. The development of appropriate responses depends on accurate identification of threats, and this has involved studies on captive animals. Furthermore, conservation programmes increasingly include active interventions such as translocation, captive breeding and reintroduction. In addition, animals are used in research to underpin these and other conservation technologies. A high standard of husbandry, in terms of welfare, of wild animals in these programmes can present considerable challenges, because, for many species, knowledge of biological requirements and how these can best be met is incomplete. Actions that are good for species conservation might not be in the best interests of the individual animals involved, and balancing conservation benefits and welfare costs in proposed research or intervention for conservation is not easy. Environmentalists tend to give priority to species conservation, while proponents of animal rights give priority to individual animal welfare. It is important that an ethical review process takes place in which conservation objectives and potential welfare costs are clearly identified and considered. The involvement of animals often cannot be replaced in this species-specific work and usually, therefore, only two Rs apply, and refinement warrants particular attention. Knowledge of the biology of the species in the wild, and previous experience of its maintenance in captivity, provide a basis for husbandry practices. Close health monitoring, observation of behaviour, and controlled studies, provide information on which to base further improvements.

656: +.158

When reindeer (*Rangifer tarandus tarandus*) were introduced to Alaska's Seward Peninsula between 1892 and 1902, other ungulates were not present and large predators were either absent or less abundant than after reindeer were established. During the next 100 years reindeer numbers and distribution increased and declined precipitously on the Seward Peninsula: wildlife species repopulated this region through natural processes or translocations by man; the non-Native human population of Alaska increased dramatically and wildlife management became an issue of national concern creating diverse public desires regarding resource use; and both range and wildlife became intensively managed through complex, politicized processes. This paper provides an historical overview of reindeer and wildlife abundance on the Seward Peninsula during the 20th century and describes the effects of wildlife on the reindeer industry. Cooperative public processes have been initiated to bring diverse public interests together; meld indigenous, scientific and local knowledge of resources; and supplement governmental wildlife management programmes. Even so, the Seward Peninsula reindeer industry has been severely impacted by wildlife, especially caribou (*R. t. granti*).

657: +.290

A period without management had transformed the vegetation of a species-rich fenmeadow, with no external change in the hydrological regime, into three communities: alder thicket (unmanaged 15 years), tall herb and sedge dominated communities (unmanaged 11 years). Following reintroduction of management (felling of alder thicket, mowing and grazing) the vegetation development was monitored and species cover was measured along a permanent transect before and during 12 years of restoration succession. Management increased the density of fenmeadow

species and made the three communities more similar. The appearance of new fen species and the increase in species density followed immediately after the introduction of management. Thereafter, only a few new species appeared and the turnover index stabilised. Management by mowing and grazing both increased species density of herbs and promoted establishment of biennials and hemicryptophytes. Other plant groups responded differently to management: mowing increased total cover, the cover of grasses, and promoted phanerophytes and chamaephytes; grazing reduced the influence of these groups and promoted 'sedge & rush' and geophytes. Restoration was particularly successful in the felled alder thicket, but the success was caused by spreading of species from the pool of species within the site and establishment of species having persistent seed bank, i.e. inherent good potential for restoration. The results are discussed in relation to use of functional plant groups and Ellenberg N- and L-indices as response indicators for monitoring restoration progress.

658: +.032

The diffuse presence of free ranging dogs (non-controlled, stray, and feral) in Italy is considered a severe conservation threat because of the potential impact on the wolf and on other wildlife species. In particular, it is generally believed that non-controlled owned dogs are rapidly increasing their number, representing a major part of the problem. The present legal framework does not allow destruction of dogs and cats, and the management of these pet species is based on mandatory marking, and on capture of free ranging animals for perpetual captivity in public kennels. The present research was aimed to: 1) collect and analyze available information on the impact of free ranging dogs on the wolf and on wildlife; 2) census owned dogs in rural areas of Italy (including urban centers with less than 30,000 inhabitants); 3) estimate the proportion of owned dogs that are free to range; 4) assess the public perception of problems posed by free ranging dogs; 5) assess the public attitude toward management alternatives; and 6) define management guidelines. Free ranging dogs resulted to prey upon all ungulate species and colonial ground-nesting birds. Dogs are the main limiting factor in translocation projects involving roe and red-deer, and represent a key obstacle to the recolonization of central and southern Italy by these species. Impact on the wolf is also discussed. Dogs were censused through direct interviews to 2,903 Italian families, randomly selected by the electoral lists. The sample was homogeneously distributed in the country, in order to test for differences among areas (n=4 sub-regions: northeast, northwest, center, south and islands). The total number of dogs is estimated at 6,099,011 +/- 307,234. Of these, 19.7% (n=1,209,973 151,280) are free to range at least part of their time. Despite the lack of reliable data on the past dog numbers, we estimated an average 5 % year increase of the total population of dogs. The high increase rate is explained by the limited number of sterilized females, and the consequent high percentage of females reproducing every year. Number of dogs is negatively correlated to the size of urban areas, and increases from north to south. Control by owners follows opposite patterns. Despite the increasing number of non-controlled dogs, Italians have a limited perception of the social, sanitary, and conservation risks caused by dogs: 51.1 % of Italians consider that dogs do not represent a problem at all, and only 3.8% of the population considers the destruction of dogs an acceptable alternative to perpetual captivity.

659: +.105

Hihi (or stitchbird, *Notiomystis cincta*) is a rare honeyeater endemic to the North Island of New Zealand. Hihi were translocated from Little Barrier Island to Mokoia Island, Lake Rotorua, in 1994. Mokoia is a small (135 ha) island with secondary vegetation, so there was some doubt as to whether the island had sufficient diversity of fruit and nectar sources to support a hihi population.

This paper reports data collected in the year after the translocation on the density, distribution and phenology of plants likely to be used by hihi. We address the following questions. (1) How many hihi food plant species are on Mokoia? (2) How are the food plant species distributed over the island? (3) Are there periods when flower and fruit sources are scarce and/or spatially confined? (4) How might the availability of fruit and nectar change with succession or additional planting? There was always a minimum of 2-3 species providing nectar or fruit used by hihi. Most (16/21) of the species providing nectar flowered during the hihi breeding period, from October-February, and most (9/16) of these were canopy tree species. The greatest diversity of fruit sources was from March-May. August-September stood out as the period with the lowest diversity of fruit and flower sources, followed by June-July. While there was no time of year when hihi clearly suffered from shortage of fruit and nectar, we suggest that they may be susceptible to shortages in future years at times when diversity of food sources is low. We recommend further planting that could make the island more suitable for hihi in the long term.

660: +.175

It is well known that many animal species are forced into extinction by causes related to human activity, and that their possibilities to survive in the future are seriously compromised due to the great loss of genetic diversity that characterizes their populations. The use of the assisted reproduction technology in threatened wild animals may help to improve their genetic status as it has been done with livestock species. Sperm, oocyte, and embryo freezing would make possible the establishment of a Genetic Resource Bank, which, in turn, would be of use in conservation programmes since Artificial Insemination, in Vitro Fertilization, and Embryo Transfer would allow this genetic material to be used so as to enrich the genetic diversity of both wild animals in nature (in situ conservation programmes) and captive populations that are being managed for a reintroduction plan (ex situ conservation programmes). However, the application of this technology involves overcoming a series of difficulties: there is a lack of basic knowledge on reproductive cycles to time artificial insemination or embryo transfer, genetic material used must be relatively abundant and of good quality, and, finally, protocols have to be designed for sperm and embryo freezing, for in vitro culture of oocytes and embryos, or for managing the female oestrus unless the methods used in their phylogenetically related domestic species can be successfully adapted.

661: +.055

During the last century, human activities have promoted large changes in habitats, leading to changes in the abundance and composition of mammal communities. Some species have been favoured intentionally (specially those with high economic importance), or unintentionally (i.e. opportunistic species), introduced (as some livestock species), or persecuted (i.e. species that affect livestock or game). In this paper, we show and explain the changes in the composition of the large mammal community in Aragon, a northeastern Spanish area where there have been extinctions (lynx, *Lynx sp.*); introductions (mouflon, *Ovis ammon*; fallow deer, *Dama dama*); reintroductions (red deer, *Cervus elaphus*); and particularly natural expansions (wild boar, *Sus scrofa*; roe deer, *Capreolus capreolus*; red deer; Pyrenean chamois, *Rupicapra pyrenaica pyrenaica*). Some taxa are currently almost extinct (brown bear, *Ursus arctos*; Pyrenean ibex, *Capra pyrenaica pyrenaica*) and others are recovering after getting close to extinction (wolf, *Canis lupus*). Three interconnected causes may explain the clear increment of ungulates in our study area: (1) the abandonment of rural activities, (2) the subsequent decrease of livestock, and (3) the increase of forest habitats. None of those species are currently below 150 % of their range in the 19(th) century. The setting up of hunting reservations and the design of a hunting legislation have

also contributed to the observed changes. Traditionally, large predators have not been favoured by human activities, while compensatory protection measures carried out have been scarce or came too late. While some of these species are probably extinct in the area, the remaining occupy currently less than one fourth of their former range and need urgent conservation measures for to recover.

662: +.055

One hundred years passed since the time when the first transport of Przewalski's horses captured in China and Mongolia by hunting expedition arrived to Europe. Its existence came through dramatic breaks in the course of 20th century. Przewalski's horse, the last living wild horse became the symbol of the all endangered species on Earth. In several transports were imported in 1900-1902 to Europe 54 wild horses but only 12 of them gave offspring. Today world-wide population numbering over 1590 horses bred in zoological gardens and breeding centers of five continents. Observations of the wild-living Przewalski's horse from the May 1968 is considered to be the last credible report. No one later report about observation of wild horses in northern Xinjiang and Mongolian Altai Gobi was verified. An airplane survey of the Djungarian Gobi desert including Baytag Bodgo mountains and areas next to the Mongolian border made by the Chinese in 1986-1987 did not confirm the existence on any free living Przewalski's horses. On 1st Symposium on preservation of the Przewalski's horses in Prague in 1959 has been charged the Prague zoo due to its creditable work in breeding of this species with keeping of the International studbook. Since 1960, the population of Przewalski's horses grew permanently, which increased hope for their return back to the wild. Possibility of reintroduction started to be discussed after year 1980 when the worldwide population reached the number of 500 individuals and the annual growth amounted to approximately 10%. In May 1985, an international symposium was held in Moscow under the auspice of UNO, FAO and UNEP, where experts agreed on the way and time schedule of transports of first chosen Przewalski's horses to Mongolian semireserves. However it remained only in the stage of intentions. The world conservation organisation like a IUCN or WWF failed at the historical moment, instead taking supervision of the whole project, they rather supported some regional and fragmentary actions and concentrated for the common and theoretical recommendation. On the end of eighties and nineties, the initiative devolved upon the side of private foundation in Germany and Netherlands. These foundation set acclimatization centers in China (Jimsar in northern Xinjiang, Wuwei in Gansu province) and in Mongolia (Hustain Nuruu National Park near Ulan Bator and Tachin Tal in Altai Gobi, in the last known refugium of the species). In this phase, mutual relationships between concerned organisations as well as persons complexified, and resulted in open indictment, which cast an unfavourable on the whole effort to return of last species of wild horse to its homeland. Hoping and expectations of zoological gardens were not met and zoos had no possibility and often no interest to participate on the reintroduction. But in last time seems that almost of contraversian position fall off and there is hope for new era of cooperation. Despite all problems, although the reintroduction has not been as successful as the Przewalski's horses returned to its former native country and today there are living individuals born here in the second generation. In Mongolia in both acclimatization centres (Hustain Nuruu and Tachin Tal) several small herds are living in the free. In China, despite significant breeding success in the acclimatization centers, the problem has not yet been solved - where to release the acclimatized horses, and they remain entirely dependent on man help and care. The only choiced place - basin along river Ulungur in the Kalameili Mountain reserve is in traditional wintering place of 8000 herdsman with more than 40.000 domestic animals including feral horses. Progress in reintroduction is therefore being made only in Mongolia. Evidence of losses of horses showed that most of falls can be attributed to injury caused by transport or by traumas from mutual attacks of horses (namely stallions in unsuitably located enclosures). In the harsh climate of the Gobi

desert, the biggest problems the horses face when getting acclimated are respiratory diseases. In all the reintroduction centres, horses suffer from blood parasites, and as regard affected by predators, especially wolves. It has become apparent that those that find it most difficult to accommodate to new conditions are the older horses. What cause problems are for Mongolia too early births of foals (April, May), which are due to the shift in the reproduction pattern from living in quite different condition in of Europe and Northern America for more than 14 generation. On April 24, 1999, for example, the temperature of -28 degreeC was recorded in the Tachin Tal in the Gobi, and one of born foal froze to death. The optimal period for giving birth in this area would be end of May to July. Despite all these problems, the number of the Przewalski's horses in the wild is growing. In 2000 transports have been completed to the NP Hustain Nuruu near Ulan Bator, where there is a stable population almost 120 horses, now with an annual growth of some 10%. The year 2000 has been a turning year in the hard condition Tachin Tal centre, where 14 foals was born in the spring, half of these in free living herds. When predicting future development of reintroduction, we have to bear in mind that the factors are still there, that in the 1960's led to extinction of the Przewalski's horse from the wild, especially in the Gobi: desertification and aridisation of semi-desert areas and steppes, limited number of water resources used part of the year by herds of domestic animal, grazing-out of vulnerable semi-desert ecosystems and the risk of cross-breeding with omnipresent feral horses. Jiri Volf, the former stud-book-keeper, on ground of his stay in the Tachin Tal region in 1997, believes that the capacity of water resources is sufficient for all large mammal species, but the question remains whether these sources are available all year, especially in hard winter time without snow.

663: -.008

Freshwater ecosystems in Asia are under grave threat. Large and growing human populations and the rapid pace of development have led to the degradation of natural environments throughout the region. Conservation of freshwater biodiversity faces particular challenges because of a lack of public awareness of its magnitude and importance. Even taxa with high public-relations value, such as fishes, are rather poorly known, and the variety of other animals associated with lakes and riverine wetlands, including charismatic and endangered megafauna, seems to have escaped wide attention. The rate and extent of environmental change in Asia are having impacts on the aquatic biota that may be greater than anywhere else on the planet. Particular threats include water pollution, from point and nonpoint sources, which is almost ubiquitous; overharvest of fishes, turtles, and crocodilians; flow regulation and impoundment of rivers; as well as drainage basin degradation and climate change. Many lakes have been so modified by human activities that they function as enormous fishponds, and the introduction of exotic species (especially, but not only, fishes) or the translocation of native taxa has contributed to the extinction of endemic species in isolated drainage basins. The prognosis is grim, and we can anticipate a loss in biodiversity and homogenization of the regional biota. Reversal of these trends will require a change in focus by limnologists and water-resource managers, and the urgent adoption of a conservation agenda for freshwater science in Asia.

664: +.175

Neonatal reptiles are here defined as an age class of young eureptilian amniotes (excluding birds) that express attributes most influenced by the pre-paritive development environment (oviduct, egg, and egg nest) and by the demands of parition and first dispersal. Neonatal character states are typically transformed, reduced, or eliminated during the first 10% of their prereproductive development. Traditionally, neonates have not been distinguished from juvenile reptiles. As a result the neonatology of reptiles has rarely been addressed in past literature. Recent studies reveal

a complex array of developmental scenarios involving character state transformations, heterochrony, unique character states in morphology, behavior, physiology, nutrition, dispersion and health. Unique morphological features (such as egg teeth) and limited skeletal ossification characterize many neonates. Distinguishing behaviors include "reversal" movements, utilization of bright color patterns, and startling movements with both serving as anti-predation mechanisms. Prolonged association with protective parents, group migration, unique agonistic behavior, and tendencies toward rapid dispersion characterize the neonates of individual species. Neonatal physiological attributes include: a special availability to inoculation by symbiont fermenting anaerobes in herbivores, rapid conforming responses to their external environments in thermal and hydric exchanges, and in the case of some turtles, extraordinary capacities for supercooling (8.9 C). Post-paritive lecithotrophy (nutrition from residual yolk) sustain both the overwintering of nestlings and the dispersion of nonfeeding young for as long as several months. Resistance to infections (such as mycoplasmas) from their maternal parents, combine with nutritive reserves of residual yolk and a common tendency for rapid dispersion to make neonates attractive candidates for augmentation and translocation programs. Coupled with the practical advantages of maintaining and manipulating small animals in a laboratory environment, these qualities distinguish neonates as particularly useful models for experimentally evaluating the relative apportionment of reproductive resources into greater numbers of offspring or into improved quality/survivorship of individual offspring.

665: +.031

Limitations for in situ conservation are discussed in the light of variable environmental conditions and population characteristics. Environmental influences like clear cutting, over utilisation, immission load, climatic change, catastrophes and diseases can set limitations for in situ conservation. Genetic limitations can be set by narrow genetic base, badly adapted populations or hybridization with other species and/or cultural varieties. Necessity for double conservation measures, reintroduction of rare species from reestablished adaptable populations and limitations for natural regeneration are discussed. The problem of species integrity versus hybridization and enlarged genetic base is mentioned.

666: -.005

Ankarafantsika is the only protected area in Madagascar with good habitat for the endangered, endemic freshwater turtle *Erymnochelys madagascariensis*, but due to exploitation many populations are already depleted. A conservation strategy for the species at Ankarafantsika was developed in 1997 and includes a captive breeding and rearing operation to produce juvenile turtles for reintroduction and population augmentation. A facility comprising 22 spacious concrete ponds and a laboratory was built in Ampijoroa and is operated by Durrell Wildlife Conservation Trust. A motor pump is used to fill the ponds with water from a nearby lake and all ponds have a drainage system. Ponds are designed differently for hatchlings, juveniles, adult females and males. Females have access to beach areas where eggs will be incubated naturally. The facility can hold at least six adult females and males and provides for at least 200 hatchlings to be raised for two to three years.

667: +.014

The lesser white-fronted goose (*Anser erythropus*) is the most threatened of the Palearctic goose species with a declining population trend throughout its distributional range. The current estimate of the Fennoscandian subpopulation size is 30-50 breeding pairs, whereas it still numbered more

than 10 000 individuals at the beginning of the last century. Reintroduction and restocking have been carried out in Sweden and Finland using captive lesser white-fronted goose stock with unknown origins. We have carried out a study of the genetic composition of captive-bred stock by sequencing a 221 bp hypervariable fragment of the mitochondrial DNA (mtDNA) control region from 15 individuals from the Hailuoto farm, Finland. Two out of the three maternal lineages detected in the captive stock are also present in wild populations. The third maternal lineage among the captive lesser white-fronted geese originates from the closely related greater white-fronted goose (*Anser albifrons*). None of the investigated wild lesser white-fronted goose individuals carried the mtDNA of the greater white-fronted goose. The presence of greater white-fronted goose mtDNA in the lesser white-fronted goose captive stock suggests that hybridization has occurred during captive propagation.

668: +.398

Bighorn sheep populations experienced a drastic reduction in both distribution and abundance until the advent of modern wildlife management, where improving viability of extant populations and translocating animals into historical habitat range have been the most important management policies. The fact that subspecies relationships among bighorn are ambiguous, together with the importance of selecting appropriate source stock and the expense of translocation projects, makes an understanding of subspecies relationships and genetic variation, within and between populations, important for the management and conservation of this species. In this study, genetic variation in 279 bighorn sheep from 13 study sites in Arizona, California, New Mexico and Alberta, Canada were examined by analyzing ten microsatellite loci to determine interpopulation differentiation and relationships between closely related taxa. All populations contained a substantial amount of genetic variation. Genetic differences between populations were large and roughly proportional to geographic distance. The significance of this to desert subspecies relationships and management is discussed.

669: -.022

Modern fishery management strategies, based on species biology and monitored with landings data, failed to sustain either exploited populations of abalone, *Haliotis* spp., or fishery landings in southern California. California law and policy require that the State restore depleted populations and explore new management strategies to sustain abalones and the fisheries they could produce. Restoration strategies will vary by species and by the causes of depletion. Fishing depleted white abalone, *H. sorenseni*, to critically low densities (apprx100cntdotha-1) in the 1970s. By the 1990s, natural mortality had further reduced the population density to 1cntdotha-1. Captive breeding and rearing, with adult out-planting, may be the only way to restore white abalone with sufficient certainty to avoid extinction. Fishing also depleted pink abalone, *H. corrugata*, but sufficient numbers of adults exist to artificially aggregate critical spawning densities (2000-4000cntdotha-1) in the wild with little risk of extinction at this time. A withering syndrome of uncertain etiology reduced isolated remnant populations of black abalone, *H. cracherodii*, to extremely low densities. Restoration of this species will require finding and identifying disease-resistant survivors to use for captive breeding and rearing. Persistence of red abalone, *H. rufescens*, in northern California and experimental success of refugia created by translocating adult pink abalone and green abalone, *H. fulgens*, in southern California, indicate that refugia-based management could sustain exploited populations and fisheries. Refugia-based strategies are being explored to restore and sustain southern California pink and white abalone populations.

671: +.028

The white-clawed crayfish, *Austropotamobius pallipes*, is the only native species of freshwater crayfish in Spain. This species sustained a first-magnitude inland fishery up to the end of 1970's, when the crayfish plague struck the Spanish waters. It is detected an overall loss of distribution area of populations inhabiting the medium and lower reaches of the main river catchments, especially in Southern and Central Spain. The number of surviving populations can be estimated in ca. 700. Remaining native crayfish populations currently inhabit marginal areas. The populations are very fragmented, occupy short stretches, and are frequently isolated from the main river system. The current distribution is the result of a sum of different factors, ie. crayfish plague, habitat alterations, extreme climatic drought, etc. The incidence and relative importance of each one varied during the last 15 years, with crayfish plague being a predominant negative factor in the seventies and eighties, and climatic drought in the nineties. The current trend of disappearance is a sufficient reason to consider the native crayfish as at risk of extinction. However neither the national legislation nor most of the regional government legislations have listed this species as endangered. An analysis of the legislation dealing with freshwater crayfish in Spain shows : (a) an uneven and generally low level of protection given to the native species and (b) a very complex fishing and commercialization regulations for crayfish that show significant changes from one region to another. This complex legislation, complemented with a general lack of data on crayfish populations, low levels of management and public involvement, and different strategies in regional governments regarding restocking programs with exotic species, makes a confusing situation. In order to decrease the general tendency of regression of *A. pallipes* a conservation program for this species needs to be implemented in Spain. This program should include a number of regulations to be followed for the particular autonomous regions of Spain. This program should include measures : (a) to restore native crayfish populations, i.e. by translocations or stocking with farm raised of summerlings, in designated areas where the risk for crayfish plague outbreaks is low, (b) to control the spread of introduced species, by controlling their means of dispersal which usually occurs by human activities, i.e. trade of live crayfish, exotic crayfish stocking programs, crayfishing, aquaculture purposes, etc., and by developing eradication methods for unwanted crayfish populations; (c) to increase the surveillance of remaining native populations by providing the areas with native crayfish the protection level required by the European Community Directives for the Conservation of Natural Habitats and Wild Flora and Fauna (92/43/EEC and 97/62/EU); and finally (d) to improve public and administration awareness.

672: +.125

The transplantation of 0.4 ha of montane grassland in the Hart Mountains was accompanied by evaluating the achievement of declared objectives for 5 years. The project is unique in central Europe with respect to the transplantation technique employed, size of translocated area and intensity of monitoring. The meadow was transplanted to a nearby location using a bulldozer with a special excavating shovel. The preservation of the flora of the whole transplanted area was successful. Disturbance indicator species appeared only to a negligible degree. Of 18 regionally threatened species present, the majority responded indifferently or positively to the transplantation; only two showed a distinct decline in population size, which was probably not caused by the transplantation alone. The preservation of the species composition of the four vegetation types occurring in the study area after a period of 4 years was also successful with all types reverting toward their pre-transplantation state. In contrast, the maintenance of the spatial vegetation mosaic failed completely. Dissection of previously coherent vegetation types and levelling of the ground surface resulted in an artificial vegetation pattern with predominantly geometric patterns. 673: +.043

The range of the Brown bear in Italy is limited to the population of central Apennines, and to a residual population of few individuals in the Adamello Brenta Natural Park (Central Alps). Moreover, some individuals are occasionally recorded on the eastern Alps, arriving from Slovenia and Austria. A translocation project aimed to re-establish a viable population of bears in the Central Alps, proposed by the Adamello-Brenta Natural Park administration, has been funded by CEE through a "LIFE" program. The project is carried out in co-operation with the Province of Trento, with the National Wildlife Institute, and with the authorities of Slovenia, where bears will be captured. Accordingly to the national and international guide lines for the translocation of wildlife (AA.VV. 1997b, IUCN 1998), aim of the translocation is the establishment of a viable population of brown bears in the Italian Central Alps. Objectives of the feasibility study are to 1) verify that there is no possibility to recover the residual population without a translocation; 2) assess if the region can sustain a viable population of bears; 3) assess if conflicts that will arise between bears and human activities are sustainable; 4) identify the main factors that could negatively affect the establishment of a population in the area. The feasibility analyses were performed in a 6,495 km² area, defined considering several parameters; 1) large enough to ensure good probability of comprehending a Minimum Viable Population (MVP); 2) centred in the Adamello-Brenta Natural Park; 3) larger than dispersal movements of released bears; 4) borders defined in higher human disturbance areas (densely inhabited valleys). The residual population has been censused through a DNA analysis of samples collected from faeces and hair. Results of this analysis confirm that only 3 individuals still inhabit the area. As no reproduction has occurred in the area since 1989, we consider that the remaining individuals are probably not reproductive, and the population can thus be considered ecologically extinct. In this respect, weit has decided to define the project as a re-introduction, instead of a reinforcement. The decrease occurred in historic time was analysed by collecting all available information on bear presence and kills in the last centuries. The data collected indicate that in the XVII century, bears were still abundant and widely distributed over most of the Alps; only after the XVIII century, distribution of the species decreased in the valleys, in relation to progressive timber and agricultural activities. After 1850, a more intensive direct persecution started, adding its effects to the increasing habitat fragmentation also caused by the increased exploitation of the high altitude areas for agriculture. In the Trento province, 192 kills are reported for the last 150 years, of which 84 only in the Brenta massif; before the bear became protected (in 1939), a decrease in the number of kills had already occurred, indicating that the bear population was already in critical conditions, and that legal protection arrived too late. From these data, we estimate that the Brenta population went below a critical threshold already in the early '70ies, when probably only 15 animals still inhabited the area. In conclusion, historical data indicate that direct persecution by humans was the main factor of dramatic bears decrease recorded until the first half of XX century, but in the last decades the population failed to naturally recover probably for demographic and stochastic factors, that can be remedied through a translocation. To assess if the area can still sustain a bear population, a habitat suitability model has been implemented by logistic regression analysis on bears presence data collected in central Alps during the last 20 years (n = 1,777), versus more than 60 parameters, including habitat characteristics and human pressure indexes, were considered. Results indicate that there are about 1,700 km² of suitable area for the bear; assuming that bears' densities can range from 2 to 3 individuals / 100 km², the area could thus support a populations of 34-51 bears, or 79-118 if including scarcely suitable areas. Such numbers are above the value indicated for a minimum viable population. Several decades will be necessary to reach a viable population in the area (18-41 years needed for a population of 70 individuals, with an year increase rate of 10-5%). In the medium term, a connection with the bears' population of the eastern Alps is possible, enhancing the probability of survival of the Central Alps bears' population in the long term. The cost of the project has been estimated, in co-operation with private professional analysts (Agri-consulting S.p.a), considering direct costs and potential impact on human activities for the total

period needed to establish a population of 50 individuals. Potential damages caused by bears to economical activities were estimated on the basis of data gathered in similar translocation projects in Austria and France; a probabilistic prediction of the impact of "problem bears" was also stated. Cost of average bear damages was estimated in 775 Euro/year per bear; to evaluate the risk related to problem bears causing very high damages, we assigned to each bear a 0.20 probability to be a "problem bear" (French and Spanish data: 3 problem bears out of 15 monitored), and a much higher level of damages was predicted for these individuals (25,826 Euro/year). The cost of the project is potentially very high, ranging from 1,422,000 to 5,482,000 euros mainly in respect to the frequency of "problem bears" causing severe damages to livestock, and to the direct (poaching) or indirect impact of human pressure on the increase of bear population, that may extend significantly the time needed to achieve a minimum viable population of bears. Human dimension aspects have been considered with care; in fact human pressure soundly represents the main limiting factor for the future population dynamics in the area, as Central Alps are presumably the area with the highest tourist pressure in the total range of the Brown bear. A survey on the attitudes of the local population towards the Brown bear, carried out through 1,500 telephone interviews by the DOXA S.r.l., indicated a positive opinion of 75% of the residents, raising to over 80% when stating that bears will be constantly monitored, and that problem individuals will be removed or destroyed. In this respect, an emergency team has been created, training rangers to aversion and trapping techniques. The telephone survey also permitted to estimate the value that people assign to the bear, through a simplified contingent valuation. The total sample was divided into 10 random sub-samples; a different fine for bears poaching was indicated to the 10 sub-samples, and it was asked if they considered the fine reasonable. Values ranged from 258 to 25,826 Euros. Results indicate that the perceived value of a bear ranges between 6,198 and 10,331 Euros, with significant differences among areas. In conclusion, the feasibility study indicates that the translocation has good probabilities to be successful in the medium-long term. The measures planned for the translocation can significantly increase also the chances of survival for bears naturally arriving to the area. The legal framework has already been updated. The predicted cost of the project is high, but it has been considered sustainable by the administrations funding the translocation, and funds for damage prevention and compensation have thus been approved. Human disturbance is a critical factor, and in this respect a risk of failure cannot be excluded; therefore, all measures aimed to solve or reduce conflicts between bears and humans are a priority, and a correct information on the project should be ensured. The possibility of attacks to humans, although very limited, makes important to plan every possible measure (selection of bears to be released, emergency team, correct information on how to behave when encountering a bear, etc) to reduce such risk. Operative guidelines include a minimum number of 9 bears to be released in four years, an intensive post-release monitoring program, comprehending the radio-tagging of all released bears. In order to assess the success of the re-introduction, the dynamic of the population will be carefully monitored. In case of low rate of increase (<2%/year), or loss of bears for poaching, a re-evaluation of the project is planned.

674: +.149

Isoodon obesulus exhibits geographic variation in body size and shape, which appears to be adaptive. The geographic range of this species is declining, so the presence of adaptive divergence is of concern for the conservation of this species, both in the long term (loss of diversity decreasing evolutionary potential) and short term (choice of source populations for translocations). In this study, skulls of *I. obesulus*, both recent (animals alive within the last 100 years) and fossil (a few thousand years old), were examined and a range of measurements obtained. Comparisons were made between the two data sets to see whether skull morphology has changed over this relatively short period. Such a change may indicate rapid evolution of these characters and

therefore the potential for fast regeneration of any lost geographic variation. Fossil skulls were smaller than their recent counterparts, had shorter 'snouts' relative to skull width and depth, and displayed no geographic variation in size and shape, whereas recent skulls were geographically differentiated. Because of the apparent rapid evolution in these characters, the implications of adaptive variation in size and shape in *I. obesulus* with regard to its conservation may be strictly short term, since any geographic variation lost may be quickly recovered if suitable conditions exist.

675: +.001

The white-clawed crayfish, *Austropotamobius pallipes*, an endangered species in Europe, was surveyed for genetic and morphological variation as part of a larger project aimed at clarifying its French stock structure. Analysis from four morphological characters discriminated two groups, one including the 8 stream populations and the other comprising a single pond population. Total mitochondrial DNA variation was examined by RFLP analysis using 11 restriction enzymes for 120 animals sampled from these 9 populations located in Poitou-Charentes region. Among the three haplotypes revealed, two were found in animals sampled from brook populations and the third haplotype was only found in individuals from the pond population. Mitochondrial DNA nucleotide diversity values within species ranged from 0.57 to 1.31%. The analysis of genetic variance showed no structuring of genetic variation by hydrographic basins and could reflect the impact of translocations by man although other explanations are possible.

676: +.035

The translocation of aquatic organisms is an issue of increasing concern. In assessing the genetic risks from translocations, a primary distinction should be made between translocation for the purpose of aquaculture and translocation for the purpose of stock enhancement. When translocation is for aquaculture, the question of interest is: what is the maximum level of escapes that should be permitted, beyond which there is an unacceptable probability of adverse genetic effects upon the natural population? Risk minimization should concentrate on management solutions that reduce escapes from aquaculture facilities. When translocation is for stock enhancement, the question of interest is: what is the maximum level of genetic differences between hatchery and wild stock that should be permitted, beyond which there is an unacceptable probability of adverse genetic effects upon the natural population? Risk minimization should concentrate on hatchery management procedures that reduce genetic differences in fitness traits between hatchery stock and wild stock from the proposed recipient population. Where translocation poses a significant risk of adverse genetic changes, then a monitoring programme should be put in place, linked to a policy that prescribes management actions for the range of possible outcomes from the monitoring. The main limitation to our ability to develop an effective risk assessment and monitoring process is our lack of understanding of how the interaction between genetically different stocks affects the genetic basis of quantitative fitness traits that adapt organisms to their local environment.

677: -.016

Genetic subdivision of a species indicates the potential for local adaptation, and the genetic differences among populations are a key component of genetic diversity. Molecular genetic markers are generally used to assess the extent and pattern of subdivision. These traits provide an abundance of simple genetic markers, and they allow comparisons across studies. However, the connection of molecular genetic variation to local adaptation and, hence, to possible genetic

problems of translocation, is weak. In the extreme case of no genetic subdivision, there is no reason to expect genetic problems with translocation. Where there is deep genetic structure, indicating substantial evolutionary independence of sets of populations, translocations may threaten basic components of genetic diversity. Between these extremes, however, predicting genetic problems of translocations is extremely difficult. The molecular markers used to measure genetic structure indicate where there has been opportunity for local adaptation, but they are not directly related to such adaptation. The relationship of the level of genetic divergence to genetic incompatibilities is very loose, although quantitative tests are scarce. However, studies of reproductive isolation between species illustrate the fundamental inadequacy of using measures of genetic divergence to predict interactions between populations. Although it is tempting to use simple measures as predictors, such use may provide a false sense of scientific rigour. There is no substitute for direct tests for variation in ecologically relevant traits and possible genetic incompatibilities among populations.

678: +.161

Some biologists have expressed concerns about the possible genetic impacts of translocation between stocks of barramundi *Lates calcarifer* (Bloch) in Australia. Recent genetic, biogeographical studies have provided an understanding of the evolution of the currently observed population structure in Australian barramundi by assessing the impacts of ice-age, sea-level changes on their distribution. These studies found that genetic differences between most barramundi populations are extremely small, have arisen in the past 17 000 years, and substantial migration and hybridization between eastern and western populations, isolated for at least 110 000 years, has occurred naturally. Some phenotypic support for these minor genetic differences can be inferred from the lack of adaptation to temperature in growth and survival responses of widely separated stocks (tropical and temperate). Based on a low level of genetic differentiation and high levels of gene flow between populations, with little evidence of local adaptation, translocation between populations should not pose a significant risk or problem.

679: +.062

Species or strains of fish may be translocated for farming, where the only access to the wild is via inadvertent escapes, or for stocking, where deliberate releases are undertaken. In either case, it is important that the translocated animals are representative of the donor population(s) in terms of genetic composition and level of variability. Many studies have shown that this ideal is difficult to achieve, the major reason being the use of inadequate numbers or composition of broodstock as founders of a strain. Also, where more than one conspecific population is involved, there may be outbreeding depression problems. In the case of farming, measures to improve the introduced strain genetically are likely to be undertaken, e.g. breeding programmes, manipulation of sex and ploidy, transgenic techniques. Such approaches are necessary economically, but can alter genetic make-up. Thus, stringent attempts must be made to minimize escapes or reduce their impact should they occur. With stocking, genetic change during captive rearing should be avoided. No strain manipulation should be undertaken, and other agents of change should be minimized. Stocking may result in hybridization with related species or with endemic populations of the same species. In either case, there can be detrimental genetic effects on the native forms. To be able to identify subsequently any genetic changes in reared strains, whether intended for farming or stocking, wild population composition should be determined, using appropriate molecular techniques. Such molecular methods will demonstrate the degree of interpopulation differentiation and, thus, reproductive isolation. The same markers should then be used in each subsequent generation (in the hatchery and after escape or reintroduction to the wild) to monitor any changes

in genetic composition or variability. Markers should include microsatellite DNA loci, but the inclusion of more than one type of marker is recommended. However, as the aforementioned markers are not considered to be influenced by natural selection, they give no information on the adaptive nature of such differences. For this reason, it is suggested that markers influenced by selection should be investigated. Monitoring a strain subsequent to deliberate or inadvertent release can be undertaken using genetic markers, either deliberately enhanced by breeding or occurring naturally. Highly variable minisatellite DNA loci have been used as family markers in farmed escape studies with Atlantic salmon. These investigations have demonstrated significantly superior survival of native strains compared with farmed salmon in natural stream conditions. These latter results, demonstrating fitness differences, were strongly indicative of local adaptation. Thus, methods exist to monitor the genetic effects of translocation and stocking. However, a holistic approach should be taken to such exercises, where genetics forms part of a wider suite of considerations.

680: +.274

Genetic improvement of aquaculture species offers a substantial opportunity for increased production efficiency, health, product quality and, ultimately, profitability in aquacultural enterprises. Technologies exist that can be implemented immediately to improve multiple traits that have economic value, while simultaneously accounting for inbreeding effects. Genetic improvement techniques for delivering genetic gain include formal definition of the breeding objective, estimation of genetic parameters that describe populations and their differences, evaluation of additive and non-additive genetic merit of individuals or families and defining the structure of a breeding programme in terms of mating plans. Novel genetic technologies involving the use of DNA-based tools are also under development for a range of aquaculture species. These gene marker technologies can be used for identification and monitoring of lines, families and individuals, monitoring and control of inbreeding, diagnosis of simply inherited traits and genetic improvement through selection for favourable genes and gene combinations. The identification of quantitative trait loci (QTL), and direct or linked markers for them, will facilitate marker-assisted selection in aquaculture species, enabling improvement in economically important traits, particularly those that are difficult to breed for, such as food conversion efficiency and disease resistance.

681: +.073

Throughout the first 90 years after their discovery, sulfate-reducing bacteria were thought to be strict anaerobes. During the last 15 years, however, it has turned out that they have manifold properties that enable them to cope with oxygen. Sulfate-reducing bacteria not only survive oxygen exposure for at least days, but many of them even reduce oxygen to water. This process can be a true respiration process when it is coupled to energy conservation. Various oxygen-reducing systems are present in *Desulfovibrio* species. In *Desulfovibrio vulgaris* and *Desulfovibrio desulfuricans*, oxygen reduction was coupled to proton translocation and ATP conservation. In these species, the periplasmic fraction, which contains hydrogenase and cytochrome *c*(3), was found to catalyze oxygen reduction with high rates. In *Desulfovibrio gigas*, a cytoplasmic rubredoxin oxidase was identified as an oxygen-reducing terminal oxidase. Generally, the same substrates as with sulfate are oxidized with oxygen. As additional electron donors, reduced sulfur compounds can be oxidized to sulfate. Sulfate-reducing bacteria are thus able to catalyze all reactions of a complete sulfur cycle. Despite a high respiration rate and energy coupling, aerobic growth of pure cultures is poor or absent. Instead, the respiration capacity appears to have a protective function. High numbers of sulfate-reducing bacteria are present in the

oxic zones and near the oxic-anoxic boundaries of sediments and in stratified water bodies, microbial mats and termite guts. Community structure analyses and microbiological studies have shown that the populations in those zones are especially adapted to oxygen. How dissimilatory sulfate reduction can occur in the presence of oxygen is still enigmatic, because in pure culture oxygen blocks sulfate reduction. Behavioral responses to oxygen include aggregation, migration to anoxic zones, and aerotaxis. The latter leads to band formation in oxygen-containing zones at concentrations of less than or equal to 20% air saturation.

682: +.154

State Forest Service has carried out a reintroduction project of Griffon Vulture *Gyps fulvus* in the Monte Velino Montagna della Duchessa Natural Reserve in the mountain of central Italy. Preliminary feasibility study was carried out to evaluate present ecological conditions in the area for the species. Reintroduction method consists on releasing adult and sub-adult individuals to fix a breeding group. The release stock was provided by spanish raptors rehabilitation centers. On July 1994 first six Griffons were released equipped with tail mounted transmitters to monitor their dispersal movements and some feathers of the griffons were decoloured before being released. Two feeding stations have been set to supply the necessary food to the griffons and to keep them in the area. In the 1997 first breeding occurs and at present the griffon colony is stable nevertheless 10 animals in the 1998 died for poisoning. Data on reproductive parameters and population dynamic are reported.

685: -.087

As one moves from the core to the periphery of a species' geographical range, populations occupy less favourable habitats and exhibit lower and more variable densities(1-4). Populations along the periphery of the range tend to be more fragmented and, as a result, are less likely to receive immigrants from other populations. A population's probability of extinction is directly correlated with its variability and inversely correlated with density and immigration rate(5-9). This has led to the prediction that, when a species becomes endangered, its geographical range should contract inwards, with the core populations persisting until the final stages of decline(2,10). Convinced by these logical but untested deductions, conservation biologists and wildlife managers have been instructed to avoid the range periphery when planning conservation strategies or allocating resources for endangered species(11-13). We have analysed range contraction in 245 species from a broad range of taxonomic groups and geographical regions, Here we report that observed patterns of range contraction do not support the above predictions and that most species examined persist in the periphery of their historical geographical ranges.

686: -.063

Emerging infectious diseases (EIDs) of free-living wild animals can be classified into three major groups on the basis of key epizootiological criteria: (i) EIDs associated with "spill-over" from domestic animals to wildlife populations living in proximity; (ii) EIDs related directly to human intervention, via host or parasite translocations; and (iii) EIDs with no overt human or domestic animal involvement. These phenomena have two major biological implications: first, many wildlife species are reservoirs of pathogens that threaten domestic animal and human health; second, wildlife EIDs pose a substantial threat to the conservation of global biodiversity.

687: -.033

Swayne's hartebeest (*Alcelaphus buselaphus swaynei*) is an endangered antelope that survives in four or five relict populations in Ethiopia. We examined the two main populations (Senkele and Nechisar) for mitochondrial (D-loop) and nuclear (microsatellite) variability in order to measure levels of genetic variation within the subspecies and degree of differentiation between populations. For comparison, we examined samples from a large population of red hartebeest (*Alcelaphus buselaphus caama*). Both *swaynei* and *caama* exhibited high levels of variation. There was significant differentiation between the populations of *swaynei* at Senkele and Nechisar, and gene diversity in Nechisar, the smaller of the two populations, was significantly lower than that in Senkele. Many mitochondrial haplotype and microsatellite alleles present at high frequencies among the Senkele individuals were missing in Nechisar, suggesting that the translocation of animals from Senkele undertaken in 1974 did not contribute notably to the gene pool in Nechisar. Subsamples taken from Senkele in 1988 and 1995 showed a significant change in allele frequencies, a change that probably can be attributed to a massive population decline this period. We recommended that both populations be protected in situ to maintain as much as possible of the diversity that exists within the taxon and that, a breeding program be established. In spite of the earlier unsuccessful attempt, we argue that translocation of animals for enhancement of population size as well as genetic variation in Nechisar should be considered.

688: +.102

The South Island saddleback (*Philesturnus carunculatus carunculatus*) is one of two subspecies of the New Zealand saddleback. Despite the endangered status of this subspecies, it was not studied in detail until 1994, when 26 birds were released onto Motuara Island in the Marlborough Sounds of New Zealand. I report the foraging behaviour and diet of this reintroduced population during the first breeding season after release. South Island saddlebacks used their bills in a variety of ways when foraging, and were predominantly insectivorous. They obtained most food from the ground and five-finger (*Pseudopanax arboreus*), and the number of prey captured generally reflected the amount of time saddlebacks spent on foraging substrates. North and South Island saddlebacks are very similar in terms of foraging behaviour, prey handling techniques and types of invertebrate prey consumed. The foraging patterns and diet of South Island saddlebacks on Motuara Island differed from all potential competitors. I conclude that the success of the South Island saddleback transfer to Motuara Island should not be threatened by a lack of food or foraging opportunities.

689: +.136

We present a comprehensive survey of genetic variation across the range of the narrowly distributed endemic Yosemite toad *Bufo canorus*, a declining amphibian restricted to the Sierra Nevada of California. Based on 322 bp of mitochondrial cytochrome b sequence data, we found limited support for the monophyly of *B. canorus* and its closely related congener *B. exsul* to the exclusion of the widespread western toad *B. boreas*. However, *B. exsul* was always phylogenetically nested within *B. canorus*, suggesting that the latter may not be monophyletic. SSCP (single-strand conformation polymorphism) analysis of 372 individual *B. canorus* from 28 localities in Yosemite and Kings Canyon National Parks revealed no shared haplotypes among these two regions and lead us to interpret these two parks as distinct management units for *B. canorus*. Within Yosemite, we found significant genetic substructure both at the level of major drainages and among breeding ponds. Kings Canyon samples show a different pattern, with substantial variation among breeding sites, but no substructure among drainages. Across the range of *B. canorus* as well as among Yosemite ponds, we found an isolation-by-distance pattern suggestive of a stepping stone model of migration. However, in Kings Canyon we found no hint of

such a pattern, suggesting that movement patterns of toads may be quite different in these nearby parklands. Our data imply that management for *B. canorus* should focus at the individual pond level, and effective management may necessitate reintroductions if local extirpations occur. A brief review of other pond-breeding anurans suggests that highly structured populations are often the case, and thus that our results for *B. canorus* may be general for other species of frogs and toads.

691: -.086

Through the Red Wolf Species Survival Plan, the captive red wolf (*Canis rufus*) population was developed with the intent of reestablishing wild populations. One part of the plan was a survey for diseases that might occur as a result of population homogeneity or that might impede breeding success and reintroduction. For this survey, complete necropsies and histopathologic analyses were performed on 62 red wolves from 1992 to 1996. Major causes of 22 neonatal deaths were parental trauma, parasitic pneumonia, and septicemia. Common neonatal lesions included pododermatitis and systemic ascariasis. Cardiovascular anomalies and systemic parasitism were found in two juveniles. Causes of death in the 38 adults included conspecific trauma, neoplasia, or gastrointestinal diseases such as necrotizing enteritis, intestinal perforation, and gastric volvulus. Lymphosarcoma represented 50% of the fatal neoplasms. Three adults died from cardiovascular failure or hyperthermia during handling, and several adults were euthanized for suspected genetic diseases. Overall, the captive population had few significant health problems, but population fitness might be improved by continued removal of potentially deleterious genes from the breeding population and by modifying the husbandry of neonates and adults.

692: +.145

The threatened status of redbreasted dace, *Clinostomus elongatus*, in Michigan inhibits study and management of remnant populations of the species. We present a phenotypic approach to evaluate the use of redbreasted dace from New York as behavioral and physiological models for Michigan

populations. We evaluated behavioral similarity by comparing patterns of microhabitat use and physiological similarity by comparing resting routine metabolic rates measured in the field. Variation between sites in available microhabitat made direct comparisons difficult; however, redbreasted sunfish in Michigan and New York showed a common preference for mid-water positions in the deepest parts of pools under overhanging structure. Field measurements at 10 degrees C showed that Michigan fish had higher metabolic rates than rates predicted for New York fish at the same temperature, though biological significance of this difference is questionable. In laboratory experiments, we measured metabolic rate and upper thermal tolerance in relation to acclimation temperatures of 6-20 degrees C using redbreasted sunfish collected from four streams in New York. Redbreasted sunfish showed a significant increase in metabolic rate as acclimation temperature increased ($Q_{10} = 2.3$). Critical thermal maxima (CTM) of New York redbreasted sunfish also increased with acclimation temperature. Obstacles related to the transferability of habitat use data and variation in physiology due to uncontrolled and unmeasured environmental factors in the field lead us to urge caution when extrapolating behavioral and physiological characteristics between widely-separated populations of a species. Despite these obstacles, we described useful patterns of microhabitat use and provided estimates of physiological tolerances that will assist resource managers in the recovery of Michigan redbreasted sunfish.

693: -.059

Przewalski's gazelle *Procapra przewalskii* is endemic to China and is classified as Critically Endangered by IUCN-The World Conservation Union. Historically, the species occurred in parts of the provinces of Gansu, Inner Mongolia, Ningxia and Qinghai but now appears to be restricted to three populations around Qinghai Lake. These three populations-Bird Island, Hudong-Ketu and Yuanzhe-have all declined since 1988. The populations have been monitored since 1994 and the smallest, on Bird Island, appears to be on the brink of extinction, with only seven individuals being recorded in 1998. In the same year, the Hudong-Ketu population comprised 56 individuals (29.4 per cent males, 50 per cent females and 21 per cent juveniles) and the Yuanzhe population 51 individuals (29.4 per cent males, 43.1 per cent females and 27.5 per cent juveniles). The causes of the declines vary for each population but include loss of habitat as a result of desertification, poaching and, possibly, wolf predation. Human activity and high juvenile mortality are major threats to the continued survival of the gazelle. Conservation measures proposed are: (i) the establishment of a special reserve for Przewalski's gazelle; (ii) a study of the wolf-gazelle relationship and control of the number of wolves if necessary; (iii) a search for remnant populations of Przewalski's gazelle in other regions in their historical range and the identification of suitable sites for translocation and establishment of new populations.

694: -.059

The causes of the declines vary for each population but include loss of habitat as a result of desertification, poaching and, possibly, wolf predation. Human activity and high juvenile mortality are major

threats to the continued survival of the gazelle. Conservation measures proposed are: (i) the establishment of a special reserve for Przewalski's gazelle; (ii) a study of the wolf-gazelle relationship and control of the number of wolves if necessary; (iii) a search for remnant populations of Przewalski's gazelle in other regions in their historical range and the identification of suitable sites for translocation and establishment of new populations.

695: -.002

Over the last 7 decades, 23 exotic fish species have been introduced into the inland waters of Greece. Some introductions were deliberately planned to take advantage of particular ecological or economic qualities of the species concerned. These include rainbow trout, *Oncorhynchus mykiss* (Walbaum), Pacific salmon, *Oncorhynchus* sp., vendace, *Coregonus lavaretus* (L.), grass carp, *Ctenopharyngodon idella* (Valenciennes), and silver carp, *Hypophthalmichthys molitrix* (Valenciennes). Other introductions, such as that of pumpkinseed, *Lepomis gibbosus* (L.), and false rasbora, *Pseudorasbora parva* (Temminck & Schlegel), were unintentional. Further transfers were made of species between various basins within the country, including common carp, *Cyprinus carpio* L., tench, *Tinca tinca* (L.), crucian carp, *Carassius auratus gibelio* (Bloch), bitterling, *Rhodeus amarus* (Bloch), and Aristotle's catfish, *Silurus aristotelis* Garman. Some species have become fully acclimatized and have built up important populations. In other cases, the transfers and introductions have had considerable negative impacts, particularly where introduced species have outcompeted native forms, as in the cases of the mosquito fish, *Gambusia affinis* (Baird & Girard), versus Greek toothcarp, *Valencia letourneuxi* (Sauvage), in the western Greek marshes, and of Aristotle's catfish versus the wels, *Silurus glanis* L., in Lake Volvi.

696: +.134

Reintroductions are often used for reestablishment of animal populations. The choice of age-class of released individuals, however, is often arbitrary or based on expediency. We developed a demographic model that predicts the relative efficiency of releasing juveniles or adults for a given life cycle. The model accounts for possible reduction of survival and fertility of released adults. It also incorporates demographic and environmental stochasticity to compare release strategies of varying duration and number of releases. We applied the model to the case of reintroduction of Griffon Vultures (*Gyps fulvus*) in southern France, for which accurate monitoring allowed us to estimate demographic rates and consequences of releases. Overall, for Griffon Vultures, it is more efficient to release adults than juveniles, despite the observed reduction of demographic parameters following release. This approach could be used for the reintroduction of other species.

697: +.190

A wide translocation program was conducted on neotropical fauna in French Guiana during the filling of a hydroelectric reservoir. Red howler monkeys (*Alouatta seniculus*) were studied because available data on their behavior in undisturbed conditions provided the basis for behavioral comparison with translocated animals. A resident howler population was present in the selected release area, but population densities were severely reduced by previous strong hunting pressure. A post-release survey was conducted during 18 months using radio-tracking and visual observations of 16 females. Most radio-tagged females settled in a stable home range. All but one of the released troops split up but all the monitored females were thereafter re-observed with resident congeners, sometimes after a period of solitary living. Most of the behavioral characteristics of the translocated individuals corresponded to previous observations on undisturbed animals. It is concluded that the behavioral abilities of this species helped them to

survive and settle in a new area. Population reinforcements or re-introduction of red howlers may therefore be conducted with a good probability of success. (C) 2000 Elsevier Science Ltd. All rights reserved.

698: +.129

Systematic study of the islands of Western Australia indicates the occurrence of 254 islands 100 ha or larger in area, with 90% in tropical seas. All but eight and 16 of these islands are free of the exotic carnivores, red fox *Vulpes vulpes* and cat *Felis catus* respectively. The few inshore islands to which these predators have spread naturally are instructive in deducing the swimming capability of the fox and cat. When distance from mainland is considered (greater than or equal to 1 km or greater than or equal to 2 km), 147 or 122 islands offer potential as sites for establishing populations of mammal species not otherwise represented on islands and with restricted distribution on mainland Western Australia. A procedure for selecting appropriate islands for translocation is outlined, emphasizing those islands without significant biological characteristics such as large colonies of nesting seabirds and the occurrence of native mammal species, but also considering island area, degree of isolation and habitats present. A prioritized list of candidate species of native terrestrial mammals, based on size of geographical range, natural absence from any Western Australian island, and the degree to which current threatening processes are not being addressed successfully, is provided for more detailed consideration. Because the cat and fox have occurred on the mainland coast of Western Australia for > 100 years and ca. 70 years respectively, it is suggested that islands within swimming distance and not yet occupied by these predators are unlikely to be colonized. These islands should therefore be considered as possible translocation sites. (C) 2000 Elsevier Science Ltd. All rights reserved.

699: +.117

Given that small populations are susceptible to extinction and inbreeding, a primary goal of re-introductions should be to maximize the initial rate of increase of a re-introduced population. We investigated how the rate of increase of newly re-introduced populations of artiodactyl species was affected by population characteristics, such as their size, sex-, and age-structure. While selecting the data of past re-introductions for our analysis, we controlled for factors that are known to affect success. The growth rate r of the populations increased with the number of animals released, up to about a population size of 20, at which point an asymptote was reached. All larger populations grew at a median $r = 0.17$, while several smaller populations declined. Small populations grew faster if they contained more mature individuals. Small, heavily female-biased populations were more variable in r than those of a more equal sex ratio. These female-biased populations also grew on average less well. Generally, populations of <20 were more variable in r than larger ones and both age and sex structure explained a significant portion of this variation. (C) 2000 Elsevier Science Ltd. All rights reserved.

700: +.161

Diet, prey availability, and breeding success were studied in a population of Bonelli's eagle (*Hieraetus fasciatus*) in the province of Granada, SE Spain. The densities of the main prey species, European wild rabbit (*Oryctolagus cuniculus*), red-legged partridge (*Alectoris rufa*), wood pigeon (*Columba palumbus*), and rock dove (*Columba livia*), representing 90.2% of the biomass, were analysed in 19 territories occupied by pairs of Bonelli's eagles and 15 potential territories that were unoccupied but appropriate for nesting. We found no significant differences in prey density between the two types of territories. Contrary to other raptor species, we found no significant

relationship between the density of their main prey species and the distance of the neighbouring pairs, either between that density and breeding success. These findings, together with the prior knowledge of nest-site selection of this eagle in the study area, can be used for proper planning of conservation strategies. These should avoid unnecessary effort to increase the eagle's food supply, and should promote the reintroduction of individuals to suitable sites for Bonelli's eagle. (C) 2000 Elsevier Science Ltd. All rights reserved.

701: +.099

A survey of mammals and birds was carried out in a semi-deciduous forest fragment of 150 ha located in a zone of intensive agriculture in Ribeirao Preto, State of Sao Paulo, south-eastern Brazil. Line transect sampling was used to census mammals and birds during six days, totalling 27.8 km of trails and 27.8 hours of observation. Twenty mammal species were confirmed in the area (except bats and small mammals), including rare or endangered species, such as the mountain lion (*Puma concolor*), the maned wolf (*Chrysocyon brachyurus*), and the ocelot (*Leopardus pardalis*). The brown capuchin monkey (*Cebus apella*) and the black-tufted-ear marmoset (*Callithrix penicillata*) were found frequently, suggesting high population density in the fragment. Regarding the avifauna, 49 bird species were recorded, most of them typical of open areas or forest edges. Some confirmed species, however, are becoming increasingly rare in the region, as for example the muscovy duck (*Cairina moschata*) and the toco toucan (*Ramphastos toco*). The results demonstrate that forest fragment of this size are refuges for native fauna in a region dominated almost exclusively by sugar-cane plantations. Besides faunal aspects, the conservation of these fragments is of great importance for the establishment of studies related to species preservation in the long term, including reintroduction and translocation projects, as well as studies related to genetic health of isolated populations.

702: -.046

A critical aspect in the viability of large copper (*Lycaena dispar*) populations in Britain is the period of winter hibernation (diapause). Studies on captive-bred larvae, overwintering in England, showed that they suffered substantially greater mortality than did a Dutch population in its native habitat. Inter-habitat variance in survivorship, at both English and Dutch sites, was only marginally influenced by habitat features per se, although current management practices in the Netherlands may contribute significantly towards overwinter losses. Under identical field conditions in England, hibernal survival of wild-caught larvae, collected in the Netherlands, was superior to that of captive-reared British stock. Conversely, when larvae from both sources were 'overwintered' in captivity differences in recorded survivorship were not significant. From these two strands of evidence we tentatively infer a genetic divergence of the two stocks. Future re-introduction of this species should therefore involve direct translocation from wild populations rather than using captive-bred populations. (C) 2000 Elsevier Science Ltd. All rights reserved.

703: -.029

The burying beetle *Nicrophorus americanus* Olivier is an endangered species known to occur in disjunct populations in 6 states. Parsimony and maximum likelihood analysis of the nuclear ribosomal DNA first internal transcribed spacer (ITS1) sequences from 10 Nicrophorinae species revealed *N. americanus* to form a distinct clade with *N. orbicollis* Say. Genetic variation within and among 5 *N. americanus* populations, collected from South Dakota, Nebraska, Oklahoma, Arkansas, and Rhode Island, was studied. Ribosomal DNA ITS1 sequences from 14 beetles revealed 48 polymorphic and 20 informative nucleotide sites. *N. americanus* genetic divergence

was between 0.16 and 4.76%. We found little evidence that these 5 populations have maintained unique genetic variation. No nucleotide sites were found that were diagnostic for any of the 5 populations examined, indicating that these populations may not be necessarily treated as separate, independent objects of conservation. However, further genetic investigation is warranted before translocations are attempted among the remaining populations of the American burying beetle.

705: +.183

To prevent species from going extinct and to restore locally extinct species to conservation areas, conservationists have been attempting to create new populations of rare and endangered species. Such efforts are still at an early stage, with the basic methodology still being developed and many efforts resulting in failures or only modest success. The purpose of this work was to develop some general rules about how to carry out reintroduction efforts using four methods to create many new populations of eight perennial species. Our results demonstrate that the chances of success were greater when planting seedling and adult material rather than sowing seeds on the sites. Using larger adult material was more successful than using seedlings. Adult transplants also flowered and fruited right away, in contrast to plants derived from seeds, which rarely flowered even after several years. Digging up the site to expose the soil and reduce competition prior to sowing seed did not result in a greater establishment of seedlings. At many sites no plants survived at all, or success was low. These results emphasize the difficulties of establishing new plant populations. To increase the rate of success, attempts should utilize many sites, numerous seeds or plants, and various methods in order to develop a workable methodology for the species in question. Because of the difficulties of establishing new populations, conservation of rare and endangered species should first protect existing populations and only secondarily rely on reintroductions to ensure species survival.

706: -.014

As a restoration strategy, translocation of endangered plant populations may be a risky procedure with uncertain outcomes. Often, very little ecological information is known about these populations before, as well as after, translocation. The endangered vernal pool plant, *Blennosperma bakeri*, is a case in point. As a consequence of vernal pool habitat destruction, many populations of *B. bakeri* have been transplanted or translocated to various receptor sites. In this study, we examine the incidence of a thrips herbivore, *Frankliniella minuta*, in natural and translocated populations of *B. bakeri* in relation to floral patch size and degree of isolation and present implications for *B. bakeri* restoration and management. At a vernal pool mitigation site in California, U.S.A., thrips were present in both kinds of *B. bakeri* populations, and the range of thrips densities in both kinds of populations was similar for adults and immatures. Significant negative relationships between patch size, patch isolation, and numbers of flower heads infested with adult or immature thrips were found only among natural patches. Natural patches tended to be smaller in size than translocated patches, but patch isolation distances were similar. Some evidence suggests that *B. bakeri* is a *F. minuta* host plant, but the impact of these herbivores on *B. bakeri* remains unclear. Our findings, although preliminary, suggest that the distribution and abundance of *F. minuta* varied with floral patchiness, thrips stage, and the natural or translocated status of *B. bakeri* populations. In addition, our results provide a starting point for understanding the spatial context of plant-herbivore interactions in artificially altered vernal pool landscapes.

707: +.184

The application of molecular techniques to conservation genetics issues can provide important

guidance criteria for management of endangered species. The results from this study establish that PCR-based approaches for sex determination developed in other bird species (Griffiths and Tiwari 1995; Griffiths et al. 1996, 1998; Ellegren 1996) can be applied with a high degree of confidence to at least four species of Hawaiian honeycreepers. This provides a rapid, reliable method with which population managers can optimize sex ratios within populations of endangered species that are subject to artificial manipulation through captive breeding programmes or geographic translocation.

708: +.146

The whiptail lizard *Cnemidophorus vanzoi* is a large-bodied teiid found only on two islands (Maria Major and Maria Minor), off St Lucia, West Indies. In May 1995, 42 lizards from Maria Major were introduced to the smaller uninhabited Praslin Island on the same coastline. Three years post-release, we studied abundance, demography and morphometrics of the translocated lizard population, during a 6-month period covering wet and dry seasons. Age, sex, snout-vent length (SVL), body mass (BM), tail length, tail regeneration, and overall condition (moulting, reproductive condition, cuts, external parasites) of 107 animals caught during the study are analysed in the present paper. Comparisons are also made with the source population. A body condition index (CI (BM/SVL)), sex ratio (adult males : adult females), age ratio (adults : juveniles), and sexual size dimorphism ratio (SVL adult male:SVL adult females) were calculated for the study population. Distance sampling and mark-re-sight surveys were used to estimate population size and lizard density. A total of 155 +/- 26 individuals were estimated. The lizard population was found to have a high growth rate ($r = 0.97-3.95$). There were significant seasonal changes in lizard abundance. Seasonal differences in lizard numbers, BM and CI suggest either severe resource limitation during the dry season, or selective aestivation. A high frequency of tail autotomy may point to intense intraspecific competition as the island is relatively free from main predators such as the black rat *Rattus rattus*. Sex ratio, sexual size dimorphism and sexual dichromatism all indicate a territorial species in a generally non-territorial family (Teiidae). Some adult males seem to maintain juvenile colours. It is suggested that the introduced population has successfully colonized its new environment and that no significant change in the animals condition or size has occurred during the 3 years since translocation.

709: +.155

1 Nutrient dynamics and growth of the feathermoss *Hylocomium splendens* were studied in a subarctic birch woodland. My aims were to estimate the species' nutrient use strategy (and its determinants: mean residence time (MRT) and annual nutrient productivity (aNP)) and to unravel possible traits related to nutrient conservation and their implications for ecosystem nitrogen flux. Three methods to estimate nutrient losses in bryophytes were evaluated: a conventional growth analysis technique, a retrospective analysis and a N-15-tracer approach. 2 Estimates for nitrogen retention varied between 3 and 10 years as a result of the different N pools considered by the three methods. Growth analysis results depended on the distinction between live and dead tissues, whereas retrospective analysis gave valuable information on N release from decaying segments but did not measure MRT within the living segments. Valid estimates of MRT were obtained by a N-15-tracer approach. 3 MRT and aNP of *H. splendens* were similar to values typically found in woody evergreen vascular plants. Efficient nutrient recycling and a relatively long segment life span were responsible for the long residence time of nitrogen. Feathermosses show efficient nutrient acquisition, nutrient recycling and acropetal transport; nutrient losses will therefore be small. 4 Dominant bryophytes may retard the nutrient turnover at the forest floor through their production of acidic nutrient-poor organic matter and their negative effect on soil temperature, and

they may therefore function as autogenic ecosystem engineers.

710: +.136

In 1990, the myrmecophilous butterfly species *Maculinea teleius* and *Maculinea nausithous* have been reintroduced into the nature reserve "Moerputten" in The Netherlands. The introduced population of *M. teleius* expanded during the first three years. In contrast, the newly established population of *M. nausithous* declined in the year after the re-introduction but expanded later. After a considerable increase in numbers, this species can nowadays be seen in three subpopulations in and outside the nature reserve. While the area populated by *M. nausithous* is still expanding, *M. teleius* can only be found on the meadow where it was released and has not dispersed at all. To enable further expansion of both species on road verges and canal borders, the management of these landscape elements had to be changed to enhance the development of rough vegetation where the specific host ant species occur. This was realized by an agreement ("Convenant Pimpernelblauwtjes") in which the province, local communities, water and nature organizations, farmers and Dutch Butterfly Conservation participate.

711: +.182

Wilful introductions of insects already have a long history. Predacious and parasitic insect species have been introduced in attempts to control pest insects and weeds in agriculture, horticulture and forestry. Nature conservation bodies also practise insect introductions, but now in order to safeguard endangered species or to restore depaupered communities. However, a very large number of insect releases were done surreptitiously by butterfly lovers. The average rate of success in establishing new populations is very low, about 10%, and similar to that of establishment by hazardous introductions. From these cases we can learn that: 1) the quality of the site as a habitat of the species involved is often overestimated; 2) success depends on the stage in development at the time of the release and this, on its turn, depends upon the species; 3) geographical differences between areas of origin of the donor population and the site of introduction may also frustrate the success because of the incompatibility of diapause and bet-hedging adjustment, and 4) the migration behaviour of the species has to be taken into account. The current paper stresses the importance of assessing the ecological potential of the species and their habitat requirements. An approach is proposed, based on analyses of biological features of the species, and some examples are presented as an illustration. Nowadays most nature conservation bodies have accepted the release of insects as a management practise. One of the conditions for release is that the species involved should have inhabited the site or its surroundings in the past, and that it has disappeared due to human activities. The Dutch government intends to subsidise management and development of nature reserves only when well-defined results are obtained, such as the conservation of a number of so-called target species. The presence of these target species in nature reserves is evidence for successful management and may thus have financial consequences. This will undoubtedly increase the demand for re-introductions.

712: +.121

We investigated the genetic and morphological status of an endemic subspecies of deer mice (*Peromyscus maniculatus anacapa*) on Anacapa Island of California through mitochondrial DNA (mtDNA) analysis, morphometric discriminant function analysis, and population viability analysis. We sought to assist the development of a management plan that may include captive breeding, reintroduction, or translocation of mice following eradication of introduced rats. The genetic and morphological data were used to investigate whether the subspecies or populations on

each of the three islets of Anacapa represent evolutionarily significant units for conservation. The status of the East Anacapa population was of particular concern because deer mice have recently been caught there following more than 15 years of no records of deer mice. Sequences of the mtDNA cytochrome oxidase c subunit II gene (COII) indicated that the Anacapa subspecies had unique haplotypes not found on neighboring islands or the mainland and thus represents a distinct unit for conservation. Further, one of these haplotypes was shared among the islets, including most of the East Anacapa mice, suggesting that the East Anacapa population had either recovered from a severe bottleneck or had been recolonized by *P. m. anacapae*, but that it was not derived from other subspecies. Discriminant function analysis of morphological data also supported classification of the East Anacapa mice as *P. m. anacapae*. The mitochondrial mtDNA sequence data yielded estimates of two to seven migrants per generation among the Anacapa islets, suggesting a functioning metapopulation. Incorporating these data and information available on the life history and demographics of deer mice, we used a novel type of population viability analysis to develop a captive breeding and reintroduction plan for Anacapa deer mice should they be eradicated along with the rats. A sine wave was incorporated into the population viability analysis to simulate population size cyclicality. Our study provides baseline information needed for developing a comprehensive conservation and management plan for a threatened island endemic.

713: +.102

Populations of the endangered *Rutidosia leptorrhynchoides* (Asteraceae) have been reestablished in conservation reserves to reduce their risk of extinction in the wild. The reproductive success (Number of seeds per inflorescence, percent seed set, germinability) of five small reestablished populations (at 5-10 years after establishment) was compared to that of two large natural remnant populations from which they were derived. Initial growth rates under glasshouse conditions were compared for seedlings derived from seed from remnant and reestablished populations. Seed set per inflorescence in all five reestablished populations was equal to or greater than seed set in remnant population plants. The resulting seed was as germinable, and in some cases more germinable, than seed derived from remnant populations; the seedlings then grew as large or larger than remnant population seedlings grown under glasshouse conditions. Fitness reductions in small reestablished populations of *R. leptorrhynchoides* are not evident at the reproductive stage. Hence, these populations have some potential to maintain natural regeneration processes and might therefore positively contribute to the conservation of this species.

714: +.240

Koalas are the only living member of their family and therefore deserve serious conservation consideration. Koalas have low levels of genetic variation within and among populations in the southern part of their range, where they have experienced many relocations and population crashes since European colonization of Australia. The importance of this change in variation is underlined by preliminary indications that levels of genetic variation may affect fitness in koalas. Techniques have been developed to help identify and monitor genetic problems in koalas and to provide the information and tools to make genetic management an integral part of koala conservation. The koala is currently at an appropriate point for conservation intervention: there is clear evidence of decline in some populations, but the existence of other robust populations offers the possibility of a variety of creative solutions to their conservation problems. Managers should aim to maintain this species' current ecological amplitude (the range of environments in which populations are found) and minimize the loss, fragmentation, or decline of populations. There are no data to suggest that any population requires genetic supplementation. The concepts of evolutionarily significant unit (ESU) and management unit (MU) can be useful in the genetic management of

koalas, including monitoring and management regimes. But ESUs and MUs can also be misleading if they are not interpreted carefully in terms of population history and the ultimate goal of management. Translocations should not involve extensive use of stock from a single source, especially those with low grade variations, and they require careful management to avoid possible problems when individuals encounter novel strains of the pathogen *Chlamydia pecorum*, because several genetically distinct strains have been found in koalas, some of which may derive from introduced species. Genetic indicators can and must make considerable contributions to koala management, but they require careful interpretation.

715: +.048

The takahe (*Porphyrio hochstetteri*) is a highly endangered flightless rail, endemic to New Zealand. Since 1984, a total of 24 takahe have been translocated from a small, alpine population of approximately 120 in Fiordland and successfully established on four predator-free lowland islands with introduced pasture grasslands. However, island takahe produce fewer juveniles per egg due to hatching failure being twice as high as it is in the natural population in Fiordland. A comparison among several small, inbred populations of New Zealand birds indicated those that are the result of translocations to new habitat types (takahe and kakapo *Strigops habroptilus*), suffered much higher rates of egg infertility than birds that have remained within their natural habitat range. For takahe, whether breeders had been translocated as juveniles or had been raised on the islands was a poor predictor of reproductive success. The coefficient of inbreeding was high for island takahe but high infertility and low juvenile productivity were features of breeding pairs whether parents were related or not. However, this result might be expected if takahe were already inbred before they were translocated to the islands. If high egg infertility is a consequence of an inbred population being translocated to a new or different habitat, then poor breeding success is something that managers may have to live with in the short term until there is local selection for better breeders. In more general terms, the results of the study have implications for the successful translocation of individuals from inbred populations. (C) 2000 Elsevier Science Ltd. All rights reserved.

716: +.086

We examined the genetic variability and structure in 20 subpopulations belonging to seven populations of the threatened snake *Vipera aspis* in the Swiss Jura mountains ($n = 114$) and in two subpopulations from central France ($n = 12$) using RAPDs (seven primers produced 70 polymorphic bands). The analysis of molecular variance (AMOVA) showed that the within-populations genetic variability accounted for 87.0% and the among-populations variability for 13.0% of the total variability. The within-subpopulation genetic variability accounted for 74.3%, the among-subpopulation variability within populations for 21.5% and the among-population variability for 4.2% of the total variability. An unweighted pair group method with arithmetic means (UPGMA)-cluster analysis based on mean Jaccard distances did not assemble the subpopulations according to their populations. The combined results of the AMOVA and the cluster analysis suggest that gene flow may have occurred over large parts of the snake's distribution area. In large subpopulations the genetic variability was larger than in small subpopulations. There was no difference in the genetic variability between connected and isolated subpopulations. We suggest that habitat management may prove to be more effective in maintaining the genetic variability of *V. aspis* in the north-western Swiss Jura mountains than any translocation of individuals. 717: +.007

Brachypelma, a genus of nine endangered tarantula species in Mexico, is the only group of spiders included in Appendix II of CITES, owing to habitat degradation and illegal trafficking. However, while the majority of the nine species of Brachypelma are thought to be threatened, little is known of their ecology and distribution. Brachypelma klaasi is the rarest species, occurring in a few isolated populations on the Pacific coast of Mexico. We present an analysis of population distribution and micro-habitat requirements of B. klaasi over different spatial scales within the biological reserve at Chamela, Jalisco as part of a wider ecological study of the endangered Brachypelma group. Burrows and dispersing spiders were confined to a southern area of the reserve covering approximately 0.5 km². Within this area, burrows were not aggregated at lower spatial scales (2(4)-2(16) m²), unlike other related species. Also, there was no evidence that intra-specific interactions (either positive or negative interactions) influenced the distribution of burrows. Distribution of burrows at low spatial scales was related to low afternoon temperatures and high humidity in mid-summer. These abiotic factors may influence the survival and development of eggs and spiderlings, and appear to be more important in governing the distribution of B. klaasi than are food resources or intra-specific interactions. We discuss how these findings may facilitate the re-introduction of captive-bred individuals of B. klaasi and other Brachypelma species.

718: -.192

The Orinoco crocodile *Crocodylus intermedius* historically habited all the Orinoco river basin in Venezuela and Colombia. The American crocodile *Crocodylus acutus* range was all the Venezuelan coast, lakes, lagoons and tributary rivers of the Caribbean sea. After the commercial indiscriminate hunting of the first half of the XX century the Orinoco crocodile was left in critical levels and in danger of extinction. The American crocodile is considered a threatened specie. In the eighties recovery programs of both species started. Census and monitoring of the wild populations, protection of its habitats and a captive breeding program for future reintroduction and recovery of its populations. For that purpose on 1998 there were four crocodile farms of the Orinoco crocodile and one of the American crocodile. The diseases observed in the farms were: NEONATES (omphalitis, congenital anomalies and intoxications); HATCHLINGS AND JUVENILES (nutritional deficiencies such as vitamins A, E and B 1 deficiencies, scoliosis, osteodystrophia, bacterial, viral and mycotic diseases, hatchling alligator syndrome. Parasitary casuistic of protozoa, nematodes and trematodes. Trauma and shock) and ADULTS (nutritional deficiencies, xiphosis, osteodystrophia, nutritional secondary hyperparatyroidism, trauma, wounds and shock). In hatchlings and juveniles annual mortality rates reached until 70% per crocodile farm. This data was collected between 1985 and 1998.

719: +.064

Restoration of formerly nutrient-poor and species-rich grasslands generally leads to an increase in species diversity. However, species without a persistent seed bank and with poor dispersal ability often do not re-establish spontaneously. Here, reintroduction is an option. If existing populations are comparable in their genetic composition, any population will do. This is not the case if populations have local adaptations. Unfortunately, whether populations are adapted locally is not easily determined, in contrast to assessing differentiation using neutral genetic markers. We used AFLP to study genetic diversity of *Cirsium dissectum* and *Succisa pratensis* within and among several Junco-Molinion plant communities in the Netherlands (up to 200 km apart) that were potential source populations, and followed the reintroduction using seeds from these populations. Also, vegetative growth phase characteristics of three populations of *C. dissectum* were analyzed under controlled conditions. Most of the genetic variation in these cross-fertilizing species was

found within populations. Small but significant genetic differences in band frequencies were found among populations (F_{st} 0.100-0.135). The first generation of reintroduced plants contained less polymorphic bands than the source populations. The genetic differences caused by reintroduction using a limited number of seeds (founder effects) were significant in all except one case (F_{st} 0.012-0.101 between source and corresponding reintroduced population), but the magnitude was smaller than the source population differentiation. In assignment tests, reintroduced populations resembled their source population more than any other population, but all populations contained sizeable proportions of plants that were assigned to most similar plants from other populations, indicating that the populations are only marginally distinct. Calculations show that reintroduction from more than one source population introduces significantly more polymorphic bands into the new population, capitalizing on the existence of band frequency differences among populations.

720: -.189

The Siamese crocodile *Crocodylus siamensis*, now regarded as one of the world's most endangered crocodylians, was formerly common in the wetlands of southern Vietnam. Populations are thought to have declined in recent years, although quantitative status assessments are unavailable. We surveyed five areas previously believed to harbour the only remaining Siamese crocodile populations in Vietnam, and our results strongly suggest that viable populations are no longer extant. Crocodiles were not observed during spotlight counts of Crocodile Swamp (Nam Cat Tien National Park) or Lac Lake. Crocodiles do not occur in Upper or Lower Krong Pach Reservoirs, and these degraded sites no longer constitute suitable habitat. Remnant populations may exist in the Sere Pok River and Tay Son Lake, but these crocodiles remain subject to persecution. Population declines are attributed to a combination of hunting, habitat destruction, incidental capture in fishing nets and collecting for crocodile farms. Reintroduction to Nam Cat Tien National Park is recommended.

721: +.199

The Canadian Swift Fox Reintroduction Programme lasted from 1972 to 1997. From 1983 to 1997, a total of 841 captive-raised swift foxes and 91 translocated swift foxes were released in the Canadian Prairies. In South Central Saskatchewan, 406 captive-raised animals and 14 translocated animals were released from 1990 to 1997. This area was used to develop new release methods (in particular, portable protective shelters (PPS)) and saw the co-operation of a nongovernmental organization (NGO) (Cochrane Ecological Institute (CEI)) with two levels of government (Heritage Canada (Grasslands National Park) and the Government of Saskatchewan). A 1996-97 survey of swift foxes in South Central Saskatchewan estimated the population to be 87 animals. No attempt has been made to establish if this population level is sustainable.

722: +.022

The Red Kite *Milvus milvus* was formerly common and widespread throughout Britain, but by the end of the nineteenth century, as a direct result of human persecution, it had been reduced to a handful of pairs in mid Wales. In 1989, a re-establishment programme began in England and Scotland, and breeding populations have already become established in southern England, the English Midlands and northern Scotland. Intensive monitoring of released birds, and studies of the populations re-establishing themselves in England, have shown that the Red Kite is well adapted to our lowland landscapes and is able to thrive at high densities in the release areas. The Red Kite's generalist diet and lack of specialist habitat requirements should enable it to regain its former status in Britain as one of our most widespread and familiar birds, provided that certain threats

resulting from human activity can be reduced. In particular, the Red Kite is vulnerable to the use of illegal poison baits, secondary rodenticide poisoning, and shooting. The Red Kite is generally very popular with local people, and is proving to be an extremely useful 'ambassador species' for raptor conservation at a time when some specialist-interest groups view increasing raptor populations as a problem.

723: +.005

The Hihi (Stitchbird, *Notiomystis cincta*) is an endemic New Zealand honeyeater that after European colonization survived on only one offshore island. Attempts to reintroduce Hihi to other islands have been unsuccessful, with populations slowly declining. The main hypothesis for these declines was an inadequate year-round supply of carbohydrate food (nectar and fruit) due to human impacts on the forest habitat. When Hihi were reintroduced to Mokoia, another island with regenerating forest, we tested whether survival was limited by carbohydrate food in the year after release. We conducted an "on-off" experiment in which ad libitum sugar water was available to birds for 2 out of every 4 weeks. We compared the masses of individual birds at the end of on and off periods to identify times when birds lost condition with no supplementary food and would be likely to starve. We also used mark-recapture analysis of resighting data to test whether mortality rates were higher when supplementary food was unavailable. The only effect of the supplementary food was that Hihi spent less time foraging for nectar and fruit and more time foraging for invertebrates. There was no time of year when birds lost mass when the food was taken away, and survival rates were not significantly lower when supplementary food was absent. The low (38%) annual survival rate could not be accounted for by shortage of carbohydrate food, and population viability analysis suggests that the population is likely to slowly decline. Our experiment shows that declines of reintroduced Hihi populations may be unrelated to food supply and that alternative hypotheses should be developed and tested. Our results also show the importance of using experimental methods, when possible, to test hypotheses about factors thought to be limiting reintroduced populations.

724: +.016

The remnant wild population of California Condors (*Gymnogyps californianus*) of the 1980s exhibited a rapid population decline caused by high mortality rates among adult and immature birds. The most prominent mortality factor was lead poisoning resulting from ingestion of bullet fragments in carcasses. Successful captive breeding has allowed many birds to be released to the wild since 1992, based originally on an assumption that exposure to lead could be prevented by food subsidy. The mortality of released birds, however, has generally exceeded levels needed for population stability calculated from simple population models. Collision with overhead wires was the most frequent cause of death in releases before 1994. Lead poisoning again surfaced as a problem starting in 1997 as older birds began feeding on carcasses outside the subsidy program. Although poisonings have been treated successfully by chelation therapy in recaptured birds, food subsidy is proving an ineffective solution to lead exposure. The best long-term solution appears to be either the creation of large reserves where hunting is prohibited or the restriction of hunting to nontoxic ammunition in release areas. Until sources of lead contamination are effectively countered, releases cannot be expected to result in viable populations. In addition, problems involving human-oriented behavior have resulted in the permanent removal of many released birds from the wild. The most promising reduction in human-oriented behavior has been achieved in one release of aversively conditioned, parent-reared birds. Rigorous evaluation of the factors reducing attraction to humans and human structures has been hampered by confounding of techniques in releases. Behavioral problems could be more quickly overcome by adoption of a

comprehensive experimental approach.

725: +.159

Translocation is an important tool in conservation biology. However, translocation success is generally low for numerous animal species, therefore experiments are required for improvement. We carried out an experimental translocation of European wild rabbits (*Oryctolagus cuniculus*). The results may be of great interest for conservation biology, although we used a common species. As rabbits are known to experience a high mortality during the first days following release, it was necessary to assess the influence of handling trauma and environment novelty, respectively, and ways of suppressing them. Both tranquillization treatment during handling and a 'soft' release protocol (acclimatization pens in the new territory) were tested. Tranquillization did not increase survival, while the effect of acclimatization depended on sex. Females survived better when acclimatized, while males showed the opposite tendency. This difference is discussed in terms of sex-specific social behaviour, which is possibly an important correlate of translocation success. Finally, environmental stress seemed to override handling stress in determining the level of early survival for translocated wild rabbits.

726: +.127

Pere David's deer (*Elaphurus davidianus*) was reintroduced to China after its extirpation in the country in the nineteenth century. The first reintroduction was made to the Beijing Milu Park in 1985 and the second to the Dafeng Milu Natural Reserve in 1986. Those reintroduction sites have different characteristics. The Beijing Milu Park is near a metropolitan region and has limited size, whereas the Dafeng Natural Reserve is located in a coastal region with little human settlement. Except for a nuclear breeding herd, the Pere David's deer of the Beijing Milu Park were shipped to other sites in eastern China to reduce the grazing pressure on the park vegetation and expand the distribution of Pere David's deer. The Dafeng Milu Natural Reserve has the potential to hold a large population of Pere David's deer if more land were acquired to expand the natural reserve. By the end of 1997, total number of Pere David's deer in China reached 671, half of which were offspring from animals in Beijing Milu Park. The Beijing and Dafeng herds remain as 2 of the largest Pere David's deer populations in China, the Beijing population accounting for 19% and the Dafeng population for 45% of the total population. Pere David's deer of Beijing Milu Park have been transferred to 12 other locations. During 1987-1997, birth rates and net growth rates did not differ between populations ($P=0.09$ and $P=0.74$); however, death rates differed ($P<0.01$). After the period of adaptation, there was a period of population expansion, during which the birth rate in the Beijing and Dafeng populations declined as the population continued to grow. However, population density explained little about variation in birth rates in the Beijing and Dafeng populations; a longer-term monitoring of those populations is needed to assess plausible density-dependent population growth.

727: +.163

Wilderness in the United States has been controversial since its establishment in 1964. One school of thought argues that wilderness policy should prescribe wilderness boundaries and prevent management. Another believes that management practices must be used to maintain wilderness values. We described and tabulated wildlife management activities practiced in all 273 designated wilderness areas in the southwestern United States. We conducted a survey of personnel involved with wildlife management in wilderness including 60 employed by the United States Forest Service (USFS), 19 by the Bureau of Land Management (BLM), 14 by the National Park Service

(NPS), 7 by the United States Fish and Wildlife Service (USFWS), and 10 by state game and fish agencies. Wildlife management activities (not including population surveys and research) occurred in 174 wilderness areas. The most frequently mentioned wildlife management activities were maintaining artificial water developments, conservation education efforts designed to protect wildlife, and removing or controlling non-native animal species.

728: +.113

The eastern wild turkey (*Meleagris gallopavo silvestris*) experienced population declines in the United States beginning in the 19th century and continuing through the early 20th century. Transgeographic reintroduction efforts have reestablished eastern wild turkeys throughout most of their historic range but effects of reintroductions on genetic composition of resulting populations are unclear. Most reintroduced populations are maintaining self-sustainable populations. However, for unknown reasons, the population in southeastern Oklahoma decreased by 77% from 1980 to 1994. We used multi-focus DNA fingerprinting to evaluate levels of similarity, heterozygosity, and allelic diversity within and among wintering flocks occurring on the Pushmataha Wildlife Management Area in southeastern Oklahoma. Results from two restriction enzyme-probe combinations revealed mean similarity, heterozygosity, and allelic diversity similar to those in other outbred avian populations. Therefore, the decline of wild turkeys in southeastern Oklahoma is not related to reduced genetic variability, but may be due to biotic and abiotic factors not accounted for in this study.

729: +.126

Populations of lesser prairie-chicken (*Tympanuchus pallidicinctus*), apparently abundant in southeastern Colorado prior to EuroAmerican settlement, reached a low during the "Dust Bowl" years in the 1930's. Restoration of native sand sagebrush (*Artemisia filifolia*) grasslands and management of grazing on the Comanche National Grasslands by the United States Forest Service have resulted in modest population increases of lesser prairie-chicken since the 1960's. Past translocation efforts to expand distribution in Colorado and increase population size were not successful because too few birds were released and habitats may not have been suitable. Continued restoration and management of degraded habitats, as well as successful transplants into suitable habitats, could result in substantial increases in both distribution and population size. Precipitation appears to be a major factor affecting population changes as reflected in annual counts of active leks and males. Present populations in Colorado are estimated at less than 1,500 breeding individuals.

730: +.445

This meeting contains abstracts of 15 papers, written in English, covering topics in ornithology, including endemism, seabird translocations, conservation biology, trophic interactions, species interactions, molecular ecology, nesting behavior, breeding success, population studies, and bird pest management in various New Zealand bird species.

733: +.164

What features of the mustelids might yield insight into issues of general importance for conservation and ecology? This review focuses attention on correlates of threat, intra-guild competition and reintroductions. Using the IUCN classification of the status of mustelid species, I constructed a statistical model of correlates of threat. This suggested that otters and martens, and

mustelids with small distributional range sizes, were the most threatened. Whether or not a species was hunted and its habitat specificity did not correlate with threat. This analysis should be treated as indicative only, because the response variable (threat) was not totally independent of the explanatory variables. There is growing evidence that intraguild predation influences mustelids. In Scotland, there is some evidence for spatial segregation between Pine Martens and Red Foxes (a potential predator), Pine Marten relative abundance was higher in woodland interior than woodland edge. Red Foxes were equally abundant in woodland edge and interior. However, habitat fragmentation (woodland patch size) was the strongest correlate of relative abundance of both species. Research on mustelids has demonstrated the importance of appropriate release techniques during reintroductions. It has also shown that reintroductions of small numbers of animals can be successful, provided that they are conducted in high quality habitats, The implication is that habitat suitability assessments need to be given high priority. In this respect, research in Britain suggests that inferring habitat needs from areas of relict distribution may lead to highly misleading conclusions.

734: +.508

Granite outcrops in Western Australia contribute significantly to the conservation of several species of mammal. In the arid zone and wheatbelt, granite outcrops are particularly important for *Petrogale* spp and the euro *Macropus robustus*. Other species such as brushtail possums and chuditch also take advantage of the extra shelter provided by granite outcrops. The many granite islands off the south coast support remnant populations of threatened terrestrial and marine mammals. Granite rocks provide mammals with refuge from heat and introduced predators, and they are capable of modifying fire and moisture regimes to the benefit of some species. Many of the larger wheatbelt nature reserves contain granite outcrops and these will be important as mammal reintroduction sites for the Western Shield fauna recovery program. Fox control has been shown to be important for medium-sized mammal conservation on granite outcrops. Rock-wallabies in particular increase in abundance and this offers opportunities for nature based tourism. Appropriate management of granite outcrops, including islands, will contribute significantly towards the enhancement of mammal diversity in Western Australia.

736: +.073

Between the second half of the 19th century and the late 1970s beavers, *Castor fiber*, became extinct in Slovakia. Between 1976 and 1988, 42 beavers were released in Austria in the area neighbouring southwestern Slovakia. On the basis of direct or literary records of beaver observations (dead or alive) and activities (tree cuttings, huts and dams), we describe the recent and present status of the beavers in southwestern Slovakia. Austrian beavers and their offspring immigrated into the Zahorska lowland and the Morava-river basin. In this area of developed and cultivated landscape, the habitat conditions are favourable to beavers. In 2000, we here found some 60-65 beavers, including 7-8 families. The Danube stream, including the still-water system, beneath the city of Bratislava has also been colonized by beavers between 1984 and 1992. In spring 1993, the construction of the hydroelectric power station near Gabčíkovo and Cunovo was completed. Since then it prevents the beavers from migrating to the still water downstream the reservoir created by the barrages. At present, there are only 3 inhabited beaver sites (6-8 beavers) here, including one with reproduction. Upstream the reservoir and barrages we found 9 beaver sites with 20-25 beavers along a 4-km-long bank. Some beavers moved from west to east into the derivation-canal and were here in danger. Therefore the colonization of the Danube still-water system downstream the barrages is now possible only from the north east via the long way of the Male Karpaty mountains (watershed) and the Vah and Dudvah rivers into the Danube. This is

assessed by the presence of beavers in the localities of Breza pod Bradlom, Mostova, Horne Saliby and Tomazikovo. The total number of beavers in the area of Lower Austria and southwestern Slovakia (Danube, tributaries and brooks) presently amounts to about 540 beavers (respectively about 450 and 90), so that it is justified to speak about a genetically viable population. To maintain and increase this number it is imperative to build an ecological bypass allowing beavers and other aquatic animals to escape the barrages. The still-water systems of the former Danube riverbed are offering several beaver sites and may be considered a potential settlement area. The beaver reintroduction and immigration from Poland into the eastern part of the Slovakia (Beskydy Mountains) is presently insignificant.

737: +.046

At least 31 species of marine mammals, marine and coastal birds, and marine and anadromous fish have disappeared temporarily or permanently from the coasts of The Netherlands and in most cases also from the south-eastern North Sea (south of 54 degrees N) during the past 2000 years. In 18-22 cases, the disappearance was probably due to overexploitation. For 9-12 species, physical destruction of their habitat was involved and, for 3-5 species, pollution probably played a part. Five species have returned to the area; these are doing very well. Three species may return through expansion of populations elsewhere. Anadromous fish and demersal fish species that have disappeared because of bottom-trawling in the North Sea have little chance of returning under the present conditions. For the gray whale (*Eschrichtius robustus*) and the Dalmatian pelican (*Pelecanus crispus*) suggestions are made to investigate the possibilities for re-introduction. (C) 2000 Elsevier Science Ltd. 738: +.136

The importance of structure in grasslands to arthropods is emphasised. Community dynamics below ground are briefly described. The characteristics of stenophagous, polyphagous, predacious and parasitoid arthropods in relation to structure are outlined. Tall grassland supports more species, individuals and a greater diversity of arthropods than short swards, but some species are characteristic of the latter. The classification of structure in grassland is briefly reviewed. Change in grassland structure occurs through the opposing forces of succession and, in most cases, management. The commonest method of management is grazing, which is characterised by selectivity in the foliage eaten, treading of the sward and deposition of dung. Cutting is sudden, but its effects of defoliation are similar to those of grazing. Burning is considered in less detail. Ploughing, rotovating, re-seeding, fertiliser application, translocation and set-aside are generally forms of agricultural or 'creative' management. Human treading can have severe effects on invertebrate diversity and abundance. Management interacts with other factors, such as seasonality, timing, topography, site-specific characteristics and connectivity to produce varied effects on arthropods. The various types of management systems, reclamation, maintenance, agricultural, rotational and others are discussed in relation to management plans and objectives in conservation. It is concluded that conservationists need to be more aware of grassland dynamics, that management by reference to past land-use must be tempered by full consideration of ecological factors and conservation aims and that 'practical' and 'theoretical' conservationists need to interact more effectively. 739: -.030

During a 7 year period 30 captive born lynxes were released after spending an average of 192 days in an in situ adaptation enclosure. 13 individuals were found dead after a mean post release

lifespan of 271.5 days due to traffic accidents, poaching or unknown disease. Impact of terrestrial traffic and potential danger from contagious viral diseases of domestic dogs and cats as well as poaching are presumed to be the main anthropogenic factors negatively influencing desired lynx population growth. There is a demand for future investigation regarding canine and viral disease seroprevalence in domestic carnivores and lynxes in the Kampinoski National Park area. 5 lynxes repeatedly preyed on domestic livestock and had to be recaptured. 4 lynxes released for a second time succeeded in hunting wild prey species. Damages on domestic livestock could not simply be deduced to the use of captive born predators at all since predator opportunism by switching from hunting game to poultry can be observed in wildborn lynxes too. Even among siblings individual variances of adaptation to the wild environment were mainly a result of differences in inborn factors influencing learning of certain behavioural skills rather than being dependant on maintenance techniques at their birth enclosures or certain ways of pre-release management. 6 adult females reared pups during one year or repeatedly. 12 distinct observations of independant juvenile individuals were reported from all parts of the park. 7 out of 8 recorded dislocations outside the National Park area over distances between 10-50 km directed toward neighbouring nature reserves and were recorded during the past two years. Descending from these reintroduction activities a reliable minimum population of 19 lynxes of which 9 individuals represent the wildborn filial generation exists in central Poland at present. During the last 5 years of the project the National Park management improved lynx habitat by acquiring former farmland increasing total area of natural succession and renaturalization of drainage canals. Thus potential lynx pup rearing areas increase. Due to the numbers of sight reports of wildborn individuals in the National Park area and due to recent lynx dislocation in two neighbouring nature reserves the projects next phase favours ceasure of further releases and monitoring natural population development.

740: +.280

We reviewed the history and conservation of *Sophora toromiro*, a species that has been extinct in the wild since 1960 but has survived as scattered individuals in botanic gardens and private collections. The short-term conservation of *S. toromiro* is dependent on the management of surviving ex situ stocks. This is being achieved through international collaboration by a working group established to coordinate the conservation management of the species. Molecular evidence indicates that the species retains greater genetic variability than expected. The greatest amount of genetic variability was located in specimens outside botanic garden collections. No unmodified natural habitat survives on Rapa Nui (Easter Island); so opportunities to establish a viable wild population are limited. Evidence from past reintroductions indicates that the best shortterm opportunity for the species is through conventional horticultural management in botanic gardens and traditional farm plots on Rapa Nui. Some extinct-in-the-wild taxa (sensu World Conservation Union 1994), such as the Toromiro, retain genetic variability and appropriate reintroduction sites exist. These taxa represent valid priorities for conservation management.

741: +.236

When translocating individuals to found new populations, managers must allocate limited funds among release and monitoring activities that differ in method, cost, and probable result. In addition, managers are increasingly expected to justify the funding decisions they have made. Within the framework of decision analysis, we used robust optimization to formulate and solve different translocation problems in which both population growth and future funding were uncertain. Performance criteria included maximizing: mean population size and minimizing the risk (1) of undesirable population-size outcomes. Robust optimization provided several insights into the design of translocation strategies: (1) risk reduction is obtained at the expense of mean

population size; (2) as survival of released animals becomes more important, funds should be allocated to release methods with lower risks of failure, regardless of costs; (3) the performance gain from monitoring drops as the proportion of a fixed budget required to pay for monitoring increases; and (4) as the likelihood of obtaining future funding increases, more of the existing budget should be spent on building release capacity rather than saved for future operating costs. These relationships highlight the importance of performance criteria and economic costs in determining optimal release and monitoring strategies.

742: +.143

Native subspecies of cutthroat trout *Oncorhynchus clarki* have declined drastically because of the introduction of nonnative salmonids, overharvesting, and habitat degradation. Conservation of most declining subspecies will include establishing new populations through translocation of genetically pure fish. Recovery of greenback cutthroat trout *O. clarki stomias* has been ongoing for 25 years, so the attempted translocations of this subspecies provide unique empirical information to guide recovery of other nonanadromous salmonids. We compared 14 translocations that successfully established populations of greenback cutthroat trout to 23 that failed to determine the factors that influenced translocation success. Of the translocations that failed, 48% were reinvaded by nonnative salmonids, 43% apparently had unsuitable habitat, and 9% experienced suppression by other factors. Reinvansion occurred most often because of failed artificial barriers or incomplete removal of nonnative salmonids in complex habitats. Of those areas that were not reinvaded, success was highest in receiving waters with at least 2 ha of habitat that had previously supported reproducing trout populations.

743: +.054

The endangered kokako *Callaeas cinerea wilsoni* (Callaeidae), an endemic forest-dwelling passerine of New Zealand, has declined over the last century to a number of small isolated populations due to widespread habitat clearance and predation by introduced predators. To evaluate the genetic consequences of inbreeding and genetic drift, we examined genetic variability within and among 3 of the major remaining kokako populations using 4 polymorphic microsatellite loci. The largest remaining kokako population in the Te Ureweras was shown to have greater variability than the smaller Mapara and Rotoehu populations. Differentiation among the populations was low to moderate. We suggest there is no genetic barrier to translocations between the populations and that translocations of some individuals between the remaining kokako populations could enhance genetic variability of small populations to levels found in larger populations (e.g. Te Ureweras). 744: +.186

We document the recolonization of an indigenous large herbivore into its historic range. Eighteen wood bison (*Bison bison athabasca*) were reintroduced into the Mackenzie Bison Sanctuary of the Northwest Territories, Canada, in 1963. The population subsequently increased in number and range, peaking at about 2400 in 1989; numbers were estimated at about 1900 in 1998. Recolonization occurred through a series of increases in local areas followed by pulses of dispersal and range expansion. This pattern was originally described for exotic species' introductions. Differences in diet and overwinter survival of calves over the bison's range suggest that intraspecific competition for food provided the stimulus for range expansion. For a conservation strategy, the reintroduction of animals into several independent sites in their historic range would facilitate recolonization and achieve a faster spread than a reintroduction into one site followed by

waiting for the population to spread as a result of its own density dependent responses.

745: -.015

The "Pepperbark" tree, *Warburgia salutaris* (Bertol.f.) Chiov., is a small to medium tree (5-10 m) facing a high risk of extinction in the wild. It is now a critically endangered species in Zimbabwe. It has undergone a considerable decline throughout its natural habitat (range) in Zimbabwe mainly due to over-exploitation for medicinal purposes. Any part of the plant can be used for treating various ailments, fetching a very high price on the market. A full botanical description, of the species, its significance for economic use, past distribution and historical background are discussed in this paper. The options available for its cultivation and successful reintroduction to its historic range are described.

746: -.127

Using the example of a reintroduced bighorn sheep population in Badlands National Park, South Dakota we demonstrate the usefulness of neutrality tests and demographic data for detecting a severe genetic bottleneck ($N_e < 10$). From demographic data the effective population size of the founding population at Badlands was estimated to be six, and a heterozygosity excess test revealed evidence of a severe population bottleneck. We discuss the criteria for intervention when there is evidence of a severe bottleneck, and propose methods of mitigating the potentially deleterious long-term consequences of such bottlenecks. These issues are presented in the context of bighorn sheep reintroductions, but the issues are also of general importance to restoration efforts involving other large vertebrates.

747: +.118

By 1950, bighorn sheep were extirpated from large areas of their range. Most extant populations of bighorn sheep (*Ovis canadensis*) in the Intermountain West consist of <100 individuals occurring in a fragmented distribution across the landscape. Dispersal and successful colonizations of unoccupied habitat patches has been rarely reported, and, in particular, translocated populations have been characterized by limited population growth and limited dispersal rates. Restoration of the species is greatly assisted by dispersal and successful colonization of new patches within a metapopulation structure versus the existing scenario of negligible dispersal and fragmented, small populations. We investigated the correlates for the rate of colonizations of 79 suitable, but unoccupied, patches by 31 translocated populations of bighorn sheep released into nearby patches of habitat. Population growth rates of bighorn sheep in the release patches were correlated to N_e of the founder group, and early contact with a second released population in a nearby release patch (logistic regression, $p = 0.08$). Largest population size of all extant released populations in 1994 was correlated to potential N_e of the founder group, the number of different source populations represented in the founder, and early contact with a second released population ($p = 0.016$). Dispersal rates were 100% higher in rams than ewes ($p = 0.001$). Successful colonizations of unoccupied patches ($n = 24$ of 79 were colonized) were associated with rapid growth rates in the released population, years since release, larger area of suitable habitat in the release patch, larger population sizes, and a seasonal migratory tendency in the released population ($p = 0.05$). Fewer water barriers, more open vegetation and more rugged, broken terrain in the intervening habitat were also associated with colonizations ($p = 0.05$). We concluded that high dispersal rates and rapid reoccupation of large areas could occur if bighorn sheep are placed in large patches of habitat with few barriers to movements to other patches and with no domestic sheep present. Many restorations in the past that did not meet these criteria may have contributed to an insular

748: +.091

Restoration of desert bighorn sheep (*Ovis canadensis*) is proceeding in several western states. Measurement of nutritional resources (quality and quantity) is not normally conducted to assess future and present translocation sites, although it has been recommended generally for evaluation of ungulate habitat. We estimated nutritional carrying capacity (based on nitrogen in forage species) of three mountain ranges in Trans-Pecos Texas where desert bighorn sheep have been translocated. We used an explicit nutritional constraint model to estimate carrying capacity on a seasonal basis. Although drought conditions prevailed during the study period, bighorns were not limited by quantity of vegetation. However, forage biomass of high nutritional quality (>1.5% N) was very low (<9 kg/ha in spring; <1 kg/ha in all other seasons). Consequently, there appeared to be inadequate forage of high N content for bighorns to meet reproductive requirements in some seasons. Estimates generated using the explicit nutritional constraint carrying capacity model appeared to be realistic relative to observed densities. Nutritional sampling and modeling can predict potential carrying capacity on areas scheduled for restoration or on ranges already stocked, predict effects of management on carrying capacity, and allow managers to compare among restoration sites. We recommend that desert bighorn managers focus on monitoring the abundance of high-quality (%N) forage species, especially during periods of drought or higher nutritional requirements (e.g., lactation, post-weanling growth).

750: +.071

The Mauna Kea silversword, *Augyroxiphium sandwicense* ssp. *sandwicense*, has experienced both a severe population crash associated with an increase in alien ungulate populations on Mauna Kea, and a population bottleneck associated with reintroduction. In this paper, we address the genetic consequences of both demographic events using eight microsatellite loci. The population crash was not accompanied by a significant reduction in number of alleles or heterozygosity. However, the population bottleneck was accompanied by significant reductions in observed number of alleles, effective number of alleles, and expected heterozygosity, though not in observed heterozygosity. The effective size of the population bottleneck was calculated using both observed heterozygosities and allele frequency variances. Both methods corroborated the historical census size of the population bottleneck of at most three individuals. The results suggest that: (i) small populations, even those that result from severe reductions in historical population size and extent, are not necessarily genetically depauperate; and (ii) species reintroduction plans need to be conceived and implemented carefully, with due consideration to the genetic impact of sampling for reintroduction.

751: +.067

The aquatic North American river otter (*Lontra canadensis*), a charismatic nonendangered mustelid, presently occupies a greatly reduced range. The species is common in toes and has economic value as a furbearer. At least 17 states and one Canadian province have undertaken recent reintroduction programs. Nevertheless, little has been published on nonparasitic diseases of river otters, and little is known of the clinical significance of most of their parasitic infections. Records of environmental contaminant-related diseases and traumatic injuries in free-ranging North American river otters are also rare. This paper reviews present knowledge of North American river otter diseases, especially those with the greatest potential for impacting reintroduction programs.

The Chamois of the Chartreuse mountains, *Rupicapra rupicapra cartusiana*, is a sub-species which, apparently, is well-adapted to the Grande Chartreuse mountain massif (Isere). In spite of that its population decreased in number, and between 1960 and 1970 reduced the amount of area used. As a remedy to this situation, in 1990 and 1992 an attempt was made to reintroduce the species by translocation. Using radiotelemetry we monitored the dynamics of space occupation by 9 male and 17 female Chartreuse chamois, translocated in April between 1990 and 1992 from the western to the eastern slopes of this range. Before translocation the animals were kept together in an enclosure on the site of release, and set free as a group. The average home range sizes used throughout this study, as measured by the minimum convex polygon method, were 8,244 ha for males and 2,244 ha for females, by the "100%" cluster method respectively 6,201 ha and 1,789 ha, and by the 90% cluster method, respectively 437 ha and 333 ha. Distance between home range center and point of release was 3,400 m in males and 1,449 m in females. If its home range center was more than 2 km away from the point of release we considered an individual to have left the release site. The reintroduction campaign was a success since 85% of the animals (n=26) settled down in their release site. Three of the four released animals (two males and two females) left the reintroduction site and returned to their range of origin. The translocated animals had a tendency to explore their new range progressively. In fact, the areas occupied during the first three months after release were smaller than later on. Apart from 3 males with a very large home range (16,000 ha, 18,000 ha and 26,000 ha, minimum convex polygon) the home ranges of all other males and females were more or less of the same size (about 2,200 ha). Nevertheless, the oldest animals had a tendency to occupy larger home ranges than younger ones. Two of the three chamois which returned to their site of origin were among the oldests ones. This is why for reintroductions by translocation we recommend to take relatively young animals, to set the date of release in early April, to release many animals (between 20 and 30) together, preferably in groups, with an unbalanced sex ratio in favour of females.

Empirical data on behavior such as space-use patterns, are important to the success of animal reintroductions. We studied space-use patterns in a growing population of Asiatic wild ass (*Equus hemionus*) reintroduced into the Ramon erosion cirque in the Negev desert, Israel. Between 1988 and 1995 we used direct observation to determine the location and association of males and females. All adult females and dominant males were individually recognized. Home ranges of dominant males overlapped little, suggesting that in this population males are territorial. After the first release of males and females into the wild, only one territory was established and it covered most of the 20,000 ha of the cirque. After 6 years the number of male territories increased as the number of males in the population increased, and average territory size decreased. Male territories were near permanent and ephemeral water sources, but the water sources were at the peripheries of the territories and were not centers of activity. When there was only one territorial male, female home ranges were almost entirely within the territory. As male territory size decreased, so did the spatial association of females with a single male. During the breeding season, males spent more time in close association with female groups, adopting what may temporarily appear to be a harem breeding strategy. Although demographic and environmental factors pose a greater threat to small populations, our data support the hypothesis that in small, reintroduced populations of territorial, polygynous species, effective population size (N_e) may be dangerously small. Our data suggest that this situation may last for several years until new males are recruited into the population. Thereafter, rapid male turnover and female use of several male territories may ameliorate this problem. We found no relationship between male turnover rate and female reproductive success.

The establishment of more male territories is key to increasing N-e and should be the basis for planning reserves for territorial, polygynous species.

754: +.235

Changes in historical disturbance regimes have been shown to facilitate non-native invasions, but reinstatement of disturbance can be successful only if native colonizers are able to outcompete colonizing invasives. Reintroduction of flooding in the southwestern United States is being promoted as a means of reestablishing *Populus deltoides* subsp. *wislizenii*, but flooding can also promote establishment of an introduced, invasive species, *Tamarix ramosissima*. We investigated competition between *Populus* and *Tamarix* at the seedling stage to aid in characterizing the process by which *Tamarix* may invade and to determine the potential ability of *Populus* to establish itself with competitive pressure from *Tamarix*. We planted seedlings of *Tamarix* and *Populus* in five ratios at three densities for a total of 15 treatments. The growth response of each species was measured in terms of height, above-ground biomass, and tissue concentrations of nitrogen and phosphorus. These measurements across treatments were modeled as three-dimensional response surfaces. For both species, *Populus* density was more important than *Tamarix* density for determining growth response. Both species were negatively affected by increasing numbers of *Populus* seedlings. Due to the large size of the native *Populus*, we predict that its superior competitive ability can lead to its dominance when conditions allow native establishment. Our results suggest that even in the presence of an invader that positively responds to disturbance, reestablishment of historical flooding regimes and post-flood hydrology can restore this ecosystem by promoting its dominant plant species.

755: +.237

The burrowing bettong was successfully reintroduced to the Australian mainland in 1992 after an absence of 50 years. The population, derived from 42 individuals translocated from a remnant population on an offshore island, has persisted for over seven years on the Heirisson Prong peninsula at Shark Bay in Western Australia. It has grown to over 260 individuals that are distributed widely through available habitat. The successful management of exotic European foxes and feral cats proved crucial to the outcome of the reintroduction. Factors contributing to the successful management of predators and to a reduction in their impact included: the choice of a narrow peninsula as the site for reintroduction (permitting cost-effective use of predator-proof fencing); effective baiting (fox and cat) and trapping (cat) strategies; the maintenance of an in situ breeding colony (to provide insurance against major loss of free-range animals to predators); choice of high quality habitat (providing reasonable cover and promoting a high and relatively stable rate of increase for bettongs, even during dry years), and choice of a site that was accessible for regular management visits. An abundance of European rabbits at the reintroduction site appeared not to be a limiting factor. The success of this reintroduction has stimulated a range of other reintroductions of endangered mammals to arid and semi-arid sites across Australia, particularly to peninsulas or other sites where exotic predators can be controlled effectively. (C) 2000 Elsevier Science Ltd. All rights reserved.

756: +.005

According to literature, toponymy and personal communication, Ospreys were common along the rocky coast of Portugal until the beginning of the 20th century. Thereafter, increasing human encroachment on the coastline, especially through persecution, caused a severe and steady decline that led to the verge extinction as the breeding population became reduced to one single pair.

Considering the critical demographic situation and geographic isolation of the population, natural recovery is unlikely. Precipitous sea-cliffs, exposed coastline and moderate to low human presence are the dominant features of Osprey breeding habitat in Portugal. Nests are built atop rock pinnacles and on cliff ledges. During periods of rough water surface at sea, fresh and brackish water fish from inland dams and coastal lagoons predominate over marine fish in the diet. Freshwater prey is often taken at long distances from nest sites, presumably involving high energetic expenditure. Planned conservation actions aim at reducing disturbance and conflict with human interests through access management, building of artificial nests in areas of low angling quality, education and negotiation with local representatives; and at reducing foraging costs by providing new freshwater foraging sites closer to the coastline. As the management of habitat and its use by humans alone will predictably be insufficient, restocking the population with young from donor populations by hacking techniques is fundamental.

757: +.116

The Osprey has been absent as a breeding species in England for about 150 years but birds occur regularly on migration. The Scottish population has increased from one pair in the 1950s to at least 130 pairs in 1998. It has been subject to an intensive programme of conservation, management and research. In 1996, an experimental project was started to reintroduce Ospreys to England. A detailed project appraisal was undertaken before the necessary government licences were approved. Eight young from Scotland were translocated in 1996 and 1997, and twelve in 1998 to Rutland water Nature Reserve, a very large man-made reservoir in central England. In order to minimise effects on the wild population, attempts were made in 1996 to take 'runt chicks' which were likely to die but this was not very successful because of problems associated with salmonella infections. Out of eight young, six were released from specially built release cages on towers and four of them migrated. In the following two years, a total of 20 young were translocated and successfully released. Chicks were kept in captivity in broods of three and fed fresh fish in secluded cages over-looking the lake. After release young birds were fed at artificial nest platforms, to mimic food supply by adult male Ospreys, for over a month and all young set off on migration in a manner similar to wild birds in Scotland. Two of the young have subsequently been recovered dead in West Africa, one in Senegal in February and the other in Guinea in August, and one was observed on migration 200 km due south of the release site. The project team have refined the techniques of Osprey translocation and intend to release 12 young in 1999 and 2000, by which time it is hoped the first birds will have returned to breed.

758: +.155

Within the framework of a European program of brown bear (*Ursus arctos*) restoration, 2 adult female brown bears were captured in May and June of 1996 in Medved Reserve, Slovenia, and translocated to the central Pyrenees, France. The 2 females (Ziva and Mellba) were fitted with radiotransmitters and monitored from release to den entrance. After release from the same site, the bears were highly mobile and were located up to 55 km (Ziva) and 52 km (Mellba) from the release site. Their home ranges encompassed 1,233 km² (Ziva) and 796 km² (Mellba) during this period. The 2 females used their home range in a multimodal fashion with areas of concentrated utilization. Ziva and Mellba denned on 27 and 23 November 1996 and emerged on 19 and 4 April 1997, respectively. Denning sites were near the release site. These preliminary results suggest that translocation can be an effective technique to restore bear populations or to save small bear populations.

760: +.345

This recovery plan succeeds the earlier plan (Cree and Butler 1993) which guided tuatara conservation during the past decade and saw major achievements that have placed the species in a far less vulnerable position. Rats have been eradicated from several island habitats, and tuatara have been translocated to other islands in the hope of establishing new wild populations. Research and enhanced animal husbandry techniques have led to successful incubation of eggs and raising of juveniles in captivity. This increased productivity has been used to augment relict populations and provide animals for new wild populations. Future work will focus on advocating for the eradication of rats from Little Barrier (Hauturu), Mauitaha and Hen (Taranga) Islands and in maintaining the pest-free status of other island habitats. Further translocations are planned as part of the long-term objective of establishing wild populations of tuatara throughout their pre-human range. The potential to use tuatara in education, to enhance public awareness of conservation issues, and for research are all promoted within the plan. All are seen as essential for long-term conservation of the species. The increased involvement of iwi is essential if the plan is to succeed.

761: -.006

Bombina variegata is included in Enclosure II of Directive CEE 92/43 owing to the decline of its populations in some European Countries (Austria, Belgium, Italy, Germany, Holland, Switzerland, ex Sovietic Union), in recent years. For this reason, apart from the real situation of its populations, this species and *Bombina pachypus* have been given particular attention during the identification of regional S.I.C. (Sites of Community Interest-Nature 2000) for the BioItaly programme in Italy. Where *Bombina*'s populations were present in the past, some activities involving in their reintroduction or the development of their habitats were proposed. Before carrying out these activities, it's necessary to study the causes of the disappearance. Moreover, during the planning and carrying out of these projects, it is necessary to consider the main ecological requirements of these Amphibians. The types of habitat identified for *Bombina v. variegata* and/or *Bombina pachypus* are: 1. torrents (with calcareous or marly substratum); 2. troughs; 3. drinking troughs and irrigation tanks in stone or cement; 4. karst ponds; 5. corrosion basins; 6. quagmires and furrows cut by tractors or cars wheels.

762: +.007

Moving of groups or whole populations of amphibians are widespread conservation tools. Unfortunately exhaustive reports and publications about translocations are not so common. Even more rare are data about long-term monitoring programs. The present work proposes and defines the following terminology about translocations: Translocation=moving living organisms from one area to another; Introduction=release of species in areas or in biotopes where the same species was historically absent (inside=intrapatric introduction, or outside=extrapatric introduction, the species'native range); Re-introduction=release of a species in areas or in biotopes where the same species is now extinct but it was historically present; Re-stocking=release of a species in areas or in biotopes where the same species is still present; Direct translocation=release of specimens immediately after catching and moving them; Indirect translocation=release of specimens born and/or raised in captivity. Different experiences of translocation of amphibians are reported and guidelines about amphibians translocations are consequently provided. Finally it is underlined that every translocation program should be carefully planned, its appropriateness carefully considered, and the results monitored in the long-term and reported in detail, irrespective of its final succes or failure.

763: -.031

In 1995 and 1998/99 single species mass mortalities of sardine/pilchard *Sardinops sagax* (Clupeidae) spread rapidly throughout this species' range in Australia from the central coast of South Australia, dramatically decreasing the population size and representing the two most extensive mass mortalities recorded for marine organisms. The behavior of each epizootic indicated that an exotic pathogen was responsible, with the fatal agent shown to be a previously unknown herpesvirus. The focal origin of both events from a limited region within the extensive Australian range of *S. sagax* was not random. Tuna (*Thunnus maccoyii*) feedlots located in the same region as the epizootics' origins are responsible for delivering to the marine environment the largest quantities of *S. sagax* imported into Australia, which provides qualitative evidence of a link between the two events and imported *S. sagax*. This link provides an example of the need to undertake a review of the current international standards for import risk analysis (IRA) that requires a disease to be identified before it can be considered a risk. Regardless of the identity of the disease agents responsible, case histories of mass mortalities need to be given due consideration in both deciding whether to instigate an IRA and also form part of the IRA. Identification of a hazard should thus not be restricted to dealing only with identifiable diseases, but should also embrace case histories of epizootic events linked to (a) previously unidentified pathogens and (b) translocation of particular species between geographically separate populations.

764: -.035

Wildlife management involves regulation of population numbers of wild vertebrate species. In some cases there are too many animals and in others there are too few. Genetic issues arise in both instances. The historical and genetic evidence for the number of mammals that were in the founder populations of successful colonizing species in Australia and New Zealand is reviewed here. Small numbers have often given rise to large populations, despite the concomitant loss of genetic variability. Restriction of the number of over-abundant and pest species by either physical or chemical methods frequently constitutes very strong artificial selection, which leads to rapid genetic change; an example of major importance in the two countries is sodium monofluoroacetate (compound 1080). Pathogenic agents, surgical sterilization, hormonal contraceptives and translocation have all been used with varying degrees of success. The strengths and weaknesses of these techniques are assessed. A method that has received much attention is immunocontraception. We argue that this attempt to use the animals' own immune system to modulate reproduction is incompatible with the basic biological function of protection against infectious disease. Immune function genes are highly variable in vertebrates, and so often genetic change in the population subjected to immunocontraception is likely to be even more rapid than is the case with lethal agents. Selection for failure to respond to the immunocontraceptive will occur, and will change immune function in general. Poor scientific description of ecosystem complexity makes it difficult to predict the consequences of immunocontraception on wildlife populations.

766: +.167

The Chatham petrel (*Pterodroma axillaris*) is an endangered species restricted to a single population on South East Island, Chatham Islands, New Zealand. The key threat to Chatham petrel breeding success is interference with chicks by broad-billed prions (*Pachyptila vittata*) prospecting for burrows for their oncoming breeding season. This burrow competition has resulted from alteration to breeding habitat by humans throughout the Chatham Islands. Understanding habitat preferences may enable managers to manipulate habitat to reduce burrow competition and will be essential in order to translocate Chatham petrels to a proposed second colony. Habitat characteristics surrounding both Chatham petrel and broad-billed prion burrows were quantified and selection ratios compared. Both Chatham petrels and broad-billed prions selected habitat

factors associated with mature forest. Chatham petrels avoided a large number of habitat characteristics, which suggests they were habitat specific, and their preferred habitat is now limited. Broad-billed prions used a wide range of habitat characteristics, which suggests they are not habitat specific. This study recommends that selection values be used when deciding on the best location to establish a second Chatham petrel colony.

767: +.119

Hihi (*Notiomystis cincta*) were reintroduced to Mokoia Island, Lake Rotorua, New Zealand, in September 1994, and two years later there was an aerial drop of brodifacoum cereal pellets aimed to eradicate mice (*Mus musculus*). Using Program MARK, we analyzed data from resighting surveys to assess whether hihi had lower than normal survival in the 6-week interval following the drop. The resighting data were collected on a regular basis over a 3-year period, from 1994-97, allowing us to control for yearly and seasonal variation in resighting and survival probabilities. We initially established that the Cormack-Jolly-Seber model had a good fit to the data and could therefore be used as the global model for our analysis. We then compared a range of simpler candidate models, some of which included a poison effect (an unusual survival rate for the interval after the poison drop). Under the best model (that with the lowest AIC), the survival probability was constant over time and there was no poison effect. The estimated survival probability for the 6 weeks after the poison drop was 0.95, which is slightly higher than the value of 0.89 expected based on pre- and post-poison intervals. The approximate 95% confidence interval for the probability of a bird dying due to poison ranged from -0.17 (i.e., a decrease in mortality rate due to the poison) to +0.04. We therefore concluded that the poison caused at most a negligible increase in mortality, and that mark-recapture analysis on resighting data provided a powerful method for assessing the impact of the poison drop. We discuss the relative costs and benefits of radio tagging versus resighting surveys of banded birds for estimating impacts of poison operations. For species with relatively high resighting rates, such as hihi, analysis of resighting surveys is a much more reliable and cost-efficient methodology.

768: +.063

Several recent studies have used "roll calls" - searches for individually-marked birds - to assess impacts of aerial poison operations on non-target species. Roll calls have advantages over methods such as 5-minute bird counts, call counts, and dead body counts, but roll calls are based on the assumption that detection rates are 100%, or that detection rates are constant over time and space. They also require more than one group of birds, at a poisoned and unpoisoned site for example, for valid statistical comparisons. With minor adjustment of field methods, however, a series of surveys can be treated as a mark-recapture experiment, allowing powerful analysis without such restrictive assumptions. Survival and detection rates can be estimated independently for each time interval, and alternative models fitted to the data for factors affecting those rates. Using the software package MARK, we analyzed data for New Zealand robins (*Petroica australis*) on Tiritiri Matangi Island to estimate impact of an aerial brodifacoum operation conducted in September 1993 to eradicate kiore (*Rattus exulans*). The population was established by translocations in 1992 and 1993, and consisted of 40 birds at the time of the operation. Taking seasonal and yearly variation in detection and survival rates into account, we estimate that 11% of robins (4-5 birds) died as a result of the poison. There was strong evidence that survival probability was lower immediately after the operation, despite the small number of birds disappearing. The poison effect was confined to the interval from September-October 1993, including the first two weeks after the poison drop, and survival for subsequent monthly intervals was consistent with the normal summer rate. Using simulation modelling based on our data from the population, we predict that the operation set

population growth back by about one year but had no longer-term impact.

769: +.287

Southeastern United States habitats dominated by longleaf pine (*Pinus palustris* Miller) and associated plant species have declined dangerously. Conservation of rare and common plants of longleaf pine habitats may be aided by starting new populations in the field. We review methods for initiating plant populations and integrate information from our studies of rare and common longleaf pine ground-layer plants of the outer South Carolina Coastal Plain. In our experience it is possible to start new populations of most longleaf pine ground-layer plants, including rare species if (1) seeds are collected from frequently burned sites with reasonably large populations of desired species; (2) appropriate media are used for seedling propagation; (3) outplanting of nursery grown seedlings or direct seeding is done during periods of sufficient soil moisture; and (4) introduction sites properly match habitat requirements (inferred from indicator plants) of desired species, and the sites can be managed with frequent prescribed fire.

770: +.021

Mexican wolf (*Canis lupus baileyi*) recovery is one of three gray wolf restoration efforts in the United States conducted by the US Fish and Wildlife Service (USFWS). The Endangered Species Act (ESA) of 1973 (16 USC 1531-1544) saved the Mexican wolf from almost certain extinction. All known Mexican wolves descend from seven founders that were captured from the wild and bred in captivity (Parsons 1996). Two challenges faced by Mexican wolf recovery include the use of naive, captive-reared wolves for release stock and sociopolitical opposition to restoring predators. Following years of planning and public involvement, reintroduction of Mexican wolves began in March 1998 (Parsons 1998). In this chapter we describe the history and ecology of the Mexican wolf and its narrow escape from extinction. Details and early results of ongoing efforts to restore this extirpated predator to the American Southwest are presented. We hope this information will be of interest and value to others pursuing carnivore restoration efforts.

771: -.076

We describe white rhinoceros (*Ceratotherium simum*) mortality at Pilanesberg National Park, South Africa, focussing on mortality caused by African elephant (*Loxodonta africana*). We reconstructed records from a range of historical sources, and estimated that up to 49 rhino were killed by elephant. There was confirmed mortality in 1994 and 1996, and based on patterns, we suggest a set of rhino mortality from elephant in 1992. Both sexes and all age classes were victims. There was no significant bias to older animals, but given the rhino population structure, there was a significant bias towards males in adult deaths. The culprits were identified as young male elephants that entered musth about 10 years younger than expected, and maintained musth for a full term at first occurrence. We attributed this to the lack of a mature bull hierarchy in the park, because these elephants were the product of translocation of young animals (<10 years old) remaining from culls in Kruger National Park. We emphasise the need for accurate monitoring and record keeping, and a focus on individual identification of key species in small reserves.

772: -.012

By the beginning of the 20th century the lynx, wolf and bearded vulture had disappeared from Switzerland and the whole of the Alps. Only brown bears survived as a relict population in the Italian Alps. The recent increase in the populations of large carnivore all over Europe has also

affected the Alps and Switzerland. The four species discussed here are coming back: the lynx and the bearded vulture through re-introductions, the wolf and the brown bear by natural immigration. Their reappearance also revives many of the potential conflicts between humans and large carnivores. We describe briefly the history of the extermination of the four species in the Alps and in Switzerland and their recovery at the end of the 20th century, and define the most prominent reasons for conflicts. The red fox has never disappeared from Switzerland. However, the population developed very dynamically during the 20th century due to a rabies epizootic, on the one hand, and an increase in the carrying capacity of the habitat, on the other.

776: +.315

Assessing the colonizing ability of a species is important for predicting its future distribution or for planning the introduction or reintroduction of that species for conservation purposes. The best way to assess colonizing ability is by making experimental introductions of the species and monitoring the outcome. In this study, different-sized propagules of Roesel's bush-cricket, *Metrioptera roeseli*, were experimentally introduced into 70 habitat islands, previously uninhabited by the species, in farmland fields in southeastern Sweden. The areas of introduction were carefully monitored for 2-3 yr to determine whether the propagules had successfully colonized the patches. The study showed that large propagules resulted in larger local populations during the years following introduction. Probability of colonization for each propagule size was measured and showed that propagule size had a significant effect on colonization success, i.e., large propagules were more successful in colonizing new patches. If future introductions were to be made with this or a similar species, a propagule size of at least 32 individuals would be required to establish a viable population with a high degree of certainty.

777: +.033

Deteriorating environmental conditions and overexploitation in situations of insufficient fish stocking or a complete lack of it led to the extinction of salmon in Polish waters. The last population of salmon in the Drawa River disappeared in the mid-1980s. The aim of this work was to re-establish salmon in Polish waters. The salmon for this purpose came from the Daugava River, when in 1985 and 1987, 50 000 and 30 000, eyed salmon eggs were bought, respectively. Up to 1996, salmon spawners were reared in the floating net cages in of the Puck Bay. Since 1994, spawns of salmon have been reared in freshwater at the fish farm "Aquamar" at Miastko. Stocking of smolt started in 1994 and by the year 2001, 2 238 653 one- and two-year-old smolts had been released. Smolts were released into rivers in the Pomeranian region, the Drawa, and the Vistula and its tributaries. Between 1994 and 2000, 78912 one- and two-year-old tagged smolts were released together with untagged ones. The first salmon in the Vistula and Drweca rivers were noted in 1996. From 1997 to 2000, salmon catches in rivers fluctuated between 413 and 9714 kg. From 1997 salmon spawners were captured for artificial spawning. The largest spawners were 120-cm long and weighed 17.5 kg. Alongside untagged spawners, single tagged salmon were also used for spawning purposes. In 1997, a total of 382 000 eggs were obtained. In later years the number of spawns obtained grew, and in 2000 the number of eggs collected was 2 260 000. In 1996, spawns from salmon raised in pools at Swierzenko were collected. In 2000, there were 1168 females (length 30-70 cm) from which 3 300 000 eggs were collected. From 1997, large nests were observed at the spawning grounds in the Drawa River. In next years salmon nests were observed in the Drawa River and also in Parseta and Wieprza rivers. Percentages of recovers from tagged salmon were very low and varied from zero to 7.35. Tagged salmon migrated all over the Baltic Sea. The most often they were caught in the Gulf of Gdansk area, near Bornholm Island and in the western part of the Gulf of Finland. Salmon entered rivers mainly into Vistula, Drweca and

Wieprza rivers for spawning purposes. Some spawners strayed and entered rivers to which they were not released as smolt. Higher percentage of homing were observed among smolt released into Vistula i Drweca rivers than among smolt released into Pomeranian rivers. Tagged salmon after the first year reached average length of 59.4 cm and average weight of 2583 g, after the second year 81.8 and 6255 g, after the third year 102.4 cm and 11800 g respectively.

779: +.165

The Louisiana Department of Wildlife and Fisheries regulates an experimental alligator (*Alligator mississippiensis*) egg collection programme which requires the return of a portion of juvenile alligators to the wild to ensure recruitment and maintain populations. Numerous studies have been and are currently being conducted by Department personnel to evaluate the success of this programme. Farm-released juvenile alligators are able to forage for food after release to the wild. Growth rates are equal to or higher in juveniles released from farms than native wild alligators matched for size and sex. The accelerated growth is maintained for several years after release. An extensive tag and release programme of farm-released juvenile alligators was evaluated by analysis of later harvest of recaptured sub-adult and adult alligators. Results suggest fairly high survival rates of farm-released alligators. No differences were found in stress hormone levels between farm-releases later caught in the wild and native-wild alligators. Farm-released juvenile alligators have attained sexual maturity and successfully nested in the wild. Numerous parameters suggest egg ranching and subsequent return of a portion of juvenile alligators to those wetlands is a successful management tool that uses a resource that would otherwise be lost to high natural mortality. A brief review of release programmes for other crocodylians is provided.

781: +.235

Large fruit-eating pigeons of New Caledonia and French Polynesia provide an excellent model to illustrate the hypothesis that sustainable management of biodiversity resources is essential under high human pressure conditions. An adult giant imperial pigeon (*Ducula goliath*) can weigh more than 800 g, making this endemic New Caledonian bird the largest pigeon in the world and of considerable interest in terms of game resources. In French Polynesia, the habitat of the Marquesas imperial pigeon (*Ducula galeata*) is limited to Nuku Hiva island, with a maximum of 200 birds present. The Polynesian imperial pigeon (*Ducula aureora*) is now very rare in Tahiti, with a maximum population of around 500 birds present only on the island of Makatea (Tuamotu). Due to the small populations and their isolation, these latter two imperial pigeons must be carefully managed to avoid their extinction. By contrast, the populations of giant fruit-eating pigeons found solely on Grande-Terre island can only be maintained by hunting regulations drawn up on the basis of a better understanding and monitoring of their ecology and by a perception of the conflictual interests of hunters and the different communities. After reviewing available data, this article analyses possible methods for monitoring and active management of these species, e.g. rational sampling strategies, awareness campaigns, translocation operations and methods for founding new populations.

783: +.168

Blue-and-gold macaws (*Ara ararauna*), once found in the Nariva Swamp in Trinidad, were extirpated in the 1960's because of nest poaching for the pet trade and habitat alteration. In 1993, the Forestry Division of Trinidad and Tobago, The Centre for the Rescue of Endangered Species of Trinidad and Tobago (CRESTT) and the Cincinnati Zoo and Botanical Garden embarked on a mission to restore this species to its island habitat. Food source and nest site surveys indicated that

this now protected wetland could still support a population of reintroduced Blue-and-gold macaws. After several unsuccessful attempts to obtain chicks for release through captive breeding, a pilot study on the reintroduction of wild-caught birds was implemented. In 1999, nine potential pairs (18 birds) were imported from stable wild populations in Guyana. After quarantines, testing and physical examinations, the birds spent four weeks in a pre-release flight cage located in a protected wildlife sanctuary within the Nariva Swamp. They were monitored by local villagers and introduced to natural foods of the area. Over a period of three months, 14 birds were released (eight males and six females). More than one-year later, nine macaws continue to be sighted in the wild. Behavioral observations of six of these birds during February to May 2001 suggest nesting activity. Trained local villagers in the communities bordering the swamp have been monitoring flight patterns and potential nesting sites of the released birds. Education programs have helped rural communities and schools to learn more about the sustainable use of the Nariva wetlands. Private and corporate sponsors and the media have raised public awareness island-wide to the significance of this conservation effort.

784: +.362

Wildlife conservationists and managers must address a wide range of issues relating to bird populations including sustainable management of the wider countryside, the protection of individual sites and site networks and properly planned species recovery. Sound approaches to these problems need to be based on a good understanding of the population processes involved. Much of the research that provides such understanding is based on ringing, which is used to measure many aspects of avian demography, particularly survival rates, recruitment and dispersal. Ringing studies have allowed the demographic causes of population declines to be identified, providing indications and tests of their environmental causes. Spatial population modelling, supported by good empirical data on dispersal, has the potential to contribute to both species and landscape conservation. The success of rehabilitation and reintroduction programmes can often be evaluated from studies of marked birds. Descriptions of patterns of movements form an essential part of the information required to manage flyway populations and site networks. Ringing is also a key component of research into the effects of hunting because it can be used to measure both harvest and survival rates. The control of gull populations illustrates the application of population dynamics principles to reduce population size. The contribution of ringing to conservation science during the 21(st) century can be enhanced by using information technology to improve the use of existing information and data, by undertaking more long-term monitoring and through giving careful attention to the design of research projects.

786: +.071

Analyses of mitochondrial control region sequences were used to infer phylogeny of Anser species, phylogeography of the lesser white-fronted goose, and genetic background of a captive stock. The genetic distances among the Anser species ranged from 0.9 to 5.5% in the complete control region sequences and supported the view of close relatedness of these species. Among the four most closely related species, the bean, pink-footed, white-fronted and lesser white-fronted goose, the branching order is uncertain. The short internal branches and low support for the branching order suggest that the species have diverged recently within short time-intervals. The mtDNA tree obtained is incongruent with the traditional view of the species relationships, but the reasons for this remain to be clarified. Two diverged mitochondrial lineages were found in the lesser white-fronted goose and a refugial origin was proposed. Basal haplotypes are geographically widespread and indicate a recent common ancestry for populations. The derived haplotypes are confined to singular breeding populations and suggest restrictions to the present

female gene flow. A shift in the frequency of the mtDNA lineages approximately coincides with a migratory divide in the Taimyr Peninsula. Low mtDNA diversity and significant difference in the haplotype frequencies observed in Fennoscandian subpopulation suggested that it should be considered as a management unit. The fossil record was examined to gain additional information about the colonisation history of the species, but was found to be of limited use. The captive lesser white-fronted goose stock used for reintroduction/restocking was shown to be incompatible with the Fennoscandian wild population. Some captive individuals carried the mtDNA of the white-fronted goose suggesting a hybrid origin. Hybridisation has probably occurred during captive propagation, but to clarify further the extent of introgression, nuclear markers should be applied. The structure and evolution of the control region were studied by comparing complete avian sequences. Saturation was found to occur at pairwise divergences of 10% as shown for third codon positions of the mitochondrial genes previously. In pairwise comparisons of the control region and cytochrome b sequences, the rate of divergence varied among the lineages. Two conserved sequence blocks showed considerable sequence conservation when compared to mammalian sequences.

787: +.312

The fossil record, particularly from the early Holocene and Pleistocene, can provide an historical basis for understanding long-term ecological change. Available data on the rate and types of environmental change in modern ecosystems is often limited to a few decades, whereas similar information provided by paleontological evidence can provide a record spanning thousands of years. This perspective becomes especially important in recognizing naturally occurring events that have a periodicity exceeding human observation. Thus the fossil record establishes a useful baseline for ascertaining whether changes impacting habitat have natural or anthropogenic causes. Fossil remains can also provide reliable documentation on the paleo-distribution of endangered species and indicate areas favorable for reintroduction. Occasionally fossil preservation permits the recovery of DNA, allowing a very precise match between fossil and extant populations. More importantly, the paleoecological reconstruction of the former habitat has the potential for identifying new ranges where endangered species may be successfully introduced. We do not advocate that the entire paleontological record will always be applicable to modern ecosystem management. However, we do maintain that part of the record from semi-deep time, extending tens to hundreds of thousands of years in the past is certainly relevant. Therefore, proper management of fossil resources is essential in preserving an irreplaceable record of environmental change. In turn, documentation of long term ecological history represents a potentially critical input in the decision-making process with regard to current ecological problems.

788: +.166

A direct comparison of the genetic linkage maps of sorghum and rice is proposed. It is based on the mapping of a common set of 123 RFLP probes scattered on the genomes of both species. For each species a composite map was established by merging two individual maps comprising many common loci. This enabled us to confirm the global correspondence scheme that had previously been established between the chromosomes of sorghum and rice. It also provided a more detailed insight into the conservation of synteny and colinearity: 69% of the loci mapped on a given rice chromosome mapped to the corresponding homoeologous chromosome in sorghum; among them, 84% formed a colinear arrangement between the two species. Local inversions and translocations were detected.

789: +.053

The genetic integrity of many salmonid fish populations is threatened by stocking of domesticated conspecifics. The purpose of this study was to assess the utility of microsatellite DNA markers for detecting loss of genetic diversity in hatchery strains, for estimating their genetic relationships, and for monitoring the genetic impact of stocking activity on wild populations of salmonid fishes. Brown trout from ten hatchery strains, one supportive breeding "strain," and five wild populations were screened for variation at eight loci. In most hatchery strains, genetic variation was comparable to that of wild populations, but three strains showed loss of allelic variation. In six of the hatchery strains, significant differentiation was observed between age classes. Genetic differentiation among all populations was moderate ($F_{ST} = 0.065$, $p_{ST} = 0.076$), and only a minor part of genetic diversity was distributed between the wild and hatchery populations. We assessed whether wild populations were introgressed by stocked hatchery trout by performing assignment tests to determine population of origin and estimating maximum potential introgression rates. The results suggested that genetic introgression by hatchery trout had occurred for only two of the five populations potentially influenced by stocking. In one of these two rivers, microsatellite data obtained from a limited number of old scale samples indicated that individuals from the original population were genetically divergent from those of the present population, suggesting that extinction of the original population had taken place. The study demonstrates that microsatellite analysis provides a useful tool for distinguishing heavily introgressed populations from those unaffected by stocking. The information can be used to assist in (1) prioritizing populations for conservation and (2) the choice of wild populations to be used as sources for the reintroduction of salmonids in areas where local, indigenous gene pools have been extirpated.

790: +.290

In many respects, amphibian spatial dynamics resemble classical metapopulation models, in which subpopulations in breeding ponds blink in and out of existence and extinction and colonization rates are functions of pond spatial arrangement. This "ponds-as-patches" view of amphibian spatial dynamics is useful in several respects. First, it highlights the importance of regional and landscape processes in determining local patterns of abundance. Second, it offers a straightforward, pond-based approach to monitoring and managing amphibian populations. For many species, however, the ponds-as-patches view may be an over-simplification and metapopulation structure may be more apparent than real. Changes in distribution may be caused by processes other than extinction and recolonization, and most extinctions probably result from deterministic factors, not stochastic processes. In addition, the effects of pond isolation appear to be important primarily in disturbed environments, and in many cases these isolation effects may be better explained by the distribution of terrestrial habitats than by the distribution of breeding ponds. These complications have important implications for both researchers and managers. For researchers, future efforts need to determine the mechanisms underlying patterns of abundance and distributional change and patterns in amphibian populations. For managers, effective conservation strategies must successfully balance metapopulation considerations with careful attention to local habitat quality. Furthermore, translocations and active management may be indispensable tools for conserving amphibians in landscapes containing multiple breeding ponds.

791: +.057

A fundamental role of government conservation agencies is to set priorities for the conservation and management of biodiversity. This is particularly important in an area such as Western Australia which has a rich and highly endemic flora with over 11,000 listed native vascular plants. Legislation provides an initial focus for priority setting through the listing and protection of threatened flora, although this excludes over 1900 Western Australian plant taxa which are poorly

known but may be of conservation significance. The priority setting process for the conservation of this flora, discussed herein, focuses on single taxa, groups of taxa within geographic regions, populations and threatening processes. This process is particularly applicable to the highly diverse and endemic flora of the south-west Botanical Province. Within this region there has been extensive habitat loss and degradation over the last 100 years. Currently the prioritisation process has identified 95 critically endangered taxa in the southwest which require immediate remedial action to prevent extinction. Actions such as translocations are already showing promise, but with this number of critically endangered taxa and limited resources there may also need to be some ranking of taxa for immediate translocation. Although the priority setting process outlined here relates primarily to taxa, we emphasise that the conservation of this flora is also addressed at ecosystem and ecological community levels, and that each approach has its merits depending upon land tenure, location within the State and, in particular, the level of land degradation. 792: -.015

Translocation is increasingly used in conservation to re-establish or augment populations of threatened species or to remove individual animals from areas of human-wildlife conflict. We assess the feasibility and utility of translocating hen harriers (*Circus cyaneus*) in the UK to enhance their distribution and abundance whilst simultaneously reducing the impact of harrier predation on red grouse (*Lagopus lagopus scoticus*) populations and shooting bags. Current knowledge of hen harrier feeding ecology? dispersal, survival and recruitment suggests that they would be suitable subjects for translocation with the aim of increasing their distribution in the UK. Assessment of habitat and food availability suggest that there are suitable recipient sites beyond the current range of the hen harrier in the UK. However, translocation would not be a sustainable method of reducing predation on grouse moors because it would have to continue indefinitely as long as grouse moors attracted harriers. Translocation of harriers to grouse moors when they have been locally extirpated would not be appropriate until levels of illegal control are reduced. Establishing new harrier populations through translocation away from grouse moors may become desirable if initiatives to reduce human-raptor conflicts on grouse moors are unsuccessful, or as an interim measure to accelerate the recovery of hen harriers in the UK.

793: +.126

Since the reintroduction of the Pere david's deer in China in mid 1980's, the Beijing and Dafeng Pere david's deer breeding populations have been established. During the past 14 years, the Beijing and Dafeng populations all experienced the periods of acclimatization and population growth. By the end of 1997, the total number of the Pere david's deer reached 671 in China. The sex ratios in both Beijing and Dafeng Pere david's deer reached balanced sex ratios and the effective population sizes also approached to sizes of the actual population in both populations. However, the carrying capacity of the Beijing Milu Park is limited, the Pere david's deer in the Dafeng Pere david's Deer Natural Reserve are mainly living in three paddocks of 1km², thus, population densities increased as the populations grew. In the 1990's, the growths of both Beijing and Dafeng populations showed density-dependent patterns, especially in the Beijing population. Hence, population regulation measures such as artificial dispersal and controlling of birth rate must be taken in order to slow down the rapid growth in the Beijing population. There is vast seashore in the Dafeng Pere david's Deer Natural Reserve. Captive-bred Pere david's deer can be released into open coast area and to reestablish wild Pere david's deer population, thus, to reduce grazing pressure by Pere david's deer in the paddocks. The relocation of Pere david's deer to Tianezhou, Shishou, Hubei is met with a success. The relocated Pere david's deer adopted the

climate of the lower reach of the Yangtze river, now the population of the Tianezhou reserve is over 200, the population growth rate is 35%. That means the lower reach of Yangtze river is suitable for further field release of the Pere david's deer. When considering manipulating population structure and releasing captive-bred individuals to the field, we should also keep a group of Pere david's deer in captivity, to continue the process of domestication of the deer. Therefore, while restoring the Pere david's deer in the nature, we will also produce a domestic Pere david's deer breed, which can be farmed in the future.

794: -.437

The current extinction of many of Earth's Large terrestrial carnivores has Left some extant prey species Lacking knowledge about contemporary predators, a situation roughly parallel to that 10,000 to 50,000 years ago, when naive animals first encountered colonizing human hunters. Along present-day carnivore recolonization fronts, brown (also called grizzly) bears killed predator-naive adult moose at disproportionately high rates in Scandinavia, and moose mothers who Lost juveniles to recolonizing wolves in North America's Yellowstone region developed hypersensitivity to wolf howls. Although prey that had been unfamiliar with dangerous predators for as few as 50 to 130 years were highly vulnerable to initial encounters, behavioral adjustments to reduce predation transpired within a single generation. The fact that at Least one prey species quickly Learns to be wary of restored carnivores should negate fears about Localized prey extinction.

797: -.170

Using radio-telemetry we evaluate and discuss effects of a prescribed fire in a Madrean community on mortality, behavior, and habitat of 3 rattlesnake species. Eight snakes exposed to low intensity fire survived, whereas a snake exposed to intense fire died. Spatial descriptors of activity did not significantly differ before versus after the fire; however, individuals moved significantly less frequently and were found in subterranean retreats more frequently after the fire than before the fire. Wooded canyons and wooded steep slopes burned intensely because of high fuel accumulation, resulting in habitat loss for *Crotalus willardi obscurus*. Reintroduction of fire is essential in maintaining a mosaic of habitats and ecosystem function. Prior to reintroduction of large-scale summer fires, consideration should be given to reducing artificially high fuel loads to preserve *C. w. obscurus* habitat and reduce mortality.

798: +.068

Asiatic wild asses and Przewalski horses initially inhabited steppe, semi-desert and desert areas, but Przewalski horses became extinct in the wild, and Mans disappeared at the beginning of the 20th century, except for a small population in Turkmenistan. The Bukhara Breeding Centre (Uzbekistan) was created in 1976 for reintroduction and conservation of wild ungulate species. In 1977-1978, Rye Mans (two males and three females), from Barsa-Kelmes island on the Aral sea, were introduced into the reserve. The group increased to 25-30 animals in 1989-1990, when eight Przewalski horses from Moscow and St Petersburg toes were introduced. We analysed the home ranges, preferred habitats and social interactions of these closely related species during 1995-1998 by seasonal and group composition. Horses and asses formed a reproductive group and a secondary non-reproductive group. The home range of the secondary group was larger than the reproductive group and seemed to be less dependent from the watering places. Przewalski horses were less adapted to semi-desert conditions (both water and vegetation needs) than kulan. (C) 2001 Academic Press.

799: +.075

We studied the thermal sensitivity of sprint speed in the captive population of the endangered lizard *Gallotia simonyi* (Lacertidae) on El Hierro island and in *C. stehlini*, an abundant, large-sized lizard from the nearby island of Gran Canaria (Canary Islands, Spain). Among adults, lizards of both species were faster than adults of other lacertids. The sprint performance curves for both species had a flat upper plateau, and the obtained values for performance breadth were high, indicating that species attained near maximum sprint speeds over a wide range of body temperatures. *Gallotia stehlini* was significantly faster than *G. simonyi* both in absolute (cm/s) and relative speed (SVL/s). Juveniles of *G. simonyi* were significantly slower than juveniles of *G. stehlini* only in absolute speed. The lower sprint speed of *G. simonyi* is consistent with the hypothesis that higher vulnerability of this species to introduced predators may have played a role in its near extinction. Juveniles rather than adults from the captive population of *G. simonyi* should be used for reintroduction to establish wild populations, because the sprint performance of adults may have been compromised by prolonged captivity.

800: +.030

We analyzed genetic variability among the four naturally-occurring populations of the endangered plant *Cordylanthus palmatus* to test whether a central tenet of conservation genetics - large populations are more genetically diverse than small populations held true in our study system and to guide long-term conservation planning for the species. Genetic variability in *C. palmatus* was moderate at the species level but relatively low in several populations. About 2% of the measured genetic variation was attributable to variation between populations. Genetic variability in *C. palmatus* did not increase with population size. The two largest populations were relatively invariable and genetically similar, and neither contained any unique alleles. (C) 2001 Elsevier Science Ltd. All rights reserved.

801: +.129

The red-legged partridge (*Alectoris rufa*) is the only indigenous *Alectoris* species in the Iberian Peninsula. Local populations are often reinforced with captive-bred individuals, sometimes including hybrids between the red-legged partridge and the exotic rock partridge (*A. graeca*). Hunters and wildlife managers oppose releases of hybrids, but their identification by visual inspection is difficult beyond the first hybrid generation. Here we report the development of a set of RAPD markers to identify hybrid partridges using blood samples. We initially screened 46 RAPD primers on a subsample of pure red-legged and rock partridges, and finally selected six primers that produced 11 markers specific of the rock partridge. The selected primers were tested on hybrids of different generations bred in captivity. This set of loci permitted the detection of 100% (n = 31) F1 hybrids, 100% (n = 14) backcrosses of F1 to red-legged partridge, all but one (95%, n = 18) hybrid of the second backcross, and 18 out of 27 (67%, n = 27) hybrids of the third backcross. Efficient detection of backcross 1 and 2 individuals is essential, as these are the ones released for re-stocking purposes in hunting states. Although we have only used blood samples, other sources of high-quality DNA, such as muscle, should provide the same results. Therefore, it would be feasible to monitor the genetic purity of partridges in farms and hunting states at different stages of production, including embryos, chicks or hunted specimens. (C) 2001 Elsevier Science Ltd. All rights reserved.

802: +.111

The Critically Endangered Antigua racer *Alsophis antiguae* is confined to Great Bird Island, a 9.9-ha (24.5-acre) islet off the north-east coast of Antigua in the Lesser Antilles. This island represents well under 0.1 per cent of the species's historical distribution range. During the past 5 years, the total number of racers aged 1 year or more has fluctuated between 51 and 114, and currently stands at approximately 80. Since 1995, the Antigua Racer Conservation Project (ARCP) has endeavoured to save this harmless snake from extinction by using a combination of education, conservation breeding, habitat restoration, local capacity building and applied research. The Antigua racer's ecology and population dynamics have become well understood after 5 years of intensive study, and the species has evidently benefited from the project's rat eradication programme. The snakes are still seriously threatened by other intrinsic and extrinsic factors, however, including inbreeding depression, frequent hurricanes, invasive predators and deliberate killing by tourists, as well as the problem that Great Bird island is too small to support more than about 100 individuals. This paper describes the activities and impact of this project to date, and outlines a series of conservation activities to safeguard the long-term future of the species, which include reintroduction of the Antigua racer to restored islands within its former distribution range.

803: +.092

Mountain gazelles were reintroduced to central Arabia during 1991-95. Hawtah reserve was searched for gazelles during the 1998-99 winter. Gazelles were seen in one wadi system and their signs were found in several others and on the plateau. Sightings were used to calculate the minimum number of gazelles in the Matham wadi system, which previously held most of the population. During October-November 1998, the minimum number was 64 per cent less than 4 years earlier. Frequent observation of recent signs in areas where no gazelles were seen suggested that daytime sightings alone were no longer adequate for monitoring this population. The decline in the number of gazelles seen, an increase in their flight distance and an apparent change in their activity patterns were consistent with the rangers' claim that poaching had commonly occurred. Poaching started after reserve management built, without adequate consultation, a new fence that was intended to bar local people from part of the reserve. Management lessons include the need for the following: continued monitoring of reintroduced populations after the initial postrelease phase; long-term dialogue with local people; effective law enforcement; and the management of aridland domestic livestock in ways that prevent inter specific competition for food causing the elimination of wild ungulates.

804: +.041

The endangered red-cockaded woodpecker (*Picoides borealis*), a nonmigratory, cooperatively breeding species limited to the older-growth pine forests of the southeastern United States, requires living pine trees for cavity excavation. Since the 1950s, alteration and destruction of critical woodpecker habitat have caused a decline in red-cockaded woodpecker populations. The red-cockaded woodpecker now exists mostly in small, scattered populations whose respective members have little opportunity to interbreed. In general, as populations become smaller and more isolated, the frequency of inbreeding increases and genetic diversity and population viability may decrease. The introduction of unrelated individuals into disjunct red-cockaded woodpecker populations may reduce inbreeding, maintain genetic variability, and reduce local extinction. We developed a technique for selecting red-cockaded woodpecker nestlings and transferring them into the nests of unrelated conspecifics. For each translocation, we paired nests of the same age and exchanged 1 nestling from each, so that 2 introductions were made with reciprocal translocation event. Nest visitation by the parents and fledging success of nestlings were monitored. Fostered nestlings were

accepted by their new parents, and the rate of successful fledging by fostered nestlings was not different from that of nonfostered control nestlings. We concluded that reciprocal intraspecific fostering of similarly aged nestlings can be used safely and effectively to translocate red-cockaded woodpeckers and may have advantages over the translocation of adults and juveniles under certain conditions.

805: +.010

Variation in mitochondrial DNA (mtDNA) was surveyed, using restriction endonucleases, in the white-clawed crayfish, *Austropotamobius pallipes lusitanicus*, from 14 populations sampled in Spain. Four additional samples from France (1), Slovenia (1) and Italy (2) were also analysed. Among the 11 haplotypes listed, only one was detected from the 154 animals sampled from Spanish populations. This haplotype was also recorded in the Fosso di Ferfereta population (Italy). Estimates of nucleotide sequence divergence among haplotypes ranged from 0.45% to 17.4%. Interpopulational genetic relationships showed that Spanish populations were closely related to those of Fosso di Ferfereta with a small genetic distance (0.0003) found between them. AMOVA revealed that most of the genetic variance (71.97%) was attributed to variation between European regions. These results are in accordance with a drastic bottleneck event during the history of the Spanish populations. Four suggestions, based on human introduction, selection and recent or ancient historical events are discussed in relation to the lack of genetic variation in the Spanish crayfish stock.

806: +.252

Peregrine Falcons (*Falco peregrinus*) of seven subspecies from four continents were bred in captivity, and approximately 1173 of their progeny were released in the midwestern United States and adjacent regions of Ontario and Manitoba in an attempt to replace the original population that was extirpated by chlorinated hydrocarbon poisoning in the 1950s. We analyzed the success of individuals of the different subspecies introduced to the Midwest. Five of the seven subspecies released have contributed to the current breeding population. Subspecies of breeding Peregrine Falcons were equally represented when breeding birds of high productivity were compared with less prolific breeders. The subspecific makeup of the breeding population did not differ significantly from that of the released population, suggesting that adaptability in this species was sufficient to override genetic differences between subspecies. Peregrines of widely different genetic stocks have thrived after release, making substantial genetic contributions to the new population.

807: +.085

The endangered Hawaiian monk seal breeds at six locations in the northwestern Hawaiian Islands. To determine whether significant genetic differentiation exists among these sites, we used microsatellite loci to examine the monk seal population structure at the five largest breeding colonies. Of 27 loci isolated from other seal species, only 3 were polymorphic in an initial screening of one individual from each breeding site. Only two alleles were found at each of these 3 loci in samples of 46-108 individuals. This extremely low variation is consistent with other measures of genetic variability in this species and is probably the result of a recent severe population bottleneck, combined with a long-term history of small population sizes. Although the smallest monk seal subpopulation in this study (Kure Atoll) showed some evidence of heterozygote deficit, possibly indicative of inbreeding, the next smallest (Pearl and Hermes Reef) had an apparent excess of heterozygous individuals. Genetic differentiation was detected between

the two subpopulations at extreme ends of the range (Kure and French Frigate Shoals). This trend was significant only at the microsatellite locus for which we had the largest sample size ($Hg6.3: R-ST = 0.206, p = 0.002$; allelic goodness of fit $G(h) = 15.412, p < 0.005$). French Frigate Shoals is the source population for translocated animals that have been released primarily at Kure Atoll. Differentiation between these sites consisted of allele frequency differences (with the same allele predominant in each location at all three loci), rather than the preservation of alternative alleles. Although the translocations have had positive demographic effects, we recommend continued genetic monitoring of both the source and recipient populations because translocated individuals are now entering the breeding population.

808: +.161

Global climate change is frequently considered a major conservation threat. The Earth's climate has already warmed by 0.5 degrees C over the past century, and recent studies show that it is possible to detect the effects of a changing climate on ecological systems. This suggests that global change may be a current and future conservation threat. Changes in recent decades are apparent at all levels of ecological organizations: population and life-history changes, shifts in geographic range, changes in species composition of communities, and changes in the structure and functioning of ecosystems. These ecological effects can be linked to recent population declines and to both local and global extinctions of species. Although it is impossible to prove that climate change is the cause of these ecological effects, these findings have important implications for conservation biology. It is no longer safe to assume that all of a species' historic range remains suitable. In drawing attention to the importance of climate change as a current threat to species, these studies emphasize the need for current conservation efforts to consider climate change in both in situ conservation and reintroduction efforts. Additional threats will emerge as climate continues to change, especially as climate interacts with other stressors such as habitat fragmentation. These studies can contribute to preparations for future challenges by providing valuable input to models and direct examples of how species respond to climate change.

809: +.143

Symphotrichum laurentianum, the Gulf of St. Lawrence Aster, is an endemic aster of Prince Edward Island, New Brunswick, and the Magdalene Islands. It is considered by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) to be of special concern in Canada and to be critically imperiled in Prince Edward Island. One goal of this study was to test germination to clarify the relationship between dormancy and germination in this species. Seeds germinated in culture media had an overall mean percent germination of 68.37% whereas seeds germinated in soil had an overall mean percent germination of 17.38%. Kinetin supplements positively affected germination rates. However, these kinetin supplements eventually led to abnormal morphological development in *S. laurentianum* seedlings. Cold treatments had no significant effects on the percent germination of *S. laurentianum* seeds. Micropropagation of this type of explant and reintroduction should therefore be considered by Prince Edward Island as potential techniques for the conservation of *S. laurentianum* on Prince Edward Island. A complementary goal of this study was to survey the Blooming Point and Covehead sites to update the population statuses of *S. laurentianum* within the Prince Edward Island National Park. The size of the *S. laurentianum* population at Covehead Pond during 1999 was very similar to the population size at this site in 1993. Population sizes showed more fluctuation at Blooming Point between 1993 and 1999. No asters were found in the East Marsh in 1999; however, there was a large increase in population numbers at the Dune Slack site. Seeds of *S. laurentianum* appear to respond well to tissue culture. Annual monitoring of *S. laurentianum* populations should also occur to ensure appropriate

management of this species on Prince Edward Island.

810: +.324

We present a case study on the differing roles of temperate and tropical ex situ facilities in supporting the conservation of a major tropical plant group. The conservation value of botanic garden palm collections is reviewed by using (1) survey data from 35 collections in 20 countries, and (2) case studies examining the conservation value and utility of botanic garden palm collections for selected species. The collections surveyed hold a total of 902 palm species from 169 genera, representing 33% of global species diversity and 84% of generic diversity. The collections hold 77 (34%) of the 222 IUCN/Species Survival Commission (SSC) listed threatened palms. Recommendations are presented on the effective role of botanic garden palm collections in light of both the Convention on Biological Diversity and the IUCN/SSC Palm Action Plan. It is concluded that temperate botanic garden collections do not adequately reflect palm conservation priorities and that a range of genetic and logistical constraints precludes repatriation and reintroduction, and accordingly, reduces their direct contribution to species recovery. The most effective application of ex situ conservation is in-country and linked with habitat conservation. We, therefore, recommend that temperate palm collections direct investments, in terms of displays and fund-raising, towards supporting in-country conservation activities in the tropics. 811: +.119

The successful removal of rodents from islands around New Zealand has enabled translocation of rare species of lizards to new sites within their former range. Four species of skinks were translocated to Korapuki Island, Mercury Islands, New Zealand: *Cyclodina alani*, *C. oliveri*, *C. whitakeri* and *Oligosoma suteri*. Responses of three of the lizard species to release were predicted using a deterministic population model then compared with the actual performance of wild populations. The population models predicted that if populations of about 30 *C. whitakeri* and *O. suteri* were released, *C. whitakeri* would be increasing by 7% p.a. and *O. suteri* would be increasing by over 35% p.a. during year five. If 20 *C. alani* were released, the population could be increasing by 70% p.a. during year five. Population expansions are being recorded for all three species, but observed population increases were lower than those predicted for two species, partly because of low catchability of immature lizards. The lowest rate of increase (up to 7% p.a.) was for *C. whitakeri*. Low rates of population expansion found in species such as *C. whitakeri* raise a conundrum: the rarer a species is, and the lower its annual reproductive output, the larger the number of individuals that may be required for translocations to succeed. Translocations may be regarded as successful when new populations are self-sustaining and comprised only of locally born animals. Despite the populations increasing, it may not be possible to claim success for the three intensively studied species on Korapuki Island until at least 20 years after release. This is because of longevity of the founders, which are still being caught up to 12 years after release. Extreme longevity, and hence prolonged post-release monitoring, is likely to be a recurrent problem for translocations of rare lizards. © 2001 Elsevier Science Ltd. All rights reserved.

812: +.055

Desert bighorn sheep (*Ovis canadensis mexicana*) became extinct in Texas, U.S.A., during the 1960s and reintroduction efforts have resulted in an extant population of about 300 free-ranging animals. We studied diet preferences of reintroduced desert bighorn sheep in three mountain ranges in western Texas, U.S.A., during 1994-1995. We predicted that botanical composition and

species richness of diets of reintroduced male and female desert bighorns differ when sexes are segregated, but are similar during portions of the year when sexes are aggregated. There were few consistent differences in diet composition between sexes. Species richness of diets of male bighorns was greater than for females. Forbs were highly preferred by both sexes but forb biomass was less than 1 kg ha⁻¹ in all seasons. Drought and impacts of historical livestock grazing on vegetation may have masked diet partitioning by sex. (C) 2001 Academic Press.

813: +.303

1. The Mauritius kestrel *Falco punctatus* (Temminck 1823) has recovered from very low numbers. In order to evaluate the severity of the population bottleneck that it experienced, we have developed a method for estimating the productivity of the nests that escaped detection. This method uses ringing records for MCMC estimation of parameters describing the recruitment of adults to the breeding population and the growth in productivity of undiscovered nests. 2. Comparison of the estimates for the two restored populations (eastern and western) showed a far lower proportion of undiscovered nests in the former, as predicted because of widespread use of nestboxes. This served to verify the method of estimation. The estimates show a steady increase in population size, in contrast with field estimates indicating a recent reduction in growth. 3. The results suggest that the alarmingly low estimates of population size in 1974 (two breeding pairs) were accurate, and that few undiscovered nests existed during the bottleneck. 4. The recovery of the population seems to have been initiated by the intensive conservation effort. The most rapid period of population growth coincides with the reintroduction programme. The results imply that the eastern population is much more reliant on intensive management for its future growth.

814: +.183

Plant diversity in Indian subcontinent is under threat mainly due to human activities and reproductive isolation of the species. It is estimated that 15-20 per cent of our vascular flora i.e. about 2,500 species of plants are under various degrees of threat of which about 1,000 species are native to tropical and subtropical regions of the country. The increasing loss of plant diversity has turned the attention of various agencies to take the immediate conservation measures and save it from further depletion and extinction. Besides protection of species in-situ, the off-site (ex-situ) conservation of species particularly of those which are rare and endangered, has become an important tool for conservation of biological diversity. Considering the urgency for conservation of plant diversity we have taken up the task of ex-situ conservation of some tropical and subtropical threatened plant species of India in the N.B.R.I. Botanic Garden. The main aim of this work is to acclimatise, cultivate, propagate and multiply such taxa under ex-situ condition and subsequently reintroduce them to natural or semi-natural habitats together with maintenance of the species ex-situ in the botanic garden.

815: +.165

Since a review of the management of the critically endangered kakapo (*Strigops habroptilus*) in 1994, management of this species has become more intensive. This paper reports on new developments in the supplementary feeding of kakapo, continuous monitoring and protection of nests from predators, translocations of kakapo between islands, and artificial incubation of eggs and hand-raising of chicks. Supplementary feeding probably increases chick survival especially when natural food supplies fail. It may also increase breeding frequency, either by triggering breeding, or raising kakapo above a nutritional threshold. Protection of nests from predators has eliminated rat predation of eggs and chicks, and continuous monitoring and rebuilding of poor nest

sites has improved kakapo nesting success. Recent translocations of kakapo between islands have aimed to prevent possibly infertile males from mating, facilitate supplementary feeding, improve the breeding prospects of some birds, test the suitability of a new island for kakapo, and facilitate the eradication of rats. Eggs have been artificially incubated and chicks hand-raised in an attempt to establish a captive population of hand-raised birds, to rescue sickly and unthrifty chicks, and to forestall likely nest failures. (C) 2001 Elsevier Science Ltd. All rights reserved.

816: +.116

It is in the nature of today's world that interventionist, rather than protectionist, management strategies are likely to be in greater demand, because an enormous area of the earth's habitable surface has already been transformed by human action. [Holdgate, M.W., 1986. Summary and conclusions: characteristics and consequences of biological invasions. In: Kornberg, H., Williamson, M.H. (Eds), Quantitative aspects of the ecology of biological invasions. The Royal Society, London, pp. 733-742] Progress with ecological restoration in New Zealand is reviewed. A useful goal for restoration is that of rebuilding, as far as possible, the evolutionary and ecological context of species in the system, i.e. reinstating earlier selection regimes. Opportunities for restoring biological components of these regimes are greater than those available for restoring physical conditions. In this country, effective ecological restoration is not possible without control or eradication of introduced mammals. Descriptive models of systems to be restored are also a necessity for achieving goals. A particular problem is that caused by past extinctions of animal species. Replacement of some extinct species, within particular trophic guilds, with ecologically appropriate and related extant species, is suggested as a possible response to this problem. (C) 2001 Elsevier Science Ltd. All rights reserved.

817: +.047

The avifauna of New Zealand has been severely depleted since human colonisation and currently contains a disproportionately high number of threatened species. Of the 23 threatened shorebird species worldwide, six are endemic to New Zealand. We review the status of New Zealand's endemic shorebirds and examine the impact on them of various threats, particularly predation by introduced mammals. The conservation status of the 10 extant species (three oystercatchers, one stilt, four plovers and two snipe) is outlined and the factors that predisposed them to predation by introduced mammals are summarised. Individual species accounts are presented, including data on population trends, known or suspected impacts of predation, identification of important predator species, other threats, and conservation measures currently in place or required. One species and two subspecies are extinct, three species are confined to predator-free islands and another is found only on the Chatham Islands group. Six survive on the mainland but three have declined to varying degrees and are assigned threatened status by Collar et al. (1994). Only one plover and two oystercatchers are still relatively numerous and/or widespread. Rats, cats and mustelids have had the greatest overall impacts. Conservation measures in place to mitigate the effects of introduced predators include the formulation of recovery plans, predator control around breeding areas, captive breeding and rearing programmes and the founding of new populations by translocation. There are often substantial differences in susceptibility to predation of closely related or ecologically similar taxa, and we stress the importance of basing conservation management decisions on relevant and detailed demographic and ecological studies. The main threat to threatened shorebirds elsewhere in the world is loss or degradation of habitat; the disproportionate impact of mammalian predators on New Zealand shorebirds is unusual but not unique. (C) 2001 Elsevier Science Ltd. All rights reserved.

818: +.160

Microhabitat use studies of translocated species are crucial to assess their adaptation to the new environment. A total of 42 St Lucia whiptail lizards (*Cnemidophorus vanzoi*), an endemic to two islets (Maria Major, 10.2 ha and Maria Minor, 1.8 ha) off St Lucia in the Lesser Antilles, were translocated from Maria Major to Praslin Island (1.1 ha) in 1995. Three years after the release, we studied the abundance, density and distribution of the translocated lizard population in the prevailing five habitat types on the island. Habitats varied from more exposed open grasslands to tall, continuously canopied woodlands. Although lizards were distributed throughout the island, some habitats were used more than predicted with respect to availability. Habitat utilization showed a seasonal shift in distribution. Line transect sampling estimated a population of 145 +/- 23 lizards on Praslin Island. There were significant seasonal differences in estimated lizard abundance indicating a change in activity during the dry season. Lizard density was significantly correlated with general habitat characteristics, rather than with any specific microhabitat variable measured. Factors affecting distribution (thermoregulation, food resources and competitive exclusion) are discussed and it is suggested that habitat use during the dry season may be best explained by thermal constraint. These results will help managers choose future translocation sites.

819: +.212

The benefits of monitoring habitat use patterns of translocated populations are widely acknowledged. However, this monitoring seldom occurs. Here, I report the habitat use and foraging patterns of a newly translocated population of South Island saddlebacks (*Philesturnus carunculatus carunculatus*) on Motuara Island, New Zealand, during the 1st breeding season after release. Reintroduced South Island saddlebacks spent most foraging time on the ground and in *Pseudopanax arboreus*. Foraging substrates used by male and female saddlebacks differed significantly. Saddlebacks focused foraging activities at 0-4 m above ground, and appeared to prefer to forage in larger trees, although the species composition of forested areas did not seem to influence the birds' choices of places to settle. With increasing population density, saddlebacks on Motuara Island may increase their areal foraging efficiency by using a wider range of plant species, vertically stratifying foraging locations within pairs, increasing use of smaller trees for foraging, and possibly by using scrub habitats more extensively. South Island saddlebacks appear to be highly adaptable in their choice of foraging sites and this plasticity may enhance the success of translocations.

820: +.304

Native unionid mussel populations have recently declined throughout North America as a result of zebra mussel (*Dreissena polymorpha*) fouling. Periodic cleaning of fouled unionids and cleaning followed by translocation have been suggested as methods for reducing mortality. *Leptodea fragilis* and *Potamilus alatus* were used to determine survival, recovery of energetic stores, and accumulation of newly settled zebra mussels after cleaning and replacement in situ. Both species had high survival, and *L. fragilis* increased energetic stores after cleaning. *Elliptio complanata* and *Lampsilis radiata* were used to compare conservation strategies for unionids fouled by zebra mussels. Survival and glycogen content were used to evaluate stress induced by cleaning and replacement in situ, cleaning and translocation, and cleaning, quarantine, and translocation, relative to the stress in fouled unionids and control (never fouled) unionids. New zebra mussel settlement was assessed to estimate the frequency of cleanings needed. Cleaned *E. complanata* and *L. radiata* maintained significantly higher glycogen levels and had higher survival than fouled unionids in all treatments; however, 30% of *L. radiata* died while in quarantine but no *E.*

complanata died. Translocated unionids were difficult to relocate in the riverine refugium. The inability to find translocated unionids, coupled with high survival and energetic stores in cleaned and replaced unionids, indicate that cleaning and replacement is an effective conservation strategy. Cleaning and replacement may be used as the 1st step to conserve small populations of fouled unionids living in environments where food is not limiting and where collection and cleaning are logistically feasible.

821: -.028

Reintroduced houbara bustards (*Chlamydotis [undulata] macqueenii*) in a large, fenced reserve in central Saudi Arabia are subject to predation pressures from mammalian carnivores. From 1993 to 1997 a total of 98 Arabian red foxes (*Vulpes vulpes arabica*) and 56 Ruppell's foxes (*Vulpes ruppelli sabea*) were translocated away from houbara reintroduction sites in a predator control exercise. Translocation distances varied from 15 to 150 km and both species showed the same likelihood of return and recapture (ca. 12%). No fox of either species was recorded as having returned from translocation distances in excess of 150 km. Red fox return appeared to be related to distance translocated up to 150 km, but this was not the case for Ruppell's fox. In this trial, translocation was not found to be a time-effective tool to reduce predation. (C) Academic Press.

822: -.134

1. In recent decades, the Eurasian lynx *Lynx lynx* has recolonized former habitat, bringing it into potential conflict with livestock. We studied the spatial and temporal distribution of lynx attacks on sheep in the French Jura between 1984 and 1998, during and after its population expansion. We estimated the local and regional impact of lynx predation on livestock. 2. The number of attacks increased from three in 1984 to 188 in 1989, concurrently with the colonization of the main sheep range by lynx. During subsequent years, 66-131 attacks were recorded annually (92-194 sheep killed per year). 3. On average, 1.6 sheep were killed per attack. Lynx preyed disproportionately on lambs and subadult sheep. A small percentage of flocks (9.5-22.9%) were attacked, most of which (75.2%) were attacked once or twice a year. At the regional level, annual sheep losses to lynx were 0.14-0.59% of the total number of sheep. 4. The major lynx-livestock problem was due to clustered attacks in a few small areas. Each year, two to six 'hot spots' (33-69% of the attacks) were identified. Hot spots covered 0.3-4.5% of the total area where attacks occurred (1835-4061 km²). Roe deer abundance was higher in hot spots and, even here, sheep only made up 3.1% of the lynx diet. These data show that lynx were not killing sheep due to shortages of alternative prey or in response to an increased need for food when rearing young. 5. The concentration of hot spots in only nine small areas between 1984 and 1998 indicated that only a few individual lynx were involved. The reappearance of hot spots at the same sites, after years of interruption and despite the removal of lynx, suggested that the ultimate factors causing hot spots were factors inherent to those sites. Further investigation is needed to identify causal factors with a view to eliminating them. These may relate to landscape features, animal husbandry practices or the behavioural ecology of lynx. 6. In future, where large predator reintroductions are planned, the potential for concentrated, localized, impact should be evaluated and mitigation measures put in place. For scattered and episodic lynx damage, financial compensation is the only realistic option at present. In hot spots, the cost-effectiveness of guard-dogs or the selective removal of some individual lynx should be evaluated.

823: +.107

Regulated river restoration through planned flooding involves trade-offs between aquatic and

terrestrial components, between relict pre-dam and novel post-dam resources and processes, and between management of individual resources and ecosystem characteristics. We review the terrestrial;(wetland and riparian) impacts of a 1274 m³/s test flood conducted by the U.S. Bureau of Reclamation in March/April 1996, which was designed to improve understanding of sediment transport and management downstream from Glen Canyon Dam in the Colorado River ecosystem. The test flood successfully restored sandbars throughout the river corridor and was timed to prevent direct impacts to species of concern. A total of 1275 endangered Kanab ambersnail (*Oxyloma haydeni kanabensis*) were translocated above the flood zone at Vaseys Paradise spring, and an estimated 10.7% of the total snail habitat and 7.7% of the total snail population were lost to the flood. The test flood scoured channel margin wetlands, including potential foraging habitats of endangered Southwestern Willow Flycatcher (*Empidonax traillii extimus*). It also buried ground-covering riparian vegetation under >1 m of fine sand but only slightly altered woody sandbar vegetation and some return-current channel marshes. Pre-flood control efforts and appropriate flood timing limited recruitment of four common nonnative perennial plant species. Slight impacts on ethnobotanical resources were detected > 430 km downstream, but those plant assemblages recovered rapidly. Careful design of planned flood hydrograph shape and seasonal timing is required to mitigate terrestrial impacts during efforts to restore essential fluvial geomorphic and aquatic habitats in regulated river ecosystems.

824: +.020

Captive breeding and reintroduction programs are rarely evaluated, and assessment criteria vary widely. We used the following criteria to evaluate a bighorn sheep (*Ovis canadensis*) augmentation program: (1) survival and recruitment rates in the captive population, (2) survival of released animals, (3) recruitment of released animals (4) growth rate of the reintroduced or augmented population, and (5) establishment of a viable wild population. Captive bighorn survival and recruitment was high, averaging 0.98 (SD = 0.05) and 71.0% (SD = 19.4), respectively. Annual survival of free-ranging captive-reared bighorn (n = 73, (x) over bar = 0.80 SD = 0.11) did not differ (Z = -0.85, p = 0.40; n = 14) from survival of wild-reared bighorn (n = 43, (x) over bar = 0.81, SD = 0.12). Recruitment was unusually low for both captive-reared ((x) over bar = 13.7%, SD = 0.24) and wild-reared ewes ((x) over bar = 13.7%, SD = 0.20). Although reintroduction did not result in population growth or establishment of a viable population, it helped prevent extirpation of the reinforced deme, preserved metapopulation linkage, and aided habitat preservation. Chronic low recruitment and low adult survivorship precluded achievement of criteria 3-5. Environmental conditions in the release area also appeared to hinder program success. Standard evaluation criteria for ongoing reintroductions allow for informative assessments and facilitate comparisons needed to refine reintroduction science as a recovery tool for threatened or endangered populations.

825: +.114

New World parrots are declining throughout their range. Blue and Gold Macaw *Ara ararauna* was extirpated from the island of Trinidad in the late 1960s through anthropogenic processes. The Cincinnati Zoo & Botanical Garden is assisting the Wildlife Section of the Forestry Division, Trinidad on a mission to restore the species into its historical range within the Bush-Bush Sanctuary in the Nariva Swamp. The Sanctuary has been protected by the government of Trinidad and is the home of the endangered Red-bellied Macaw *Ara manilata* and West Indian Manatee *Trichechus manatus*. Zoo and Wildlife personnel participated in three separate releases, beginning in December 1999 through to March 2000. The initial release consisted of an identical sex group of macaws followed by two additional releases of pairs/groups of birds. Of 18 Blue and Gold

Macaws, 14 were released into the Nariva Swamp and are currently being monitored by the Wildlife Section, Zoo personnel and surrounding community. Translocation of wild populations of parrots has proven to be a viable solution to restocking wild populations that have been regionally extirpated.

826: -.065

River engineering work has historically been responsible for the decline and extinction of a number of endangered freshwater pearl mussel [*Margaritifera margaritifera* (L.)] populations and potentially remains a significant threat. The impact of different types of river engineering work on a number of Scottish *M. margaritifera* populations is examined and discussed. *M. margaritifera* is now fully protected under law in most countries and guidance is urgently needed so that river managers can integrate ecological and socio-economic factors when considering the impact of proposed activities on *M. margaritifera* populations. To safeguard the remaining important populations, a simple conflict resolution framework is suggested for the appraisal of proposed developments in rivers with pearl mussel populations. Operations likely to harm mussels and permanently damage their river bed habitat should not proceed. In exceptional circumstances (outlined), the translocation of small numbers of adult mussels may possibly be considered as a potential management tool, but mussel translocation has been little used and should be considered experimental and last resort. 827: +.286

Instances of range contraction and population decline in bird species in Europe are more common than cases of recovery following decline. Here we report on the recovery and expansion processes of an endangered bird species in Europe, the purple swamphen (*Porphyrio porphyrio* L., Rallidae), with special reference to the Iberian Peninsula, its main distribution area in Western Europe. After a drastic decline during the first half of the 20th century, which restricted its range to a few areas in southern Spain, the Iberian population has recovered. Currently, the species occurs in a range similar to the one it had at the beginning of the 20th century, and has even colonized new areas. These processes seem to be the result of both human-mediated (effective protection of the species and suitable habitats; success of reintroduction programs as expansion focuses of birds colonizing nearby and distant regions [> 300 km] wetlands) and natural factors (inter- and intra-seasonal cycles of wet and dry years). Thus, we found a significant relationship between rainfall and bird abundance and productivity, suggesting that such inter- and intra-seasonal cycles may have significant effects on demographic parameters that could be related to the expansion process. Finally the species shows remarkable adaptability, as proven by data on breeding success in recently colonized areas and the ability to breed shortly after reintroduction. We hypothesize that saturation of breeding habitats in established areas, a reasonable habitat continuity and favorable environmental conditions, and protection have facilitated the dispersion of birds.

828: +.041

In the XIX century the Ruddy Shelduck was regarded as a common species in Ukraine. Now it is in the Red Data Book of Ukraine and on the Berne Convention List. In 1885 it appeared in the Ascanian Zoo, and a year later there were 16 birds. Nowadays, in the summer and autumn their numbers range from 700 to 1200. The territorial centre of the population are the zoo ponds and the botanical garden, where 48-65 pairs nest. This semi-wild population has been formed as a result of successive acclimatization measures: forming broods with foster parents (*Tadorna ferruginea*, *Cairina moschata*, *Anas platyrhynchos*), creating artificial nests, regular feeding, and the

availability of unfrozen water in the pond. Free-living birds migrate from Ascania Nova to other places, even to distant regions.

829: +.039

Reintroduction of populations of endangered species is a challenging task, involving a number of environmental, demographic and genetic factors. Genetic parameters of interest include historical patterns of genetic structure and gene flow. Care must be taken during reintroduction to balance the contrasting risks of inbreeding and outbreeding depression. The Mauna Loa silversword, *Argyroxiphium kauense*, has experienced a severe decline in population size and distribution in the recent past. Currently three populations with a total of fewer than 1000 individuals remain. We measured genetic variation within and among the remnant populations using seven microsatellite loci. We found significant genetic variation remaining within all populations, probably related to the recent nature of the population impact, the longevity of the plants, and their apparent self-incompatibility. We also found significant genetic differentiation among the populations, reinforcing previous observations of ecological and morphological differentiation. With respect to reintroduction, the results suggest that, in the absence of additional data to the contrary, inbreeding depression may not be a substantial risk as long as propagules for the founding of new populations are adequately sampled from within each source population before additional inbreeding takes place. The results further suggest that if mixing of propagules from different source populations is not required to increase within-population genetic variation in the reintroduced populations, it may best be avoided.

830: -.041

Habitat loss and fragmentation affect forest birds through direct loss of breeding habitats, detrimental edge effects such as increased nest predation and brood parasitism, and possibly by limiting movements among remaining forest patches. Despite indirect evidence suggesting that landscape-scale bird movements are constrained by open areas, skepticism remains because birds routinely cross inhospitable terrain during migration. Here, we report evidence from 201 independent homing trials showing that landscape composition and configuration influence the movements (1-4 km) of two neotropical migrant (Black-throated Blue Warbler, *Dendroica caerulescens* and the Ovenbird, *Seiurus aurocapillus*) and one resident (Black-capped Chickadee, *Poecile atricapillus*) forest bird species in Quebec, Canada. Trials consisted of translocating territorial, mated males and measuring the time they needed to return to their territories (homing time), as well as the probability with which they returned to their territories within 30 h (homing success). Birds took more time and were less likely to return to their territories as forest cover decreased in the landscape. Once the simple linear variation due to forest cover was removed from landscape configuration variables, their influence on homing time and success was nonexistent or subtle, suggesting that landscape composition has greater predictive value than landscape configuration to infer constraints on forest bird movements. Indeed, and contrary to our expectation, mean nearest-neighbor distance between forest patches had no impact on homing time or success, but its coefficient of variation was positively correlated with homing time and negatively correlated with homing success. On the other hand, homing time and success were not influenced by the number of forest patches or the amount of edge per unit of forest cover. These results were consistent for all three bird species that we studied. Our data support the hypothesis that movements are constrained when forest birds travel in deforested and fragmented landscapes outside migratory periods. Such an impediment is likely to disrupt habitat selection processes, reduce the colonization of isolated forest patches, and ultimately, alter population structure and dynamics.

831: -.036

In order to detect the evolutionary potential of two endangered species, *Brassica insularis* (Brassicaceae) and *Centaurea corymbosa* (Asteraceae), within and among-population genetic variation for both quantitative traits and allozymic markers was examined. Four populations of each species were studied, representing a large proportion of extant populations. High values of theta (ST) (0.213 and 0.364 for *B. insularis* and *C. corymbosa* respectively) suggested that low amounts of gene flow occur among the study populations. In each species, the genetic distance based on allozymes (estimated by the ratio $(\theta(ST)/1-\theta(ST))$) was positively correlated with the geographical distance, indicating isolation by distance. In contrast to previous studies in either outcrossing or selfing plant species, and especially for *B. insularis*, population differentiation for quantitative traits (theta (ST)) was generally found lower than differentiation for allozymes (theta (ST)), suggesting that the populations studied were experiencing similar selective forces acting upon the quantitative traits measured. Such forces would be strong enough to counteract local genetic drift. Interestingly, for both species theta (ST)'s were statistically independent of geographical distance, in contrast to the marginally significant positive isolation by distance shown by theta (ST). Altogether, these results suggest that theta (ST)'s might not always be used as conservative estimates of $Q(ST)$'s, and might instead overestimate the evolutionary potential of endangered species. This would be especially expected in narrow-endemic species, whose ecological niche is often so restricted that indeed homogeneous selective forces are likely to occur, whereas small population sizes and restricted dispersal are likely to produce strong differentiation for neutral variation. In fact, knowledge of both neutral and quantitative diversity patterns allows identification of those traits undergoing natural selection, and could be useful in designing reinforcement or reintroduction programs. However, this approach might have limitations too, in the presence of outbreeding depression due to locally coevolved gene complexes, (C) 2001 Elsevier Science Ltd. All rights reserved.

832: -.091

The freshwater fish Banded Grunter *Amniataba percoides* is endemic to northern Australia, and this paper is the first record of the species from New South Wales waters. Six specimens (range total length, 43.5-144.6 mm) were collected from the Clarence River near Grafton. The identification of a Banded Grunter in a consignment of Silver Perch *Bidyanus bidyanus* fingerlings from a commercial hatchery in Queensland implicates aquaculture in the translocation of this species. Banded Grunter is a hardy, aggressive, omnivorous fish that is known to disperse rapidly over large distances to a wide range of habitats, and the establishment of a population in the Clarence river system may pose a serious threat to the endemic fauna, including the endangered Eastern Freshwater Cod *Maccullochella ikei*. Because of the potential threat of Banded Grunter, it has been declared a noxious fish under the New South Wales Fisheries Management Act.

833: -.055

The Stock Island tree snail, *Orthalicus reses reses*, went extinct in its native range in the Florida Keys in 1992. Fortunately, *O. r. reses* has been introduced elsewhere and further reintroductions are currently planned. Before these reintroductions are implemented, it is important to try and determine which factors were most likely to have caused the decline and extinction. While habitat destruction was probably the ultimate reason why there were so few tree snails, it is likely that an interaction of habitat fragmentation and the invasion of an exotic predator caused the final decline that led to the extinction in 1992. We examined the last 93 *O. r. reses* shells to infer cause of death. In addition, using surrogate Florida tree snails, *Liguus fasciatus*, we conducted experiments

on two previously unstudied causes of mortality: predation by red imported fire ants, *Solenopsis invicta*, and mortality from falls caused by wind. We found that the majority of the last *O. r. reses* shells were intact, indicating that mammalian and bird predation were not the greatest causes of mortality. Mortality caused by wind knocking tree snails onto the rocky hammock substrate appeared to be a potential source of mortality, but few of the tree snails exhibited signs of breakage. Mortality from fire ants appears to be one of the most likely causes of the recent decline and extinction of *O. r. reses*. Experiments indicated that in a semi-natural enclosure, fire ants were capable of killing all ages of *L. fasciatus*, even during aestivation. Fire ants are currently found throughout the last known habitat of *O. r. reses* and were first discovered in this area at the time of the decline.

834: -.152

The identification of taxonomically appropriate Populations of endangered species for captive breeding and reintroduction programs is fundamental to the success of those programs. The Saudi gazelle (*Gazella saudiya*) was endemic to the Arabian peninsula but is now considered extinct in the wild and is potentially a candidate for captive breeding and reintroduction. Using 375 base pairs of mitochondrial DNA (mtDNA) cytochrome b gene derived from museum samples collected from the wild prior to the presumed extinction of this species, we show that *G. saudiya* is the sister taxon of the African dorcas gazelle (*G. dorcas*). Reciprocal monophyly of *G. saudiya* mtDNA haplotypes with *G. dorcas*, coupled with morphological distinctiveness, suggests that it is an evolutionarily significant unit. These data indicate that captive populations identified previously as potential sources of *G. saudiya* for captive breeding appear incorrectly designated and are irrelevant to the conservation of *G. saudiya*. The polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis of several private collections of living gazelles in Saudi Arabia provides no evidence for the survival of *G. saudiya*. We recommend that field surveys be undertaken to establish whether *G. saudiya* is indeed extinct in the wild and that other private collections within the Arabian peninsula be screened genetically. We urge caution when captive animals of unknown provenance are used to investigate the phylogenetics of cryptic species groups.

835: +.164

Since 1954, several southern African institutions have established captive breeding programs to ensure the long-term survival of the African wild dog (*Lycaon pictus*). To aid this, a studbook was assembled to provide genetic and demographic information for the southern African captive populations, comprising the largest existing regional population of captive African wild dogs. These populations were investigated over three time frames: during 1985-1990, during 1991-1996 and populations alive in January 1997. The captive-breeding programme is successful with a positive population growth, a significant lowering of inbreeding and mean kinship and an increased genetic diversity. However, genetic variability levels appear lower and levels of inbreeding appear higher compared with wild populations. In addition, there have been no successful long-term re-introductions into the southern African wild using captive-bred dogs, mainly due to the lack of close collaboration between captive breeding and nature conservation institutions. The ultimate success of a conservation programme not only depends on proper demographic and genetic management of the captive population, but primarily on the successful collaboration of all scientific, captive breeding and conservation agencies involved. 836: -.014

Although the rarity of an endangered plant species can seldom be ascribed to its breeding system, knowledge of its breeding system may be critical to its recovery. The federally listed endangered *Ziziphus celata* (Florida ziziphus), a woody clonal shrub narrowly endemic to xeric upland habitats of the Lake Wales Ridge in central Florida, USA, is known from only five populations, four of which are sterile and perhaps uniclinal. Altogether only 11 genotypes of Florida ziziphus have been identified by allozyme electrophoresis. We studied the breeding system of Florida ziziphus and found that it is an obligate outcrosser and that some genotypes are cross-incompatible. We have been able to demonstrate the cross-compatibility of only 11 of the 44 test crosses performed to date (25%), as measured by fruit yield. Cross-incompatibility is most likely due to shared self-incompatibility (S) alleles among the few remaining genotypes of these fragmented populations. The identification and translocation of compatible mating types to create reproductively viable populations is essential for the recovery of Florida ziziphus. (C) 2001 Elsevier Science Ltd. All rights reserved.

837: -.020

We performed a line transect survey (352.4 km) of primates in the Serra de Paranapiacaba, at one of the largest relatively undisturbed fragments of the Atlantic rainforest of Southeastern Brazil (ca. 1400 km²), in August 1998. The brown capuchin, *Cebus apella nigrinus*, was the most common species found in the area (20 groups, density estimate: 5.31 +/- 2.05 individuals per km², mean +/- SE). Nine groups of the brown howler monkey, *Alouatta guariba clamitans*, and eight of the woolly spider monkey, *Brachyteles arachnoides arachnoides*, were also recorded, with preliminary density estimates of 0.79 +/- 0.40 and 2.33 +/- 1.37 individuals per km², respectively. Density estimates for these species in other fragments of Atlantic rainforest are reviewed, showing that densities in Paranapiacaba are among the lowest reported. It is suggested that the higher densities reported for isolated populations in small forest patches (< 50 km²) is related to the absence of main primate predators, the density compensation phenomenon and the ecological plasticity of some primate species. In contrast, local extinction in many small patches is probably related to hunting pressure. Given the important primate populations found in the Paranapiacaba fragment, conservation strategies for the studied species should give priority to effective protection of the largest remnant fragments from illegal hunting and deforestation, rather than translocation of individuals or captive breeding programs to introduce monkeys in small forest fragments vulnerable to hunting and of uncertain future.

838: -.028

We suggest that reintroductions, like biological invasions, have two phases: establishment when a new population becomes self-sustaining, and spread when a population increases its distribution. Stochastic effects on mortality and sex ratios are most likely to determine whether a population becomes established, while factors influencing birth rates will probably most influence spread. Using this establishment-spread structure, we evaluate the autecological suitability of regions in England for pine marten *Martes martes* reintroductions. Risks of mortality from predator control, traffic accidents and predation by foxes were used to evaluate suitability for establishment. Mortality risk was higher in all potential release regions in England (selected as having 25% or more woodland cover) than in regions of current pine marten distribution in Scotland; risk of predation was higher in the latter. Indices of prey abundance were used to evaluate suitability for populations to spread. Prey indices in potential release regions were generally higher than in regions of current distribution. A relation between prey, woodland cover, and known pine marten densities suggested that potential release regions are capable of supporting relatively high densities of pine martens, though these might be reduced by higher mortality. We concluded that all

potential release regions are suitable for pine marten populations to spread. However, reintroductions should first be to regions with lower risk of mortality, in case higher levels of the latter prevent establishment. The suitability of relict regions of distribution in northern England was low until post-war afforestation, suggesting that habitat suitability constrained recovery of relict populations. These regions remain less suitable for reintroductions.

839: +.044

Koalas have undergone a series of sequential founding events on islands in south-eastern Australia in recent times, Populations in South Australia at the Eyre Peninsula and Mt Lofty Ranges were founded in the 1960s from a colony on Kangaroo Island. The Kangaroo Is. colony was derived from animals introduced to French Island from mainland Victoria over a century ago. In this study, we first use microsatellite markers to quantify levels of genetic variation within the South Australian koala populations and the relatively unperturbed Strzelecki Ranges population from mainland Victoria. This analysis revealed low levels of allelic diversity (1.7 ± 0.2 to 2.7 ± 0.5) and heterozygosity (0.208 ± 0.088 to 0.340 ± 0.110) in the three South Australian koala populations relative to the Strzelecki Ranges population, which has the highest levels of allelic diversity (4.7 ± 1.1) and heterozygosity (0.476 ± 0.122) in Victoria. Second, we measured the incidence of testicular aplasia, a unilateral or bilateral failure in testicular development, in the Eyre Peninsula and Kangaroo Is. populations, and in the ultimate founding population at French Is. Testicular aplasia was present at a frequency of 4.3% in French Is., 12.8% in Kangaroo Is. and 23.9% in the Eyre Peninsula, but was undetectable in the non-bottle necked Pilliga State Forest population of New South Wales. The incidence of testicular aplasia correlated positively with effective inbreeding coefficients derived from heterozygosity values (0.13 ± 0.06 in the Pilliga State Forest, 0.57 ± 0.17 in French Is., 0.63 ± 0.12 on Kangaroo Is. and 0.77 ± 0.12 in the Eyre Peninsula), which may indicate inbreeding depression. These findings are of concern when evaluating the long-term conservation and viability of the South Australian koala populations, which may benefit from genetic augmentation in the future. Finally, unconfirmed reports suggested that animals from other states in Australia were introduced into the Mt Lofty Ranges population. Therefore, we quantified differentiation between the three South Australian populations and the Strzelecki Ranges and French Is. populations, based on microsatellites and mtDNA d-loop region variation. R-statistics and Goldstein's delta mu square distance revealed that differentiation at nuclear loci between populations paralleled known recent population history, except for the close relationship between Mt Lofty Ranges and French Is. This suggested a recent contribution to the Mt Lofty Ranges populations of animals derived from the French Is. translocation program. Furthermore, mtDNA d-loop analysis found no evidence of contributions to the gene pool from animals of New South Wales or Queensland stock, implying that the population was derived exclusively from Victorian stock.

840: +.044

Conservation breeding for reintroduction is becoming a popular option for restoring threatened populations. Whereas post-release results are widely reported in the conservation literature, little empirical information is presented on the captive populations that often make such releases possible, even though fecundity, fertility and survival rates can have an impact on the outcome and cost of wild population re-establishment. We present results of survival analyses carried out on a captive population of houbara bustards to determine peak periods of mortality, and by identifying sources of variations in mortality to recognize the potential impact of management practices on productivity. There were two main mortality peaks: during incubation (53% survival of fertile eggs), and by 6 months posthatching (75% survival of hatchlings). Management-related variables

influencing survival of eggs and chicks included the year when laid, the cohort of females laying them, and possibly sex. Most posthatching deaths were due to trauma and infectious diseases. Trauma-related deaths usually follow collisions with cages, and imply selection for the captive environment, an undesirable trend in populations maintained for reintroductions. Reducing losses during incubation would have the largest impact on production of birds for reintroduction, enabling the release of more birds, and reducing the overall costs of the project.

841: +.174

The swift fox (*Vulpes velox*) is a rare, house-cat-sized carnivore that can race across native prairie at speeds of up to 60 km/hr. Although swift foxes were once so abundant in Canada that 117 025 were trapped between 1853 and 1877, this species was extirpated from Canada and northern Montana by the late 1930s. Since 1983, a reintroduction program has been underway to restore this species to Canada and the most recent releases were made in Grasslands National Park, Saskatchewan in 1997. A Canadian swift fox census during the winter of 1996-1997 revealed that the reintroduced population was located within two regions: 1) approximately 192 foxes were estimated to span the Alberta/Saskatchewan border south of the Cypress Hills; and 2) approximately 89 foxes were thought to exist along the United States border in and around Grasslands National Park, Saskatchewan. Concurrent with the Canadian swift fox reintroduction program, mounting evidence suggested that Canadian fox releases had also established a small swift fox population in north-central Montana. However, a coordinated international effort has not been previously conducted to assess the extent and composition of the shared swift fox population in Canada and Montana. The focus of the 2000-2001 census was: 1) to estimate changes in the distribution and abundance of swift foxes within Canada since the 1996-1997 census; 2) to estimate the distribution and abundance of swift foxes in adjacent areas of Montana. The 1996-1997 census area of 108 Canadian townships was resurveyed and supplemented with 80 Montana townships to form a total study area of 17 326.1 km². Following training at the Calgary Zoo, six field teams conducted catch-and-release surveys in 80.3% of the study area townships from November 4, 2000 until February 15, 2001. Significant results were as follows: 1. In total, 149 swift foxes were live-trapped: 97 in the Alberta/Saskatchewan border area population, 14 in the Grasslands National Park region, and 38 in adjacent Montana areas. By comparison, 32 swift foxes were caught during catch-and-release efforts during the Canadian 1996-1997 swift fox census. In 2000-2001, 98.6% of captured foxes were unmarked, which means that they were wild-born in the Canadian/Montana population. This is a greater proportion of wild-born foxes than that recorded in 1996-1997, when 81.3% were unmarked. 2. The known distribution of swift foxes in Canada and Montana has substantially increased through the results of this census. In the Alberta/Saskatchewan border area swift foxes were found in 18 townships in 1996-1997 and during the 2000-2001 census they were found in 38 townships. In the Grasslands National Park region, swift foxes were found in 7 townships during the previous census, whereas they have now been located in 13 townships. In Montana, where a previous census of this kind had not been conducted, swift foxes were found in 25 townships. Hence, the 1996-1997 census found swift foxes in 25 townships whereas the current survey yielded evidence of swift foxes in 76 townships; this represents a three-fold increase in the known swift fox distribution. 3. The number of swift fox captures in Canada has tripled since 1996-1997, in areas that were previously surveyed at the same time of year. Similar recapture rates between the 2000-2001 census and the 1996-1997 census indicate that the threefold increase of the Canadian swift fox population in replicated areas is not due to higher trapability of foxes during this census but, in fact, that this represents a statistically significant, three-fold increase in the fox population in these areas. 4. Fox body condition and age ratios are similar to those of the 1996-1997 census, but there has been a significant shift from a male-biased sex ratio previously to a female-biased population during this census. 5. The increase

in swift fox population size since 1996-1997 differed significantly between the Canadian swift fox subpopulations. Captures in the replicated regions of the Alberta/Saskatchewan border subpopulation have significantly increased by a factor of 3.5. By comparison, the 1.6-fold increase in the Grasslands National Park region is not statistically significant. 6. In newly surveyed areas, 50% of 16 townships in the Alberta/Saskatchewan border area had successful captures for a total of 22 foxes. By comparison, only 9% of 11 newly surveyed townships in the Grasslands National Park area had successful captures totalling one fox. In Montana, which had not been previously surveyed, 31.8% of the 66 townships had swift foxes totalling captures of 38 individuals. 7. Capture success for replicated and new areas combined was highest in the Alberta/Saskatchewan border area with 1 new capture every 10.0 trapnights, intermediate in Montana with 1 new capture/33.2 trapnights, and lowest for the Grasslands National Park region with 1 new capture/38.6 trapnights. 8. Application of the same population estimation technique utilized in 1996-1997 suggests that the Alberta/Saskatchewan border population consists of 560 individuals (compared to 192 previously), the Grasslands National Park area contains 96 individuals (compared to 87 previously), and the sampled Montana area contains 221 foxes. This suggests a total population size of 877 foxes. 9. Previously the Canadian swift fox population has been thought to consist of two isolated subpopulations. The comparative results in Canada suggest that this population has experienced a significant increase since 1996-1997. Furthermore, the present census suggests that the foxes in Canada and Montana now form one loosely-connected population.

842: +.112

More than 1000 pairs of tree-nesting Peregrines once occupied the European lowlands from Germany to Russia. In northern and eastern Germany a population of about 500 pairs of pure tree-nesters existed among which only a very few occasionally nested on buildings and cliffs. This population which was definitely affected by toxic agro-chemicals in its nutritional chain became completely extinct after 1972 throughout the whole tree-nesting area. The habit of tree-nesting is definitely based on imprinting and tradition. On this premise a reintroduction project was started in 1990 in north eastern Germany in which young Peregrines reared in captivity were imprinted to tree-nesting habits before and after their release. This will be continued until 20 sites are occupied by tree-nesters in Germany. Up to now (2000) 201 young Peregrines were released successfully; an additional 29 fledglings came from 3 wild broods found established in old pine woods since 1996. All Peregrines of the new eastern German population which has been established since 1981 are individually marked by ring combinations which permit the reading by telescopic means of whether the birds are coming from trees, buildings, or cliffs and are released or fledged from wild broods. Also the year and site they came from is identifiable. To monitor the success of the project, a table of survival was calculated (Tab. 1) which shows that 22 adult Peregrines may exist from all released and wild fledged birds together in the year 2000. All the falcons at the 3 tree-nesting sites were found to be released from the project, thus confirming the effectiveness of imprinting to this type of nesting. Another 11 falcons from the project group were identified as mates at buildings and cliffs. This indicates a 50% return to the inborn nesting type. However, up to now not a single falcon fledged from cliffs or buildings changed to tree-nesting. The exchange between falcons of different nesting types corresponds to a one way road with the blocked direction toward tree-nesting. As a consequence of this new finding a tree-nesting population can only become established and remain self-sustained in areas without or with very scarce nesting sites on buildings or cliffs. Nesting sites on buildings should not be offered in tree-nesting areas! This initial success can only be maintained if more young Peregrines fledge from trees than from buildings in the tree-nesting areas. On all accounts an early protection against losses of species should be preferred to expensive and not always practicable reintroduction.

843: +.067

The endangered red-cockaded woodpecker (*Picoides borealis*) is well adapted to fire-maintained pine ecosystems of the southeastern United States. Management practices vary greatly among land ownerships. In some wilderness areas and state parks, a "no management" policy has eliminated use of prescribed fire, artificial cavities, and woodpecker translocation, tools that have proved effective elsewhere in recovering woodpecker populations. We compared forests with essentially "no management" to actively managed forests of similar tree ages and similar red-cockaded woodpecker population demographics. We also compared sites that had received no management in the past to the same sites after management. In every case, populations in forests that did not use state-of-the-art management for woodpeckers declined severely compared to those in managed forests. Because managed forests typically used all available management techniques concurrently, it was not possible to separate and rank effectiveness of specific management activities. One exception was the Wade Tract in Georgia, where prescribed fire was the primary activity for herbaceous layer and hardwood management in a high-density, stable woodpecker population. Wilderness areas, which are intended to be pristine places that preserve biodiversity, are losing red-cockaded woodpeckers, a keystone species in the ecosystem, at an alarming rate. Collectively, 9 groups of red-cockaded woodpeckers were present in 4 wilderness areas in Texas national forests in 1983. At the close of the millennium, only one woodpecker group remained and its continued existence is unlikely without management. The very fragmented features of present-day landscapes and intervention by humans impair the effectiveness of natural disturbance processes, primarily growing-season fire, that historically produced and maintained open pine savannas with grass-forb herbaceous layers in the pre-Columbian forests of the southeastern U.S. therefore, active management must be used if the red-cockaded woodpecker is to persist.

844: +.109

Prairie dogs (*Cynomys* spp.) have declined greatly in abundance during the past century, and this warrants efforts to restore populations. Restoration often requires translocating animals to previously occupied areas. Workers should follow standard protocols for animal handling and care. Translocation involves selecting source populations and release sites, capturing and transporting animals, preparing release sites with attendant soft-release infrastructure, and monitoring and managing animals. Source populations should be free of plague and genetically appropriate for the translocation strategy. Release sites ideally have physical or historical evidence of previous occupancy, but also may be selected based on soils, slope, and vegetation. Capture, transport, and release of animals must comply with federal, state, and local regulations. Animals have been commonly captured with live traps, by flooding their burrows, or by using a specially adapted vacuum truck; those captured in plague-prone areas are treated to control fleas. Captives usually are hauled to release sites in covered pickup truck beds or trailers. High-quality release sites have short vegetation (< 12 cm tall) and pre-existing burrows; sites without these qualities may need modification. Retention baskets or fenced enclosures, sometimes combined with artificial underground nest chambers, have been used to reduce dispersal and predation. Control of predators may be needed prior to or following release. Post-release monitoring to detect and remedy potential problems such as dispersal and predation is recommended, and providing a food subsidy may reduce dispersal and elevate survival.

845: +.086

The river otter (*Lontra canadensis*) is an important North American furbearer species that was eliminated from most of its range by the early 1900s. Many state agencies have undertaken

restoration efforts, although no comprehensive study on the extent or type of management exists. I conducted telephone interviews with wildlife agency biologists in the 49 continental states (USA) to update status and management of river otters, with emphasis on reviewing the use of reintroduction as a management tool to restore extirpated otter populations. As of 1998, river otters occupied at least portions of their historic range in every state except New Mexico. Between 1976 and 1998, 21 states and 1 national park implemented reintroduction projects, releasing 4,018 river otters. States conducting reintroduction projects obtained otters from a variety of sources, but 14 (64%) used at least some otters obtained from coastal Louisiana. All states implemented postrelease evaluations, including radiotelemetry studies by 15 projects. Based on various forms of direct and circumstantial evidence, most biologists stated that reintroductions were successful in restoring extirpated otter populations.

847: +.181

The Hihi *Notiomystis cincta*, a New Zealand honeyeater (Aves: Meliphagidae), became extinct everywhere except one offshore island following European colonization. Attempts to establish Hihi on additional islands in the 1980s had poor success, and this was attributed to food limitation. These islands had all been modified by human use, and had a lower diversity of natural carbohydrate (fruit and nectar) sources than the source island, particularly in winter. When Hihi were released on two additional islands, Mokoia and Tiritiri Matangi, we used supplementation experiments to test whether condition and survival of birds were limited by availability of carbohydrate food. Sugar water was provided on an on-off basis from autumn through spring in the year after the release. Birds were weighed at the beginning and end of fed periods, and survival for fed and unfed periods was estimated using mark-recapture analysis on sighting data. Armstrong and Perrott (2000) reported that supplementary feeding had no effect on condition or survival on Mokoia, and annual survival was about 40%, both in the year of the experiment and in subsequent years when food was supplied continuously. This paper reports contrasting results for Tiritiri Matangi. Supplementary feeding on Tiritiri Matangi increased both condition and survival, and overall survival was substantially higher than on Mokoia-66% in the year of the experiment and 76% the following year when food was supplied continuously. It therefore appears that supplementary feeding can be used to improve survival of Hihi on Tiritiri Matangi, whereas survival is constrained to a low level by other factors on Mokoia. These results emphasize the value of habitat manipulation experiments for developing appropriate management strategies for reintroduced populations.

848: -.049

This study investigates the reproductive potential of 22 rare and threatened Western Australian taxa in the genus *Verticordia* (Myrtaceae) over a 5-year period. Considerable inter- and intra-specific variation in both seed production and germinability was demonstrated for the majority of taxa. The seed to flower ratio, or "seed set", ranged from 0% to 68% with an overall mean of 21% in 82 accessions representing seed from 48 populations of the 22 taxa. Percentage germination ranged from 7% to 100% with an average of 49% for 68 accessions. The precariously low annual reproductive capacity of some of the more restricted and critically endangered taxa threatens their survival and unexpected disturbance events may result in population decline or even localised extinction. Mitigation measures such as the reintroduction of plant material into new sites and the enhancement of existing populations through additional plantings may be warranted for many of Western Australia's rare and threatened *Verticordia*.

849: -.002

An optimal control model of wildlife management is developed to analyze, the transitory dynamics set forth by the reintroduction of animals that provide benefits but can also come into conflict with humans. The shadow price of these resources can be positive or negative, potentially creating a nonconvexity. The conditions under which reintroduction is not desirable are determined, and those characterizing the initiation of costly population control are investigated. An application to deer management illustrates the relevance of the nonconvexity and the magnitude of losses stemming from delays in implementing optimal management. The impact of distributional concerns on efficiency is discussed. (C) 2001 Academic Press.

850: +.110

The reconstruction of recent historical population sizes allowed us to investigate the influence of random evolutionary processes on present-day genetic diversity in populations of *Dryopteris cristata*. This long-lived, allotetraploid fern is, rare and endangered in the study area at the southwestern border of its European distribution. Random amplified polymorphic DNA (RAPD) diversity of 280 individuals from 14 populations of *D. cristata* was extraordinarily low, suggesting an ancient bottleneck in the species.' history. Analysis of molecular variance (AMOVA) of 25 different RAPD multiband phenotypes revealed significant genetic variation among three geographical regions (15%) and among populations within regions (34%); 51% of total variance was attributed to variation within populations. High population differentiation indicated limited gene flow among populations, and genetic divergence was not correlated with geographical distance. There was no relationship between genetic variation within population, estimated as molecular variance, and present-day population size. Populations with recent historical bottlenecks of fewer than 25 individuals showed a substantial and significant reduction in genetic variation, compared with populations without bottlenecks. Comparatively high levels of genetic variation were still maintained in small remnants, (60-110 individuals), of formerly large populations. Average deviations of frequencies of widespread polymorphic markers within populations from their frequencies in the whole dataset were significantly higher in small or recently bottlenecked populations than in constantly large populations, thus providing evidence for random sampling effects during genetic bottlenecks and drift in small populations. The present investigation demonstrates the importance of population history for understanding present-day genetic diversity within natural populations, as well as for conservation biology.

851: +.082

We present analyses of our transect survey data from consecutive years at 11 sites in Wisconsin during 1990-99 for the regal fritillary (*Speyeria idalia*), which is listed under state law as endangered, and the closely related but more widespread and abundant Aphrodite fritillary (*Speyeria aphrodite*). Within year, the date of peak survey numbers at each site ranged over a period of several weeks or more for each fritillary. Within year and site, the Aphrodite fritillary peak was typically a few days to a week prior to the regal fritillary's peak. Both fritillaries exhibited large annual fluctuations which were significantly correlated between the two species. Relatively larger regal fritillary densities were consistently associated with active non-fire managements (grazing, cutting), relatively lower densities with burning, and widely varying densities with non-management. More unfavorable outcomes from burning occurred at sites where the entire habitat patch was fire-managed. Similar but less sensitive was the Aphrodite fritillary, which did not respond as strongly or clearly to burning, although higher densities were associated with unintensified non-fire managements. In Wisconsin and adjoining areas, the Aphrodite fritillary appears useful as a substitute in tests of techniques for habitat restoration or reintroduction for the regal fritillary. Since the Aphrodite fritillary may be less sensitive than the regal fritillary, success

with the former certainly doesn't prove suitability for the latter. But unless and until the method works for the Aphrodite fritillary, it is almost certainly unsuitable for the regal fritillary.

853: -.057

In June 1998, 30 mala (*Lagorchestes hirsutus* undescribed central Australian subspecies) were translocated from a semi-captive colony in the Tanami Desert, Northern Territory to Trimouille Island, part of the Montebello Islands Conservation Park, off the Pilbara coast of Western Australia. Mala are 'Extinct in the Wild' according to IUCN (1994, 2000) Red List Categories and Criteria. The translocation was made possible by the eradication of black rats (*Rattus rattus*) and confirmation of the absence of feral cats (*Felis catus*), which were recorded on the island in the 1970s. Post-release monitoring up to October 2001 showed that mala were breeding and expanding the area occupied.

854: +.030

The northern leopard frog (*Rana pipiens*) is designated as Threatened in the province under the Alberta Wildlife Act (Alberta Environment 1996) and is nationally listed by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) as a Special concern species (COSEWIC 2000). The leopard frog has exhibited population declines and is currently extirpated from much of its former range in Alberta. The historic distribution of the leopard frog in Alberta is closely associated with major river drainages that may reflect optimal breeding and hibernation sites. Information on current known leopard frog populations indicate that it is largely extirpated from the central parkland and has virtually vanished from the North Saskatchewan River drainage basin and is completely absent from the upper Red Deer River drainage basin. Isolated and fragmented, remnant leopard frog breeding populations in southern Alberta are vulnerable to disturbance and degradation, potentially leading to further local loss of the species. The northern leopard frog has exhibited little ability for natural dispersal back into historic parts of its range. A management decision was made in 1998 to begin a reintroduction project for the leopard frog. The goal of the project is to re-establish the leopard frog in historically occupied habitats in the headwaters of the upper Red Deer and North Saskatchewan River drainage basins, consequently allowing natural downstream dispersal along these watersheds. The northern leopard frog conforms to many of the requirements proposed in conservation literature for successful translocations. In April 1999, a pilot captive rearing program was initiated at the Raven Brood Trout Station (Sustainable Resource Development) located southeast of Caroline, Alberta and in the upper Red Deer River drainage. The facility offers infrastructure, managed access, and two rearing ponds that provide a controlled environment in which leopard frogs can be reared and temporarily confined. Several release sites were chosen in the area proximal to the Raven Brood Trout Station based on historic leopard frog records and the presence of potential suitable breeding, summering and over-wintering habitat. A second year of managed captive rearing of leopard frogs was undertaken in 2000. To date, approximately 2500 juvenile leopard frogs have been captive reared and released into the wild near Caroline, Alberta. However, apart from a single observation in the spring of 2000 of a 1999 released frog, no released leopard frogs have been captured or observed since. During the captive rearing process, water quality, growth and development of the tadpoles, natural history observations, and population numbers were recorded and monitored. Prior to release into the wild, a percentage of the captive reared juvenile leopard frogs were randomly weighed and measured. All captive reared leopard frogs were marked using a Visible Implant Elastomer (VIE) tagging system. The bio-compatible marker was located in the webbing between the toes of one of the hind feet of each young-of-the-year leopard frog, producing an unique color and foot combination. The marking technique allows for the long-term monitoring of released frogs and the

evaluation of the survival success at each release site and in each year of release. The following report details the results of the 2000 captive-rearing program of the northern leopard frog reintroduction project.

855: +.074

Lions (*Panthera leo*) resident around the shores of Lake Kariba in Zimbabwe are vulnerable if their home ranges include communal lands inhabited by subsistence farmers. The primary cause of death is strangulation in wire snares set by game-meat poachers but illegal poisoning of carcasses, legal safari hunting and natural predation also contribute to mortality. A protected enclave of land on the lakeshore supported a resident pride of lions which was gradually eliminated in 1995. Tourist demand warranted an attempt to reintroduce lions which was assisted and probably accelerated by the capture and temporary confinement of an adult female lion and her three cubs in a stoutly constructed boma. The female came into oestrus and attracted several itinerant young male lions back to the area. The subsequently released lion family and five immigrant males formed the basis of a new resident pride which reproduced and behaved normally, attracting other lions who challenged the social hierarchy.

856: +.148

The restoration of wildlife populations to historically occupied ranges is an important goal of modern wildlife management. In Arizona, USA, efforts have begun to reintroduce the Gould's subspecies of wild turkey (*Meleagris gallopavo mexicana*) into its former range in the southeastern part of the state. However, individuals or descendants of the Merriam's subspecies (*M. g. merriami*) may remain in the reintroduction area from earlier releases and could potentially interbreed with reintroduced Gould's turkeys. We used 3 fundamentally different genetic markers to determine whether the wild turkeys currently occupying the Huachuca Mountains in southeastern Arizona were descended from the Gould's turkeys translocated there during the 1980s, or whether interbreeding had occurred with descendants of Merriam's turkeys from a translocation during 1950. We found consistent genetic differences between relict populations of the Merriam's turkey in Arizona and the Gould's turkey in northern Mexico. The Huachuca Mountains wild turkey population consistently grouped with the relict Gould's populations and showed no evidence of interbreeding with the Merriam's subspecies. In addition, we found evidence that the Huachuca Mountains population was less genetically diverse than the relict populations, and we recommend that this population be monitored for signs of inbreeding depression. The molecular markers developed for this study are important tools for future management of wild turkeys.

857: +.045

Fire is being experimentally reintroduced to the forests of southern Ohio to determine its effectiveness in restoring and maintaining mixed-oak (*Quercus* spp.) forest communities. We studied the effects of repeated burning (1-4 years of annual burning) and recovery (1 year after burning) on the breeding bird community. Burning resulted in incremental but temporary reductions in the availability of leaf litter, shrubs, and saplings, but it did not affect trees, snags, or understory vegetation cover. Of 30 bird species monitored, 4 were affected negatively and 2 were affected positively by burning. Population densities of Ovenbirds (*Seiurus aurocapillus*), Worm-eating Warblers (*Helmitheros vermivorus*), and Hooded Warblers (*Wilsonia citrina*) declined incrementally in response to repeated burning and did not recover within 1 year after burning, suggesting a lag time in response to the changes in habitat conditions. Densities of Northern

Cardinals (*Cardinalis cardinalis*) fluctuated among years in the control units, but remained low in the burned units. Densities of American Robins (*Turdus migratorius*) and Eastern Wood-Pewees (*Contopus virens*) increased in response to burning, but these increases were apparent only after several years of repeated burning. In general, burning resulted in short-term reductions in the suitability of habitat for ground- and low-shrub-nesting birds, but it improved habitat for ground- and aerial-foraging birds. Overall, there were no changes in the composition of the breeding-bird community. Total breeding bird population levels were also unaffected by burning. Our results suggest that prescribed burning applied on a long-term basis or across large spatial scales is likely to have adverse effects on ground- and low-shrub-nesting bird species, but other changes in the composition of the breeding-bird community are likely to be minimal as long as the closed-canopy forest structure is maintained within the context of prescribed burning.

858: +.141

Returning confiscated animals to their native habitats is desirable when it makes a positive contribution to the conservation of the species. Release of captive individuals is complex and controversial, however, particularly when risks are potentially high, as in the case of orphaned apes. We describe the decision-making process that led to the successive release of 20 wild-born orphan chimpanzees (*Pan troglodytes troglodytes*) into the Conkouati Reserve in the Republic of Congo. Recommendations of the Reintroduction Specialist Group of the World Conservation Union's Species Survival Commission were followed closely. The conservation status, ecology, and behavior of wild chimpanzees, the biological, social, economic and political context of the release site; and the health and genetic status of the candidates for release were all taken into account in the planning and execution of the project. Rigorous post-release monitoring of behavior and health allowed documentation of the outcome. The project was of benefit to the chimpanzees that were released but also brought broad benefits to the site through effective protection from poaching and deforestation, and direct and indirect benefits to local people. The genetic and behavioral diversity of chimpanzees require a variety of conservation strategies to reduce threats and maintain as many viable wild populations as possible.

859: +.000

The capercaillie (*Tetrao urogallus* L.), a large forest gamebird reintroduced into Scotland in the 1830s, has been declining since the 1970s. This has been attributed to a reduced reproductive rate associated with climate change, and deaths of full-grown birds flying into forest fences. Here, three independent estimates are combined to show that in the 1990s the mean annual rate of decline for adult hens was 18% (S.E. 5%). Without fence deaths, it is calculated that the hen population could have increased at an annual rate of 6% (S.E. 10%). If recent trends persist, the bird will soon be extinct again in Scotland, but without forest fences it would probably survive. (C) 2001 Elsevier Science Ltd. All rights reserved.

860: +.227

A model of the joint dynamics of change in population size N and evolution in a quantitative trait z , as a result of a general form of density dependence, local stabilizing selection, and immigration of individuals deviating from the local optimum, is analyzed. For weak selection and migration, a reduction in total equilibrium population size below the initial level without immigration, K , is shown to occur if the immigrants deviate more than $\sqrt{8} p 2.83$ genetic standard deviations from the optimum and if the rate of migration m is sufficiently large relative to the strength of stabilizing selection s . For the Lotka-Volterra form of density dependence, two additional

equilibria are shown to exist below K , provided that the strength of selection is large relative to the strength of density dependence. Reintroduction of an initially extinct population is possible if the immigrants are not too maladapted and if the genetic variance is sufficiently large. For a simplified version of the model corresponding to competition between similar species or different haplotypes, the equilibrium population size is always exactly at K if m

861: +.312

Rates of hybridization and introgression are increasing dramatically worldwide because of translocations of organisms and habitat modifications by humans. Hybridization has contributed to the extinction of many species through direct and indirect means. However, recent studies have found that natural hybridization has played an important role in the evolution of many plant and animal taxa. Determining whether hybridization is natural or anthropogenic is crucial for conservation, but is often difficult to achieve. Controversy has surrounded the setting of appropriate conservation policies to deal with hybridization and introgression. Any policy that deals with hybrids must be flexible and must recognize that nearly every situation involving hybridization is different enough that general rules are not likely to be effective. We provide a categorization of hybridization to help guide management decisions.

862: -.061

The macroinvertebrate benthos of Scott Creek, an intermittent stream in the Mt Lofty Ranges, was assessed to determine whether it could sustain a population of platypus (*Ornithorhynchus anatinus*), a species that has been locally extinct for about 100 years. The benthic fauna was compared to that of Rocky River and Breakneck River, two streams on Kangaroo Island where platypus have been introduced. Little difference was observed in the abundance and biomass of macroinvertebrates in the three streams, suggesting that Scott Creek does produce a sufficient food supply. The resource may be marginal, however, as Scott Creek in common with the two island streams contracts to pools in late summer/early autumn where the platypus populations are limited by this habitat truncation. Further assessment is needed of the physical suitability of Scott Creek for platypus reintroduction (e.g. consolidated banks, over-hanging plants, permanent pools) and the risk of predation by foxes.

863: +.092

Black bears (*Ursus americanus*) were extirpated from most of their range by the early 1900s by habitat destruction and unregulated hunting. Since then, bear habitat has recovered in many areas, but isolation may prevent natural recolonization. Black bear translocations often have limited success because of high mortality rates and low site fidelity. We tested 2 reintroduction techniques designed to overcome those problems. The first technique used a winter release whereby pre- or post-parturient female bears were removed from their dens and placed in new dens at the release area. The second technique involved translocating female bears to the reintroduction area during summer and holding them in pens for a 2-week acclimation period before release. We translocated 8 female bears with cubs with the winter-release technique and 6 female bears with the summer-release technique. After release, total distance moved, net distance moved, mean daily distance moved, and circuitry for winter-released bears ((\bar{x}) over bar = 18.3 km, 7.1 km, 1.4 km, and 0.36, respectively) were less than summer-released bears ((\bar{x}) over bar = 97.6 km, 63.4 km, 5.1 km, and 0.74; $P=0.010, 0.040, 0.019, \text{ and } 0.038$, respectively). Also, survival of winter-released bears (0.88) was greater than that for summer-released bears (0.20, $P=0.001$). Population modeling indicated that at least one additional stocking of 6 adult females with 12 cubs would greatly

increase chances of population reestablishment. The winter-release technique has distinct advantages over the summer-release technique, limiting post-release movements and increasing survival of translocated bears.

864: +.168

The dependence of seeds of terrestrial orchids on specific fungi for germination provides a means of locating these fungi in the wild and to investigate the role of appropriate fungi in the germination of orchid seed and development of seedlings under natural field conditions. Seed baits, comprising orchid (*Caladenia arenicola*) seed enclosed in fine nylon mesh, were placed at sample points along four transects through two orchid populations in bushland in Western Australia. Seed germination was scored and compared with adult orchid plant distribution and soil factors. A small fraction of available seed (< 1 %) germinated to a stage of tuber formation where survival over the subsequent dry season would have been possible. Germination increased in the vicinity of adult *C. arenicola* plants, but other factors, such as soil potassium levels and presence of leaf litter, were also correlated with seed germination. The measurement of the spatial variability in germination events within an orchid habitat demonstrated the availability of new recruitment sites. This information is required to assess the natural recruitment capacity and the potential for orchid reintroduction in natural habitats.

865: -.023

The European otter (*Lutra lutra*) is considered an endangered species in Europe. Therefore European zoos started a co-operative breeding programme - a so called European Endangered species Programme (EEP) - for this species in 1990. An important goal of the European otter EEP is to maintain an ex-situ (i.e. captive) population without imports of animals from the wild. Moreover, this population will be an important resource for reintroduction projects for this species. A reintroduction project of European otters in The Netherlands started in July 2002. Genetic management to avoid inbreeding and to maintain genetic variation is a pre-requisite to maintain a viable population. Examples of management strategies are described in this paper.

866: +.141

European zoos, associated in the European Association of Zoos and Aquaria (EAZA), established cooperative breeding programmes for zoo populations in 1985. European Endangered species Programmes (EEPs) and European Studbooks (ESBs) for some 250 species have been established as at March 2002. The goals of these programmes are to maintain viable zoo populations without (or with limited) import from the wild. These populations can serve, whenever feasible, as sources for reintroduction of endangered species. Retention of genetic variation in populations of endangered species is a prerequisite for their future survival. This means that conservation efforts should also include genetic management of zoo populations, especially when reintroduction is part of a conservation programme. Therefore, maintenance of sufficient levels of genetic variation and minimising inbreeding are important objectives of zoo breeding programmes. Population biologists who work for zoological gardens have developed various strategies, models and computer tools to assist zoo biologists in the co-operative management of zoo populations.

867: -.045

Burrowing Owls (*Athene cunicularia*) are undergoing mild to relatively severe local and regional population declines throughout much of western North America. In Canada, Burrowing Owls are

declining precipitously and are listed as endangered. In the United States of America, Burrowing Owls continue to decline in many states, but they are not listed federally. In Mexico, there is little quantitative data, but the species is listed as threatened. Here, we propose a conservation plan with five major action components: status, management and conservation, education, research, and administration. Given continued declines of Burrowing Owls in many parts of western North America, we urge increased cooperation among interested agencies and organizations to implement effective conservation of this species.

868: +.066

British Columbia (BC), designated the Burrowing Owl (*Athene cunicularia*) as endangered in 1980. In 1989, non-government organizations and local resource users, under the direction of the Ministry of the Environment, Lands, and Parks, launched a cooperative, captive-breeding and release program to restore Burrowing Owl populations in BC. The first phase of this program (1992-97) emphasized refining breeding protocols and identifying critical habitat features necessary for owl survival and reproduction in the wild. Successive releases provided insight into the feasibility of re-establishing populations to the grasslands of the Thompson-Nicola region. Results indicate that 1-yr old, captive-bred owls are capable of: 1) surviving at release sites, 2) raising broods, 3) over-wintering at or near release sites, and 4) migrating south and sometimes returning to release sites the following spring. Given these general results, the potential for a successful reintroduction of Burrowing Owls in BC exists, provided that more owls are released, and key habitat is enhanced. The second phase will emphasize ecosystem restoration, taking into account historical changes in natural processes (i.e., fire, grazing, and the resulting impact on faunal and floral composition on grassland habitats). In the second phase, the number of released owls will be increased to 50 pairs/year.

869: -.034

Burrowing Owls (*Athene cunicularia*) have been recorded nesting in most of Minnesota's western counties. Considered common in the early 1920s, by the mid-1960s only 9-10 breeding pairs were known with estimates of no more than 20 pairs in the west-central part of the state. Ten breeding records exist for the period 1965-85. In 1984, Burrowing Owls were listed as Endangered by the State of Minnesota. In 1986, we began surveys and site management for nesting Burrowing Owls and experimented with a reintroduction program. From 1986-90, 13 nests were found at eight sites, with a mean reproductive success of 3.5 fledglings/pair. The maximum number of breeding pairs/yr was four. Nest burrows were found in alfalfa fields (37.5%), pastures (37.5%), roadside ditches (12.5%), and fencelines between row crop fields (12.5%). We released 105 wild, preflighted juveniles: nine in 1986, 18 in 1987, 21 in 1988, 27 in 1989, and 30 in 1990. Young owls were kept in hack pens with roofs and sides made from cotton mesh fish netting. Burrows inside each pen and in surrounding fields were available to the owls. Crippled adults were placed in each pen with the juveniles but were not released. We documented eight mortalities, all of which were fledglings recovered in the release area. No owls were found, or reported, after leaving their hack sites. No successful nestings occurred from 1992-98.

870: -.091

The Chinese alligator is one of the world's most critically endangered reptiles. Although there is a relatively large captive population, in the wild small groups of alligators are limited to a few small ponds in an agricultural landscape in southeastern Anhui Province. As part of an effort to develop plans for the conservation of Chinese alligators in the wild, we investigated aspects of the

reproductive ecology of wild alligators during a survey of the last remaining groups. We also compiled published and unpublished information on the reproduction of alligators in captivity and in the wild. Nesting was only reported from four sites in 1999, and we describe two of these areas. Because of the intense human use of the landscape, alligators seek small patches of relatively undisturbed vegetation for nesting, and these fall into two main categories: vegetated hillsides, usually covered with pine trees, and small islands in agricultural ponds. Our observations of one nest on a pine hillside suggest that pine needles may make a poor nest substrate leading to lethally low temperatures for developing embryos. The selection of sites for the reintroduction of alligators should take the nature of potential nesting habitat into consideration.

871: +.141

The ecology of four relict Irish populations of pollan (*Coregonus autumnalis*) is compared with that of the species elsewhere, and used to advocate conservation. The threats to these populations from introduced/invasive species, habitat degradation, climate warming and commercial exploitation are summarized and the legislation governing conservation of the stocks is reviewed. Conservation options (legislation, habitat restoration, stock translocation and stock augmentation) are outlined and their practicality and efficacy considered. A preliminary search indicates that there are a number of lakes that appear to be suitable for pollan translocation. (C) 2001 The Fisheries Society of the British Isles.

872: -.018

In a survey of the west-central Italian rivers Ombrone, Fiora, Albegna and Bruna, among established exotic species, the Iberian barbel *Barbus graellsii* was recorded in Italian fresh waters for the first time. Morphological identification was supported by comparison of cytochrome b sequences with those from related barbel species. Other exotics of particular note were *Barbus barbus*, *Pseudorasbora parva* and *Leuciscus cephalus*, together with the Padano-Venetian *Chondrostoma genei* and *Padogobius bonelli*. Native species still present included *Leuciscus lucumonis*, *Telestes muticellus*, *Rutilus rubilio* and *Padogobius nigricans*, but were now more restricted to upper reaches and smaller watercourses. The deleterious effect of alien species on native forms is discussed with particular reference to probable competition between *C. genei* and *L. lucumonis*, and between the two gobies. The checklist of species introduced to the fresh waters of Italy is now, updated to 34. For the Italian freshwater fish fauna in general, the conservation status of three native species (*Acipenser naccari*, *Salmo marmoratus* and *Knipowitschia punctatissima*) has been improved but five species are believed to be at risk (*Salmo carpio*, *L. lucumonis*, *Scardinius scardafa*, *Gobio benacensis* and *P. nigricans*) and four anadromous species (*Petromyzon murinus*, *Lampetra fluviatilis*, *Acipenser sturio* and *Huso huso*) no longer breed in Italian fresh waters. The processes of change in the composition of the Italian freshwater fish fauna as a whole may be summarized as successively 'padanization', 'danubization' and now 'globalization'. (C) 2001 The Fisheries Society of the British Isles.

873: +.132

1. Wilkinson (2001) argues that we cannot assume that hybrids between local and alien genotypes will have low fitness, and therefore, as low hybrid fitness has been presented as justification for using only locally provenanced material in habitat restoration schemes, provenance is not important. 2. His observations on fitness are important, correct and deserve wider recognition. 3. Nevertheless, I dispute his conclusion about the importance of provenance, for two main reasons. One is that his argument is based on questionable objectives for biodiversity conservation. The

second is that, even if we accept these underlying objectives, the fitness of hybrids is only one of numerous relevant issues.⁴ Use of locally provenanced seed should be standard practice, except where the introduction of non-local genotypes is specifically justified in terms of conservation genetics.

874: +.160

1. Many habitat creation schemes specify that biological material of local provenance should be used in reintroductions. This has come to be the 'text book' approach. However, very little discussion of the theory underlying this idea has been published in the scientific literature. This paper aims to initiate this much-needed discussion.² A major reason for the use of local provenance is the claimed importance of conserving locally adapted genotypes, which are assumed to show high fitness. Using both genetic arguments and a consideration of Quaternary environmental change I argue that this reason will seldom be important.³ I make tentative suggestions of when local provenance is likely to be important and when it can be given a low priority in habitat creation schemes.

875: +.087

Most of Brazil's electricity is generated by hydroelectric power plants that require the flooding of huge areas and affect the stability of local ecosystems. The area of the Porto Primavera power dam was flooded in 1998 and a rescue programme was executed to save the fauna sheltering on treetops or emerging islands. Using DNA fingerprinting we estimated the genetic variability in a sample of 23 Bare-faced Curassow *Crax fasciolata* rescued in this area and found that the mean heterozygosity was $H = 0.89$. Although similar data on other natural populations of cracids is not available, the mean heterozygosity observed in the present sample is in the range found for free-living populations of two species of reintroduced cracids whose origin was captive breeding of a limited number of founders. We suggest that a collaborative captive breeding and reintroduction programme between the facilities holding the birds caught at Porto Primavera should start immediately to avoid the loss of genetic variability due to the small number of founders in captivity. Habitat protection, responsibility in fauna management and measures that prevent or correct the isolation of habitat fragments are needed to establish an equilibrium between progress and conservation in developing countries.

876: +.099

Brazilian Merganser *Mergus octosetaceus* is considered to be one of the rarest and most threatened species in the Neotropical region, yet little is known about its distribution and life-history. We studied the population of Brazilian Merganser in and around Serra da Canastra National Park (SCNP) in Minas Gerais, Brazil, during 1996, with additional observations from 1997 to 2000. In this paper we report the sighting of previously undiscovered pairs and present some new behavioural data, including a description of calls performed by males and females, feeding behaviour, home ranges, parental care and population density. We also describe a previously unreported plumage of the young. A total of 39 individuals were recorded, comprising 12 adults (six pairs) and 27 Young. Brood size ranged from two to four (mean 2.7), being smaller than in other *Mergus* spp. (e.g. Goosander *Mergus merganser*). Two pairs were located within the SCNP, and four on unprotected stretches of river outside. Home range was large compared with other *Mergus* spp., each pair using on average 9 km of river. Range size was thought to be related to the availability of suitable nesting and feeding sites. SCNP and its environs contain very little mature gallery forest with trees large enough to provide nest sites (most having been selectively logged in

the past). There is also competition for nest sites with other birds and mammals. All suitable habitat surrounding the SCNP is now occupied by adult birds, leaving none for young birds. Further research is needed to determine the fate and dispersion routes of juveniles. Future conservation priorities for Brazilian Merganser in and around SCNP include the installation of nest boxes to test whether the availability of good quality nest sites limits breeding success. A captive breeding programme could be established using eggs from these nest boxes. This would help to ensure the survival of this species and to provide birds for future reintroduction programmes should they be deemed necessary. Further surveys, with subsequent establishment of reserves at key sites, are required throughout the Brazilian Merganser's range.

877: +.071

Despite numerous, generally unsuccessful attempts to reintroduce threatened Australian mammals, the factors leading to their failure have not been fully clarified, although predator control would appear to be of paramount importance. An experimental approach was taken in attempting to establish a population of bridled nailtail wallabies in an area of apparently suitable habitat and low fox density, but on the edge of the species' former range. The 133 wallabies released since late 1996 comprised four groups: captive-bred animals, wild caught from the single remaining wild population, animals that were captive bred and acclimatised at the translocation site in a 10 ha predator-proof enclosure, and animals which had been bred in the enclosure. Survival was highest in those bred in the enclosure and highly variable among captive-bred animals. Survival estimates for wild recruits suggested the population would maintain a positive rate of increase under prevailing environmental conditions. Spotlighting surveys suggested the population had increased to approximately 400 animals by late 1999. Above average rainfall during 1996-1999 and no apparent predation suggests caution in describing the translocation as a success. Ongoing monitoring is critical, because it is uncertain how the population will cope with drought and inevitable predation events, and whether the population will expand and persist outside of limited preferred habitat. (C) 2001 Elsevier Science Ltd. All rights reserved.

878: +.080

The free-flowing Clinch and Powell River Basin, located in southwestern Virginia, United States, historically had one of the richest assemblages of native fish and freshwater mussels in the world. Nearly half of the species once residing here are now extinct, threatened, or endangered. The United States Environmental Protection Agency's framework for conducting an ecological risk assessment was used to structure a watershed-scale analysis of human land use, in-stream habitat quality, and their relationship to native fish and mussel populations in order to develop future management strategies and prioritize areas in need of enhanced protection. Our analyses indicate that agricultural and urban land uses as well as proximity to mining activities and transportation corridors are inversely related to fish index of biotic integrity (IBI) and mussel species diversity. Forward stepwise multiple regression analyses indicated that coal mining had the most impact on fish IBI followed by percent cropland and urban area in the riparian corridor ($R^2 = 0.55$, $p = 0.02$); however, these analyses suggest that other site-specific factors are important. Habitat quality measures accounted for as much as approximately half of the variability in fish IBI values if the analysis was limited to sites within a relatively narrow elevation range. These results, in addition to other data collected in this watershed, suggest that nonhabitat-related stressors (e.g., accidental chemical spills) also have significant effects on biota in this basin. The number of cooccurring human land uses was inversely related to fish IBI ($r = -0.49$, $p < 0.01$). Sites with greater than or equal to 2 co-occurring land uses had > 90% probability of having < 2 mussel species present. Our findings predict that many mussel concentration sites are vulnerable to future extirpation. In

addition, our results suggest that protection and enhancement of naturally vegetated riparian corridors, better controls of mine effluents and urban runoff, and increased safeguards against accidental chemical spills, as well as reintroduction or augmentation of threatened and endangered species, may help sustain native fish and mussel populations in this watershed.

879: +.128

The European sturgeon, *Acipenser sturio*, was an important component of the fish communities of all large German rivers, in particular the River Elbe, until the end of the 19th century. At that time about 4.000 specimens were caught in the River Elbe system annually. Since 1890, a dramatic decrease of the stocks occurred. The main reasons were: overfishing, hydroconstruction, and pollution. The last subpopulation was observed in the River Eider until the end of the 1960s. Until the end of the 1980s, politicians and also ecologists did not consider restoration measures for the sturgeon feasible. In 1994, after the German unification, the joint action of both fish culturists and scientists led to the foundation of the "Society to Save the Sturgeon (*Acipenser sturio* L.) e.V." with the aim to initiate and coordinate activities for the restoration of *A. sturio* into German rivers. A project for the remediation of the species was begun in 1996 with financial support of the Federal Ministry of Environment. At the same time juvenile *A. sturio*, originating from an artificial reproduction in 1995, were transferred to the Leibniz-Institut of Freshwater Ecology and Inland Fisheries in Berlin as nucleus of a brood stock. The main objective was to obtain maximum growth under safe rearing conditions in order to initiate early gonad maturation of the 27 fish of the brood stock (range of total length in April 2002: 85 cm [2.558 kg] to 118 cm [7.410 kg]). Furthermore, unsolved questions concerning feeding and gonad maturation are investigated using different sturgeon species which are more readily available such as *A. ruthenicus*, *A. baerii*, and *A. oxyrinchus*. Genetic studies were performed to characterize various populations (Baltic, North and Mediterranean Sea) of *A. sturio*. Thus providing an important background for sound strategic decisions concerning the selection of donor stocks for re-introduction measures. It was shown that the brood stock (originating from the French Gironde system) is genetically identical to the historical material originating from the Elbe system (based on museum samples). In addition, the genetic characterization of the intra-specific differences of the Gironde population as well as the French and German brood stocks were performed in order to develop a genetic breeding plan. Investigations on potential spawning habitats for the River Elbe and its tributaries Stör and Oste are in preparation.

880: -.021

We present comparative success of various trapping methods trialed during control of feral cats at a site for the reintroduction of threatened mammals at Shark Bay, Western Australia. Our results come from 31 703 trap-nights that caught 263 cats (an average of 0.83 per 100 trap-nights). Cats differed markedly in their vulnerability to trapping depending on whether they primarily scavenged at rubbish tips or around human settlement or whether they hunted for their food in the bush. Cage traps were an effective means of controlling the former, with 9.4 cats captured per 100 trap-nights. Scavenging cats included a higher proportion of sub-adults and kittens and lower proportion of adult males than hunting cats. Variation between years in capture success for hunting cats was largely explained by the abundance of rabbits relative to that of cats and whether the rabbit population was increasing or decreasing. These factors accounted for a nine-fold difference in trap success. The number of cats caught in any particular trapping session could be explained by location (rubbish tip or town versus bush), trapping effort (typically greater effort yielded higher captures), abundance of cats at the site (captures were highest when cats were abundant), and season (captures were highest in the first half of the year when the young of the year were

becoming independent). Concealed foot-hold traps, in a range of possible sets, provided effective methods for capturing cats that hunt, except where capture of non-target species was a critical limiting factor. Cage traps caught cats at a comparable rate to foot-hold traps for standard sets, but caught a significantly different cohort. Concealed foot-hold traps caught a higher percentage of adult cats, particularly males, than did cage traps. Mouse carcasses and rabbit pieces were significantly more effective as lures when rabbits (the major food of cats at the site) were at low densities, whereas the success of commercial scent lures was unrelated to food availability. Significantly more cats than expected were caught using food as an attractant at times of food shortage (late summer, autumn and early winter) for both scavenging and hunting cats. In contrast, scent lures caught significantly more cats than expected in spring and summer when cats were defending access to mates and/or territory. Hence, no single trap type, trap set, or lure provided unequivocally superior performance over others. Control is likely to be best achieved by a variety of trapping methods and lure types used in combination, supplementing well timed poisoning efforts. Trap success is likely to be maximised by trapping at times when the dominant prey of cats are scarce relative to the number of cats and are decreasing in abundance.

881: +.075

Burrowing Owl (*Athene cunicularia*) populations are declining in many portions of their range, and research and management efforts into stemming declines are underway. One tool with promise is the artificial burrow, which can supplement nesting opportunities and play a role in research, mitigation, translocation, and reintroduction studies. However, few studies directly assess important burrow and surrounding topographic features upon which owls choose sites and then construct and install artificial burrows accordingly. In this study we (1) measure physical, vegetative, and topographic characteristics of Burrowing Owl nest sites in the Snake River Birds of Prey National Conservation Area (SRBPNCA); (2) compare used and unused burrows to determine features important in nest-site selection; and (3) use this information to help guide current and future construction and placement of artificial burrows in the SRBPNCA. Owls nested in abandoned American badger (*Taxidea taxus*) burrows in areas with more than one burrow, close to roads and irrigated agricultural fields, and characterized by sparse and low vegetation dominated by normative plant species. Only one feature studied, tunnel entrance angle, corresponded with choice by owls; odds of burrow use decreased 17% with each 1 degree increase in slope of the tunnel entrance. Owls nesting near irrigated agricultural fields also had higher productivity. We discuss applications of our results to construction and placement of artificial burrows in the SRBPNCA and similar shrub-steppe environs in western North America.

882: +.174

Reintroduction efforts have established small, scattered flocks of Trumpeter Swans (*Cygnus buccinator*) in the Midwestern United States. Management of these flocks as distinct population units is debated among wildlife managers. The purpose of this study was to quantify generic differences among three recognized populations of Trumpeter Swans. Blood and tissue samples were collected during 1999 and 2000 and analyzed using horizontal starch-gel electrophoresis. Trumpeter Swans from the High Plains Flock and the Greater Yellowstone Population, from which the High Plains Flock was derived, were genetically indistinguishable. However, both flocks differed from the Pacific Coast Population in allele frequencies at the adenosine deaminase (ADA) locus. Founder effects may have influenced both the High Plains Flock and the Greater Yellowstone Population. Results also suggest unidirectional gene flow from the Pacific Coast Population into the other populations. The High Plains Flock may be a suitable source of individuals to increase the size of the Greater Yellowstone Population while maintaining similar

allele frequencies. Additional higher resolution genetic surveys are warranted.

883: -.065

Restoration of Trumpeter Swans (*Cygnus buccinator*) to their former range in Ontario has involved many techniques, some more successful than others. Rearing methods included cross-fostering on wild Mute Swans (*Cygnus olor*), artificial incubation, and incubation and rearing by their own Trumpeter Swan parents. Egg hatchability was low (\bar{x} over bar = 56%) for eggs laid by captive pairs and was suspected to be due to inbreeding. Few toxic contaminants were found in unhatched eggs, but 15-17% of unhatched eggs that had been artificially incubated were infertile. Eggs cross-fostered under wild Mute Swans had lower hatchability than those incubated by Trumpeter Swans, and cygnets raised by Mute Swans survived less well to fledging. Time budgets revealed that rearing methods significantly influenced behavior but differences disappeared by 26 weeks of age. However, wild-hatched swans, when adults, bred somewhat but not significantly more frequently than those hatched by their own, captive parents. Translocating adult wild-caught Trumpeter Swans did not prove to be an effective reintroduction technique; none of the six translocated adults were resighted after the first year. Annual survival rate of wild-hatched males and females more than 2 years old was 0.831; survival rates did not differ between captive- and wild-hatched swans in any age or sex category. The most common cause of death was lead poisoning. Released Trumpeter Swans bred for the first time at two to eight years of age. Four adults were taught to follow an ultralight aircraft to a predetermined wintering site. They returned on their own in the spring but did not migrate back to the wintering site during the next autumn.

884: +.173

Reintroduction is defined as an attempt to establish a species in an area that was once part of its historical range, but from which it has been extirpated or become extinct. Historically, one of the most successful programs was the reintroduction of 254 American black bears (*Ursus americanus*) from Minnesota to the Interior Highlands of Arkansas in the 1960s; that population has grown to >2,500 today. More recent efforts have involved fewer but better monitored animals and have sometimes employed techniques to improve site fidelity and survival. In Pennsylvania, for example, pregnant female American black bears were successfully translocated from winter dens, the premise being that the adult females would be less likely to return because of the presence of young cubs. That winter-release technique was compared to summer trapping and release in Tennessee; winter releases resulted in greater survival and reduced post-release movements. Homing has not been a problem for small numbers of brown bears (*Ursus arctos*) reintroduced to the Cabinet-Yaak ecosystem in Montana and Idaho and to the mountains of Austria and France. Reintroduction success appears to be correlated with translocation distance and is greater for subadults and females. As with any small population, reintroduced bear populations are susceptible to environmental variation and stochastic demographic and genetic processes. Although managers have focused on these biological barriers, sociopolitical impediments to bear reintroduction are more difficult to overcome. Poor public acceptance and understanding of bears are the main reasons some reintroduction programs have been derailed. Consequently, the public should be involved in the reintroduction process from the outset; overcoming negative public perceptions about bear reintroduction will be our greatest challenge.

885: +.230

During the past 20 to 25 years, dramatic declines and disappearances of amphibian populations have been observed and documented worldwide. One of the species that has experienced such a

dramatic decline is the southern Rocky Mountain population (SRMP) of the boreal toad (*Bufo boreas boreas*). Although once considered fairly common in most mountainous areas in southern Wyoming, much of Colorado, and northern New Mexico, it is much less common today, and absent from some of the areas where it occurred historically. Reasons for the decline are being investigated. Although causes for the decline have not all been completely investigated or clearly identified, discovery of boreal toad die-offs due to the chytrid fungus (*Batrachochytrium dendrobatidis*) in 1999 point to this pathogen as the proximate cause of deaths of boreal toads in at least two populations. In general, lack of suitable habitat does not appear to be a significant limiting factor for boreal toads in the southern Rocky Mountains. As a result of the observed decline in population, the boreal toad has been listed as endangered by both New Mexico and Colorado, and the Wyoming Game and Fish Department lists the boreal toad as status NSS1 (Native Species Status 1). It is presently considered "warranted but precluded" for federal listing under the Endangered Species Act (ESA), and is considered a "Sensitive Species" in the Rocky Mountain Region of the USFS. An interagency recovery team was formed in late 1994, and has been working on the conservation and recovery of this species since that time. These actions led to the writing of a boreal toad recovery plan for Colorado, a draft Conservation Strategy, and a draft Conservation Agreement. The various documents resulting from the actions and agreements described above created redundancy and confusion about the purpose and intent of each document as related to the other. Therefore, it was agreed in 1997 that it would be advisable to combine the components of the various documents into one comprehensive Boreal Toad Conservation Plan and Agreement (Conservation Plan). The first edition of the Conservation Plan was produced in 1998, and this document is the first revision of that plan. The intent of this document is to provide comprehensive guidance for the recovery and management of the boreal toad and its habitat in the southern Rocky Mountains, and to provide a means for all involved and interested parties to make a formal commitment to the implementation of the actions recommended in this plan. Federal, State, and private parties wishing to commit to participating in the implementation of parts of, or the entirety of this plan, can make that commitment through Conservation Agreements, which are appended to this document. These agreements will be brief and concise statements that can be edited, deleted, or appended at any time, without the need to revise the entire plan. This approach will expedite the process of implementing the Conservation Plan, as it does not require the "up front" approval of all potentially involved agencies before implementation. If some agencies are not willing or able to sign an agreement immediately, they can do so at a later date without holding up the work of those agencies that are ready to make an immediate commitment and begin implementing the plan. Work on boreal toad recovery and management has been going on since about 1994, based on the guidance of the Recovery Team, the State of Colorado's Boreal Toad Recovery Plan, and subsequently, the Boreal Toad Conservation Plan and Agreement. Work to date has involved several state and federal resource management agencies, personnel from universities, and various other interested parties, including local land use planners and private land owners. Management activities to date have included (1) the conducting of surveys of historic and potential suitable habitats to locate toad populations, (2) the annual monitoring of known breeding populations, (3) research to identify and evaluate biotic and abiotic limiting factors to toad survival, (4) research to better define boreal toad habitat and boreal toad biology/ecology, (5) development and testing of techniques and protocols for captive breeding and rearing of boreal toads, (6) experimental reintroductions of toads to vacant historic habitat, (7) protection of boreal toads and their habitats via coordination with land management agencies - in particular with the USFS, (8) work with local land use planners and developers aimed at avoiding or minimizing potential impacts of private land development on boreal toads and their habitat, and (9) efforts to increase public awareness of this species and its plight via informational/educational activities and public involvement in searches for new populations of boreal toads. As of the summer of the year 2000, the boreal toad is known to still occur in eleven counties (Routt, Larimer, Grand, Eagle,

Summit, Clear Creek, Pitkin, Gunnison, Chaffee, Hinsdale, and Mineral) in Colorado, and one county (Albany) in southern Wyoming. Unconfirmed but reliable reports indicate that boreal toads may also still occur in Jackson, Garfield, Boulder, Lake, Park, Saguache, and Conejos counties in Colorado, and in Rio Arriba County, New Mexico. Significant progress has been made with the boreal toad recovery and conservation effort in the past five years, and it is anticipated that much can be accomplished towards recovering this species in the next five to ten years, provided adequate funding and personnel are available. The discovery of the chytrid fungus and its role in the decline of boreal toads has introduced a significant new factor into the recovery and conservation effort, and will require additional research and possible modification of management approaches. The Recovery Team recognizes that both personnel and funding are in short supply, and will pursue innovative approaches to accomplish needed work, including partnerships and other cooperative efforts. However, without a significant commitment of funds and time from all the involved agencies, recovery may be difficult, if not impossible, to achieve in the foreseeable future.

886: +.081

We examined reproductive performance of yearling males in a recently established free-ranging elk (*Cervus elaphus nelsoni*, Erxleben) population in southeastern Kentucky. Sixteen of 18 (89%) adult females bred by yearling males produced a calf. The calving period, determined for 11 cows, peaked in mid-June; however, 3 females bred by yearlings did not calf until mid-July or August. It is not possible to attribute the extended calving period to breeding by yearling males, as it may have been a result of poor physical condition of females or the disruption of social bonds after translocation the previous winter.

887: +.114

Current Status: The Sonora tiger salamander is federally listed as endangered without critical habitat. As of this writing, the subspecies has been found in 53 ponds in the San Rafael Valley of Arizona. **Habitat Requirements and Limiting Factors:** This salamander requires standing water from January through June for breeding and larval growth. Adult, metamorphosed salamanders inhabit adjacent grassland and oak woodland terrestrial habitat when not in ponds. **Threats to Sonora tiger salamanders include the following:** 1) restricted distribution, 2) disappearance of natural standing water habitat, 3) predation by non-native fish, bullfrogs, and crayfish, 4) genetic swamping by introduced, non-native barred tiger salamanders, 5) disease, 6) low genetic diversity, and 7) collection for bait or translocation by anglers. **Recovery Priority: 3 on a scale of 1 to 18.** The priority is based on its being a subspecies (rather than a full species) with a high degree of threat and high recovery potential. **Recovery Objectives:** 1) Reclassify from endangered to threatened status. 2) Delist. **Recovery Criteria:** The Sonora tiger salamander may be reclassified to threatened status when approximately 90 percent of salamander's currently-occupied range and approximately 90 percent of current breeding ponds are protected and maintained to prevent habitat loss and degradation, predator introductions, barred tiger salamander introductions, and collection of salamanders for bait. **Scientifically credible monitoring over a five year period must indicate that the number of Sonora tiger salamander populations is not in decline and that there are no new factors that threaten the persistence of Sonora tiger salamanders.** The Sonora tiger salamander will be considered for delisting when quantitative criteria in terms of number of breeding populations and amount, distribution, and type of available habitat are defined and met. **Criteria will be based on research, continued monitoring, and population viability analysis. In addition, regulatory mechanisms and land management commitments must be implemented that provide for adequate long-term protection of the Sonora tiger salamander and its habitat. These**

commitments and mechanisms should address habitat maintenance and protection, management of non-native predators, disease transmission, introduction and collection of salamanders, interbreeding with non-native salamanders, and public education. Finally, the Sonora tiger salamander must be unlikely to need protection under the Endangered Species Act in the foreseeable future. Actions Needed: 1. Maintain and enhance habitat where salamanders have been found, and create new habitat, if deemed necessary. 2. Control non-native predators (fish, bullfrogs, and crayfish) by enforcing and enhancing existing policies prohibiting the introduction and pond to pond transport of these taxa and by removing populations of non-native fish, bullfrogs, and crayfish. 3. Control introduction, transport, and collection of tiger salamanders in the San Rafael Valley by enforcing existing policies prohibiting these acts and by removing populations of barred tiger salamanders. 4. Create and enforce policies to minimize frequency of die-offs. 5. Monitor salamander populations and their habitat on public and, if permitted, private land, to observe threats as they arise and fulfill research objectives. 6. Conduct research to acquire demographic and dispersal information and develop a population viability analysis, better understand salamander disease, conduct genetic analyses, investigate reports of low pH, and determine distribution of crayfish and methods of crayfish removal. 7. Develop public education and information programs. 8. Practice adaptive management. Total Cost of Recovery (minimum): \$1,016,000 Date of Recovery: If recovery criteria are met, reclassification to threatened status could be initiated in 2007.

888: +.056

Significant loss of rare plants and their habitats have occurred on the coastal plain of Virginia through urbanization, drainage of wetlands, fire suppression, and land use changes. Existing conservation practices such as easements and preserves have been somewhat successful in preserving biodiversity but have neglected the role that highway rights-of-way could serve as restoration areas for rare plants and their ecosystems. We propagated a number of rare plant species, many only still surviving on powerline rights-of-way, and reintroduced them in appropriate habitat on mitigation projects and cloverleafs along Virginia Department of Transportation highway rights-of-way. Key elements of our program include: utilization of indigenous plant stocks from the local area, registry of reintroductions with state authorities, management of sites through mechanical or chemical means, and monitoring of the population biology of introduced plants. Highway rights-of-way represent a potentially underutilized area for rare plant conservation and could augment species preservation and recovery efforts.

889: +.068

The European Commission's LIFE-nature programme has funded a five-year programme (1997-2002) on integrated management of the ecosystems of Mediterranean evergreen oak. The programme is being applied at two calcareous sites: La Clape close to Narbonne, and Le Gardon close to Nimes and Pont du Gard. Due to the decline of traditional sheep grazing, the environment has tended to close in with the consequence that *Brachypodium retusum* grassland has been replaced by garrigue. Tourist activities (hiking, climbing) are threatening the survival of the Bonelli Eagle. Furthermore, the *Centaurea corymbosa*, which is endemic to La Clape, now numbers just six populations attached to just a few cliffs, may disappear unless there is artificial reintroduction. The programme has identified management methods that protect these species or habitats. They consist in secluding the areas inhabited by the birds by deviating paths and climbing routes, artificially clearing the environment by mechanical means or controlled fire so as to restore the grasslands, together with evergreen oak-, Aleppo pine- and riverain-based silvicultural practices. By organising active consultations between elected officials, users of the

forests and scientists, this LIFE programme has paved the way towards Natura 2000 objectives documents in anticipation of contract-based management aimed at safeguarding the threatened species and habitats.

890: +.090

The wolf is a fundamental element of natural ecosystems. The ecological needs of this predator include large suitable habitats and abundant natural prey. The conservation of viable wolf populations is therefore beneficial to biological diversity and to the environment. The wolf almost became extinct in Italy during the second half of the last century, when the species' range was limited to a few scattered areas of the Apennines. Since the '70s, as a consequence of legal protection, the abandonment of many rural areas, and the increase in the number of wild prey, the wolf rapidly increased its range. In the early '90s it reached the western Alps, where there is now a transboundary population of about 50 wolves. In total, 400-500 wolves are estimated to live in the country, but this number should be considered only as an order of magnitude, as no reliable censuses of the Italian wolf population are available. In the medium term a further expansion of the species to the entire Alpine region is predicted, thereby the definition of common policies among neighbouring States has become urgent. The wolf causes relevant management problems, primarily because of its impact on livestock; consequently, Italy is characterised by diffused poaching considered to be the main cause of mortality for the species. The wolf is a non-hunted species since 1971, is strictly protected under the national laws (L. 157/92, D.P.R. 357/97) and several international directives. Although quantitative data is lacking on the relative impact of the different causes of mortality, leading Italian wolf experts consider main limiting factors for the species to include: poaching (accounting for a 10-20% loss of the population yearly); conflicts with farmers and hunters (at the origin of a large proportion of poaching); competition and genetic pollution with free roaming dogs (the presence of several dog-wolf hybrids has been recorded). Other factors (habitat loss and fragmentation, human disturbance, demographic factors, range fragmentation) are considered of secondary importance. Despite the fact that the biology of the species (presenting low densities and moving over very wide areas) calls for the development and application of national or transboundary conservation policies, the present Italian legal and administrative framework (characterised by a decentralisation at decisional levels and by a complex repartition of roles and competencies) limits the possibility to develop coherent action at the national scale. The scope of the action plan is to maintain and recover, in coexistence with people, viable populations of wolves. In order to achieve this aim it is important that the population of the Italian peninsula is maintained at its present level of size and range; the recolonisation of the entire Alpine region is promoted; wolf-human conflicts are mitigated. The present action plan has a 5 year term of validity. The plan is based on available scientific information, however, given the lack of data on many aspects of the wolf biology and dynamics, it is also based on the estimates of leading Italian experts on wolf biology. The plan is coherent with national and international provisions, and is based on the assumption that it is fundamental to increase a positive attitude of people towards wolves. Involvement of local communities in the decision-making process, is thus fundamental and would furthermore avoid that a top down process take place during the definition of a policy on the issue. Thus, the present action plan does not cover all the instruments required for the implementation of a wolf conservation policy, but it does define the key elements of a strategy for wolf conservation, as well as identify priority actions, and describe the critical steps that need to be undertaken for an open and transparent consultation process. In this regard, the plan proposes the creation of a "National Wolf Committee" (open to all main stakeholders) with the mandate to discuss, develop and revise a national policy on the issue. Furthermore, the creation of a "Standing Committee for Wolf Conservation in the Alps" among Italy, France and Switzerland is also proposed in order to discuss

and define common positions on the wolf conservation and management in the Alpine region. It is critical to undertake studies and activities aimed at increasing present knowledge on wolf distribution, population size, dynamics, impact on human activities and efficiency of prevention measures. In particular, efficiency, reliability and standardisation of monitoring must be increased. In this regard the production of a handbook for wolf monitoring is proposed and preliminary guidelines for wolf monitoring are reported as an appendix to the action plan. Other key elements for the conservation of the wolf include: the reduction of poaching; education and information campaigns; a revision of the policy on the control of free-roaming dogs; strict regulation of the existing non-Italian wolf and dog-wolf hybrids breeding farms; cautious control of the small stock of captive Italian wolves (15 individuals); the recovery of roe and red deer in central and southern Italy; an assessment of the role of functional connectivity areas (corridors); the development of a coherent policy on damage prevention and compensation (priority given to prevention, compensation conditioned to prevention, priority use of the available resources in the key areas for wolf conservation and potential corridors). Compensation must be based on the following principles: the entire market price of the loss is covered; all the indirect costs are covered; compensation is paid very rapidly; no distinction between dogs and wolves is applied; on-the-spot inspection is always carried out immediately after the claim. The alternative of providing incentives to farmers in key areas for wolf conservation should be explored, if available resources are not sufficient to cover all losses, priority should be given to key areas for wolf conservation and to corridors, rather than to other areas of wolf presence. No compensation shall be paid in areas where the species is not present and that are non-critical for wolf conservation and expansion. Any translocation of wolves is strictly banned and prevented; captive breeding programs (aimed at future reintroduction into the wild) are not considered a useful option. The introduction of the possibility to control the wolf for limiting damage to livestock is acceptable only if this measure (mitigating the conflicts with people and thereby reducing poaching) does not determine an increase in the overall mortality of the population. In this regard, the development of a more efficient monitoring system is a critical requisite. Wolf control is thus excluded for the term of validity of the plan. Although even the biggest national parks are not sufficiently large to allow wolf protection, protected areas can play a key role in wolf conservation by promoting education, information, monitoring, regulating tourism, etc.

891: +.152

From time immemorial, though particularly in the recent two hundred years, the wolf has been persecuted and exterminated with all available means. This has brought about a significant reduction in the area of its occurrence all over Europe and in Poland as well. Rational modeling of wolf population in Poland, understood as far-reaching activities aimed at protection and conservation of the species, is the fundamental prerequisite for re-introduction of the wolf into western Europe. A noteworthy form of wolf protection are the so called "Wolfs' Parks" in which the animals stay in conditions resembling nature - on a large enclosed area with look-outs erected around the fencing.

892: +.063

Reintroductions of Delmarva fox squirrels (*Sciurus niger cinereus*) to suitable habitat have been a recovery tool used for this endangered species. In Maryland, we attempted reintroductions at 11 sites beginning in 1978. The last reintroduction was completed in 1992. At each site, 8-42 individuals were released during spring or fall over a 1-3 year period. Attempts were made to release an equal number of males and females. Monitoring at reintroduction sites by live-trapping has documented recruitment and establishment of populations at 9 sites. Criteria used for

determining population establishment follows that of the Delmarva Fox Squirrel Recovery Plan (U.S. Fish and Wildlife Service 1993). Because 7 of these populations were established with <24 individuals, supplemental releases of Delmarva fox squirrels were conducted to bolster genetic diversity. This paper summarizes the history of Delmarva fox squirrel reintroductions in Maryland, provides the results of recent live-trapping efforts at the sites, and discusses success of these efforts.

893: -.035

The Seychelles kestrel *Falco araea* is classified as a Vulnerable species with main breeding populations restricted to two islands of the Seychelles group (Mahe and Silhouette). An attempted reintroduction to Praslin in 1977 has had poor results. It is the world's smallest kestrel species and is adapted to preying on small lizards in forest habitats. The habitat preferences, territory size and distribution on Silhouette island was studied confirming previous reports of a preference for lowland habitats. The Silhouette population is estimated at 48 pairs, showing no significant change from the previous (1981) estimate. Exceptionally small territories (as small as 9.0ha) were found in habitat mosaics of lowland forest on bare rock, associated with abundant cliff nesting sites and high lizard population densities. The larger island of Praslin supports very few kestrels and as the size distribution of lizards on that island is skewed towards large individuals, this may result in food scarcity. Combined with nest site scarcity the paucity of small prey may cause the lack of significant population recovery on Praslin.

894: +.270

For *Cicindela puritana* to be a viable member of New England's biota, there must be more than the current two occurrences. Assessment of the chance that the species can spread, whether on its own or through reintroduction, required identifying vacant habitat patches, which in turn, required refining the description of the species' larval habitat. Analysis of larval microhabitat variables identified sand texture as the most important determinant of habitat suitability. I then surveyed a 79 km stretch of the Connecticut River in Connecticut looking for suitable habitat patches. Of 32 beaches, none that appeared to be suitable was nearer than 12 km from currently occupied patches. Dispersal is unlikely to lead to establishment of new populations, so I recommend reintroducing *C. puritana* to an area in the vicinity of Windsor, CT where there are beaches on three islands that appear to be suitable larval habitat.

895: -.141

Annual trends in numbers of ungulate species on a 15 km² reserve from 1993 to 1998, were evaluated in the context of lion *Panthera leo* reintroduction during 1996, and subsequent predation by them. The ungulate prey base was enumerated annually by aerial counts and a road count that took place during 1998. The lion prey record was obtained from direct observations of a radio-located pride of eight lions and daily reserve management records. All ungulate species that underwent precipitous declines were also the most important prey to lions, comprising over 80% of their prey, and they were preyed upon according to their availability. Lion predation was causal for the declines in wildebeest *Connochaetes taurinus*, blesbok *Damaliscus pygargus phillipsi* and warthog *Phacochoerus africana*, while the decline in kudu *Tragelaphus strepsiceros* was only partly ascribed to lions, as other non-lion related mortality sources were identified. The only ungulate species to increase subsequent to lion reintroduction was the impala *Aepyceros melampus*, which was furthermore under-selected by lions. The uncontrolled population growth of impala could have elicited ecological degradation, and it was advised to either not stock impala, or

otherwise control their numbers if lions are unable to do so. Lion hunting success and kill rate, were 21% (n=63) and 1 kill/4.4 days, respectively. Three bushpigs *Potamochoerus larvatus* were killed but not utilised, and this finding is corroborated by an intensive study in Kwazulu-Natal, and this aversion is discussed. Predators can cause unprecedented declines of their prey where the prey are confined to small reserves that have no refuge from predation. On an annual basis, prey may need to be augmented to sustain predators on small reserves.

896: +.029

Translocation of wild birds is a potential conservation strategy for the endangered red-cockaded woodpecker (*Picoides borealis*). We developed and tested 8 large-scale translocation strategy models for a regional red cockaded woodpecker reintroduction program. The purpose of the reintroduction program is to increase the number of red-cockaded woodpeckers by moving subadult birds from large populations to smaller populations that are unlikely to increase on their own. A major problem in implementing the program is determining where birds will be moved because the larger donor populations cannot supply enough birds for all small recipient populations each year. Our goals were to develop translocation strategies and model which ones would (1) result in the most groups of wood peckers in a given amount of time, (2) most quickly reach the goal of at least 30 groups of woodpeckers in every population, and (3) result in the fewest population extinctions. We developed lump-sum strategies that moved all the translocated birds to 1 population each year, and partitioning strategies that divided the birds among several populations every year. In our simulations, the lump-sum strategies resulted in the most woodpeckers for the overall program and the highest number of population extinctions. Partitioning strategies had the lowest population extinction rate but produced the lowest rate of increase in the number of woodpecker groups. The model that partitioned birds to the 6 largest recipient populations with fewer than 30 groups was the best overall strategy for meeting our goals because it reached 30 groups in every population the fastest, produced many birds, and had only a moderate population extinction rate. We suggest that adhering to a single strategy that meets the goals of the participants should simplify the program and reduce its cost.

897: +.114

Wild populations of eastern grey kangaroos (*Macropus giganteus*) can pose serious management problems when conditions favor a high population growth rate. Contraception methods are becoming an ethically more acceptable alternative to culling or translocation when dealing with population control of large mammals. We investigated behavioral effects of levonorgestrel contraception in this species. A total of 82.4% of female eastern grey kangaroos treated with levonorgestrel implants did not reproduce, whereas only 12.5% of control females did not reproduce. Levonorgestrel contraception had no significant effect on time spent feeding, scanning, grooming, moving, and sexual interactions with males during the observation sessions. However, control females spent more time in open paddocks feeding than contracepted females over a 24-hr period. Males preferred to associate with groups containing more (and a higher percentage of) control females.

898: +.095

The paper attempts to describe Italian mammal diversity in an evolutionary context. With 122 species according latest researches, Italy holds the richest mammal assemblage among European countries. Specific taxa are often represented by clearly distinctive lineages and several of them appear restricted to the Italian peninsula. Poor knowledge of taxonomy and uncritical application

of IUCN threat categories at the national level could produce a flawed set of conservation priorities, independently from the rigorous application of the proposed guidelines for national Red List assessments. Furthermore, classical conservation assessments and protective legislation only consider traditionally named taxa, often privileging insular taxa of artificial origin but neglecting most of the results of genetic and molecular studies on intraspecific variation. The aim of the present work is to outline the need to incorporate phylogenetic and biogeographic data in the assessment of conservation priorities among mammals in Italy, in order to maximise the national contribution to biodiversity conservation in Europe. To this end, distribution, threat status, intraspecific and supraspecific taxonomy of the native mammal fauna should be analysed in a global context. Phylogeographic patterns emerging from previous studies indicate the general inadequacy of continental European populations serving as sources for re-stocking or re-introductions operations in Italy and the other European peninsulas. Thus the importance of integrating international guidelines on reintroductions with a clear understanding of national biogeographical peculiarities is highlighted.

899: -.022

Live wild animals are confiscated by local, regional, and national authorities for a variety of reasons. Once they have taken possession of these animals, these authorities must dispose of them responsibly, in a timely and efficient manner. Prevailing legislation, cultural practices, and economic conditions will influence decisions on appropriate disposition of confiscated animals. Within a conservation context, there are several possible options from which to choose: 1) to maintain the animals in captivity for the remainder of their natural lives; 2) to return the animals to the wild; 3) to euthanize the animals, i.e., humanely destroy them. The IUCN Guidelines for the Placement of Confiscated Animals discuss the benefits and risks involved in each of these options. These Guidelines should be read in conjunction with the IUCN Guidelines for Re-introductions (IUCN 1998), annexed hereto. They should also be read with reference to the CITES Guidelines for the Disposal of Confiscated Live Species of Species Included in the Appendices (Resolution Conf. 10.7) and the IUCN Guidelines for the Prevention of Biodiversity Loss due to Biological Invasion. Returning confiscated animals to the wild is often considered the most popular option for a confiscating agency and can garner strong public support. However, such action poses real risks and problems and generally confers few benefits. These risks and problems include, but are not limited to, the following.

1. The mortality of animals released from captivity is usually high. Confiscated mammals and birds captured as juveniles have not learned the skills they need to survive in the wild. Other animals may be weakened or otherwise affected by their time in captivity and, thus, less able to survive. Finally, there is little chance of survival if the animals are released at a site that is not appropriate for the ecology or behavior of the species.
2. Animals released into the wild outside of their natural range - if they survive at all - have the potential to become pests or invasive. The effects of invasive alien species are a major cause of biodiversity loss, as such species compete with native species and in other ways compromise the ecological integrity of the habitats in which they have become established.
3. Having been in trade or a holding facility often in association with other wild animals and, in some instances, domesticated ones, confiscated wild animals are likely to have been exposed to diseases and parasites. If returned to the wild, these animals may infect other wild animals, thus causing serious, and potentially irreversible, problems.
4. In many instances, confiscated wild animals have been moved great distances from the site of capture and changed hands several times, such that their actual provenance is unknown. It may, therefore, be impossible or very difficult to establish an appropriate site for return to the wild that takes into account the ecological needs of the species, the animals' genetic make-up, and other attributes that are important to minimize risks (e.g., competition, hybridization) to wild populations at a release site.
5. in cases where the provenance

is known, the ecological niche vacated by that animal may already be filled by other individuals and replacing the animal could result in further undesired disturbance of the ecosystem 6.

Responsible programs to return animals to the wild (c.f. IUCN 1998) are long-term endeavors that require substantial human and financial resources; hence, they can divert scarce resources away from other more effective conservation activities. If returning confiscated animals to the wild is to be consistent with conservation principles and practice, it should a) only be into a site outside of the species' natural range if such an action is in accordance with the IUCN Guidelines for Reintroductions for a conservation introduction; and b) only be practiced in cases where the animals are of high conservation value and/or the release is part of a management programme.

Any release to the wild must include the necessary screening and monitoring to address potential negative impacts, as set forth in the IUCN Guidelines for Re-introductions (IUCN 1998).

Retaining confiscated wild animals in captivity is a clear - and, in most cases, preferable - alternative to returning them to the wild. Clearly, returning animals to their owners will be required in cases of theft. There are a number of options for keeping animals in captivity; however, each of these also has costs and risks. * As confiscated animals are likely to have been exposed to diseases and parasites, if held in captivity, they may infect other captive animals, causing serious, and potentially irreversible, problems. * Finding an appropriate home for confiscated animals can be time-consuming, and caring for the animals during that time can be expensive. * Wild animals have specific nutritional requirements and require specific care. Short-term and long-term humane care of confiscated wild animals requires space, finances and expertise not readily available in many countries. * Transfer of ownership from a confiscating government authority to a private entity - individual or non-commercial or commercial care facility - can raise complicated legal and ethical issues, which are difficult - and time- consuming - to address. Sale or transfer of ownership may - or may be seen to - stimulate demand for these animals and exacerbate any threat that trade may pose to the species. It may also give the appearance that the government condones illegal or irregular trade or, in the case of actual sale, is benefiting from such trade. In addition to avoiding risks to wild populations engendered by return to the wild, keeping confiscated animals in captivity provides other benefits, for example: * Confiscated animals can be used to educate people about wildlife and conservation, as well as the consequences of trade in live wildlife. * Confiscated animals placed in captivity can provide breeding stock for zoos, aquariums, and other facilities, thus potentially reducing the demand for wild-caught animals although the opposite effect may also occur. * In specific instances where the provenance of the confiscated specimens is known, these animals can provide the nucleus, and breeding stock, for possible reintroduction programs. * Confiscated animals can be the subject of a range of non-invasive research, training and teaching programs with important potential benefits for conservation. Euthanasia must be considered a valid alternative to placing animals in captivity or returning them to the wild. Although it may appear counter-intuitive to employ euthanasia, it is by definition a humane act and can be wholly consistent with both conservation and animal welfare considerations. Further, although many confiscating authorities may be wary of criticism elicited by a decision to euthanize confiscated animals, there are a number of reasons to justify its use, including the following: * In many, if not most, circumstances, euthanasia offers the most humane alternative for dealing with confiscated wild animals. 8 * Euthanasia eliminates the genetic, ecological, and other risks that release to the wild may pose to wild populations and ecosystems. * Euthanasia eliminates the serious risk of spreading disease to wild or captive populations of animals. * Euthanasia will often be the least costly option. Establishment of an overall policy framework, with specific procedures for confiscating authorities, will facilitate consideration of the above three options for disposition, including the logistical, legal, and ethical questions that these authorities must address

A radio-tracking study was carried out on a re-introduced population of grey partridges in a 10.6-km² study area located in central Italy, in order to assess mortality rate and to evaluate the feasibility of carrying out large scale re-introductions of the species. Thirty-nine grey partridges were caught by live-traps during winter 2000 and equipped with backpack radio-transmitter. Released birds were offspring of partridges re-introduced previously on the study area and no significant differences were found in survival probabilities between sexes, age classes (juveniles or adults), and weight classes (<400 g or greater than or equal to 400 g), with the exception of the juveniles-adult comparison with the weight class greater than or equal to 400 g. Kaplan-Meier estimates give an average survival of 73.4 days (SE = 15.5). GLM analysis showed an overall interaction effect of the sex, age, and weight ($P = 0.03$). Mortality increased during the covey break up, if compared to other periods, although the differences were not significant; the same was for males, for adults, and for both weight classes, while significant differences resulted for female and juvenile survival rate among periods. Predation was the main mortality source for radio-tagged grey partridges (71.0%), followed by disease (25.8%). The high mortality rate found in our study could be explained in part with the origin of the population that was originally re-introduced using hand-reared grey partridges. Some important negative characters of reared birds, such as the poor anti-predator behaviour and the low diseases resistance, could carry over during the first and following wild generations.

901: +.249

This 20-chapter textbook provides an introduction to genetic principles and practices in conservation and covers topics such as evolutionary genetics of natural populations, loss of genetic diversity in small populations, inbreeding and loss of fitness, population fragmentation, and much more. It is written for the advanced undergraduate and graduate students of conservation, as well as conservation biologists and wildlife managers. Each chapter includes exercises and problems, and the answers are given at the end of the book. Bibliographical references, a glossary, and an index are also included.

902: +.125

During the past two centuries, the meandering Lower Rhine has increasingly suffered under wastewater pollution, engineering projects for shipping traffic, and under settlements built on the former floodplain. However, in the past three decades the pollution has been remarkably reduced through the implementation of sewage treatment plants. This has resulted in a resettlement by both generalist and non-indigenous macrozoobenthos species (MZB) as well as by fish. Because the current species abundance pattern may change from year to year, it may be suggested that the river community (syn. biocoenosis) is continuously impacted by detrimental environmental conditions such as the residue from chemical spills, dispersal of dominating non-indigenous NIZB species, strong fluctuations in the water load of the channel (correlated with long-term exposures of the river banks during low water levels), as well as by the lack of connected backwaters in floodplain areas. In 1987, the Rhine Action Programme focused on the reintroduction of long-distance migrating fish into the ecosystem of the River Rhine, in particular of Atlantic salmon. Migrating fish and their successful reproduction are important ecological signposts that can signalise an optimal rehabilitation of a river ecosystem. Thus, when studying the health of the ecosystem of a large river, the ecological state of salmon spawning grounds in the catchment area must also be taken into consideration. This paper focuses on current ecological problems and makes suggestions for future studies on the Lower Rhine and its tributaries.

903: +.245

The transplantations of *Formica lugubris* carried out in Italy till 1981 were to defend forests against phytophagous Insects and, following the first good results, populations of the species were transplanted in different apenninic areas. In subsequent years pine-woods have lost their economical value almost everywhere and *Bacillus thuringiensis* has become available. However, new studies were studied in the original environment of *Formica lugubris*, observing that environmentally suitable areas, only partially occupied by *Formica lugubris*, were slowly colonized with small populations which break away from large strong neighbouring colonies. The observations above gave birth to a new hypothesis of transplantation, whose objective is to reintroduce the species in some alpine areas of origin, from which it has been eliminated due to human interventions. So the propagation speed of the species into biologically suitable areas would become faster and the forest environment would be enriched by an important element of biodiversity, leading towards conditions of ecological balance more quickly.

905: +.017

In order to conserve the native ichthyofauna and as mitigation procedure to prevent the impact generated by the interruption of the free displacement of fish in the Laja river (Biobio Region), a translocation program for native fish was carried out. Between the years 1997 and 2000 the species composition, community and population structure of the ichthyofauna were studied, determining the need to transfer individuals of three native species with conservation problems: *Diplomystes nahuelbutaensis*, *Trichomycterus areolatus* and *Percilia irwini*. The translocation campaign was carried out in January of the 2001, capturing a total of 1835 fishes, of which 1653 was restocking. The number of survivals of the three species was high during the three phases of the campaign, being upper 90% in each one of them. 852 *P. irwini* were captured and 760 restocked; 643 *T. areolatus* were captured and 591 restocked, and 340 *D. nahuelbutaensis* were captured and 302 restocked. In the three species the highest mortality occurred in the juveniles. *T. areolatus* and *P. irwini* showed greater mortality during data recording (weight and body length), while *D. nahuelbutaensis* resulted more sensitive to the transfer. In all the cases, this mortality was lower to 7%. To enlarge the efficiency of this strategy of conservation we suggested: (a) to avoid the juvenile extractions, (b) to eliminate the phase of taking data of each specimen captured, (c) to reduce the time of fish stored in containers, and (d) to transport the fishes in low densities.

907: +.158

The Reintroduction Plan of Stripless treefrog in Mt. Mendizorrotz (Gipuzkoa province, Basque Country) has started in 1998. The results and monitoring performances are exposed at the present study. Some new pools were constructed for translocation of adults, juveniles and tadpoles. A total number of 675 adults (540 males and 135 females), 40 juveniles and 10.039 bred in semicaptivity tadpoles were translocated from their emergence pools to the arranged Berio, Goienetxe, Arpita and Egiolleta pools resulting in a diverse acceptance degree. In three of the reintroduced pools we confirm the presence of the species in later visits, proving its reproduction in only one of them in 2000. Likewise, 457 adults (330 males and 127 females) were translocated from one to another swimming pool in Berio for increasing population reproductive success.

910: -.009

Since December 1997, 700 blood plasma samples from 31 different species of captive and free-living birds of prey from Spain were analyzed by hemagglutination inhibition (HI) test for the presence of antibodies to avian paramyxovirus (aPMV) 1, 2, and 3. Out of 700 birds, 120 tested positive for aPMV-1, 10 birds had antibodies to aPMV-2, and 4 birds tested positive against

aPMV-3. Prevalence of antibodies against aPMV-1 was significantly higher in captive than in free-living birds of prey and in Falconiformes than in Strigidae and Accipitridae. Infection or exposure in captive birds may be due to the use of avian-derived food in rehabilitation and captive-breeding centers. This may be of concern at the time of reintroduction of these birds into free-living populations.

912: +.112

Genetic monitoring of reintroduced plant populations can allow assessment of the success in establishing new populations that genetically resemble native populations. We used a PCR-based method (Intersimple Sequence Repeats) to quantify genetic variation in four reintroduced populations of *Abronia umbellata* ssp. *breviflora*, an annual forb native to the Pacific Coast that is state-listed endangered in Oregon. The reintroduced populations ranged in size from 18 to 4,111 individuals in the year they were sampled. Genetic variation was also quantified in the natural population that served as the seed source for the reintroduction efforts. A total of 77 loci (bands) was observed using two ISSR primers, providing 65 polymorphic loci. A significant, positive regression was observed between the log of population size for the five populations and genetic variation when measured as percent polymorphic loci (P), expected heterozygosity (H-e), and with a dissimilarity index ($1 - S_{xy}$) based on band sharing. Two of the reintroduced populations maintained approximately 90% of the genetic variation we observed in the source population. Based on these results, we predict that reintroduced populations of *A. u.* ssp. *breviflora* that have at least 1,000 individuals should maintain 90% of the genetic variation of the source population.

913: +.040

Although there is a consensus of opinion that habitat fragmentation has deleterious effects on animal populations, primarily by inhibiting dispersal among remaining patches, there have been few explicit demonstrations of the ways by which degraded habitats actually constrain individual movement. Two impediments are primarily responsible for this paucity: it is difficult to separate the effects of habitat fragmentation (configuration) from habitat loss (composition), and conventional measures of fragmented habitats are assumed to be, but probably are not, isotropic. We addressed these limitations by standardizing differences in forest cover in a clearly anisotropic configuration of habitat fragmentation by conducting a homing experiment with three species of forest birds in the Bow Valley of Banff National Park, Canada. Birds were translocated (1.2-3.5 km) either parallel or perpendicular to four/five parallel barriers that are assumed to impede the cross-valley travel of forest-dependent animals. Taken together, individuals exhibited longer return times when they were translocated across these barriers, but differences among species suggest a more complex interpretation. A long-distance migrant (Yellow-rumped Warbler, *Dendroica coronata*) behaved as predicted, but a short-distance migrant (Golden-crowned Kinglet, *Regulus satrapa*) was indifferent to barrier configuration. A resident (Red-breasted Nuthatch, *Sitta canadensis*) exhibited longer return times when it was translocated parallel to the barriers. Our results suggest that an anisotropic arrangement of small, open areas in fragmented landscapes can have a cumulative barrier effect on the movement of forest animals, but that both modelers and managers will have to acknowledge potentially counterintuitive differences among species to predict the effect that these may have on individual movement and, ultimately, dispersal.

914: +.104

The method and results of monitoring between 1993 and 1995 the reintroduction of 16 beavers originating from the native Rhone population to the North of Alsace are presented. The presence

of the species is attested in 18 localities in the North of Alsace (Fr.) and Bade region (Ger.). The current strengths, which can be estimated to 50-60 individuals are distributed in 26-28 sectors of activity of which 8-10 are occupied by established couples. An important potential of colonisation exists on both sides of the Rhine. However, there are various limiting factors too : obstacles formed by the channelled Rhine, deaths caused by road traffic or by non selective methods of elimination of the coypu and muskrat. Stemming from 4-5 founding couples at the most, the very narrow genetic base of this new sub-population could be widened. Indeed there are possibilities of natural exchanges with those already established in the centre and the South of Alsace and in the nearby Saar basin, and besides this, projects of reintroduction in the German floodplains of the Rhine (Bade and Palatinate regions) studied since the 70's could be executed especially with beavers coming from the native Elbe population.

915: -.015

Two major drainages of southeastern Australia, the Snowy River and the Murray River, were artificially linked by a major hydroelectric project during the early 20th century. This development diverts Snowy River flow into tributaries of the Murray River via a series of extensive tunnels. In 1990, fish surveys of the upper Murray River system recorded *Galaxias brevipinnis*, an aggressive migratory species previously unrecorded from the drainage. We used genetic analysis to discriminate between alternative hypotheses for Murray River *G. brevipinnis*: (i) anthropogenic translocation via the Snowy River diversion or (ii) a previously undiscovered natural population. Landlocked *G. brevipinnis* from the Murray River (43 fish, eight control region haplotypes) and Snowy River (39 fish, 11 haplotypes) exhibit similar levels of mtDNA diversity, share six haplotypes, and are not significantly differentiated for microsatellite loci ($p = 0.0884$). Coastal samples exhibit higher haplotypic diversity (40 fish, 20 haplotypes) but share only three haplotypes with Murray River and are significantly differentiated from Murray River samples for microsatellite loci ($p = 0.0008$). Our data are consistent with the translocation hypothesis but are generally inconsistent with a natural origin for Murray River *G. brevipinnis*. The suggested human-mediated translocation represents a risk to native fauna.

916: +.118

Beaver (*Castor canadensis*) through their dam building activities, store water, trap sediment, subirrigate vegetation, and subsequently improve habitat for fish, wildlife, and livestock. Many landowners realize the benefits that Beaver can bring to a riparian area and are interested in using them to improve this habitat. From 1994 to 1999 we trapped and relocated 234 Beaver to 14 areas throughout Wyoming to improve riparian habitat and create natural wetlands. We attached radio transmitters to 114 Beaver and subsequently determined movements and mortality of released Beaver, and the overall success of our releases. Mortality and emigration (including transmitter failure) accounted for the loss of 30% and 51%, respectively, of telemetered Beaver within 6 months of release. Kaplan-Meier survival estimates were 0.49 (SE = 0.068) for ISO days and 0.433 (SE = 0.084) for 360 days, and did not differ significantly between age classes. On average, 17 Beaver were transplanted to each release site, and at 11 locations, in an attempt to augment single Beaver that had become established and increase transplant success, we transplanted Beaver in two or more years. Success of an individual Beaver's relocation was unrelated to any of the variables we tested, although 2-3.5 year-old Beaver had higher average success (measured in days of occupancy at the release site) than older animals. Animals < 2 years old had 100% mortality and emigration losses within 6 months of release. High predation and mortality rates of our released Beaver may be due to habitat (our streams were shallow with no ponds and provided little protection) and extensive predator communities. We established Beaver at 13/14 of our release

sites and they eventually reproduced. Our results show that Beaver can be relocated successfully but losses from mortality and emigration need to be considered and planned for.

917: +.168

The present paper summarizes the outcome of a roundtable discussion on reintroductions or restocking as a management strategy for native European crayfish, which took place during the European Crayfish conference in Poitiers, France in September 2001. Aspects related to the suitability of the target habitat, the stocking material and the stocking procedure itself are important to consider during any reintroduction measure: Apart from general water quality and structural parameters, a suitable habitat is ideally geographically isolated from other surface waters and human activities such as intensive fishing pressure. However, it is of striking importance to make sure that the target habitat is free of crayfish plague, e.g. by experimental in situ exposure of native specimens. Over-exploitation should be avoided if the stocking material originates from other surface waters and genetic aspects should be considered in stocking material originating from both natural surface waters and crayfish farms. Information for the stocking procedure itself are summarized from experiences gathered in various European countries. As an overall result of the discussion, the following three key questions related to reintroductions of native crayfish arised: 1. Why are the native crayfish not present (anymore) in the target habitat? 2. Do native crayfish survive in situ exposure as a test for crayfish plague? 3. Is the reintroduction or restocking measure successful in establishing a self-sustaining stock of native crayfish?

918: +.265

Irish white-clawed crayfish stocks show high genetic uniformity between systems, although individual populations usually show good heterozygosity. The inference is that they were derived from a single immigrating stock, related to those in Western France. Irish crayfish stocks occur widely and often in good numbers in lakes and streams; they are protected and rarely fished, and there are no alien species. Their use for reintroduction into depleted areas within Ireland, including Special Areas of Conservation, is examined. Irish crayfish also have potential value for restocking depleted continental locations, under stringent conditions of environmental suitability and genetic conformity.

919: -.110

Freshwater crayfish are among the most endangered animals in Europe. Information on freshwater crayfish in the Italian province of South Tyrol was insufficient until the recent studies on their historical and present distribution, which showed the alarming facts that only 15 standing and running waters remained as freshwater crayfish habitats, carrying the native *Austropotamobius pallipes* and the allochthonous *Astacus astacus*, *Orconectes limosus*, and *Pacifastacus leniusculus*. Still ongoing alterations or degradation of water bodies have contributed to the high degree of population decline and loss. While the exotic crayfish *O. limosus* and *P. leniusculus* could develop higher densities, most of the autochthonous *A. pallipes* populations were weak and consisted only of a few individuals. Three populations of *A. pallipes*, however, remained in a good condition, representing potential sources for recovery programs. Protection measures currently carried out in South Tyrol involve breeding, restocking and reintroduction of autochthonous *A. pallipes* individuals in ecological intact water bodies.

920: -.068

Populations of rare clonally spreading species are increasingly being shown to be composed of one or a few genotypes. Clones have potentially unlimited life but two factors, genetic erosion due to random events and increasing accumulation of genetic load in older genotypes, combine to expose them to sexual failure and loss of fertility. Non-breeding clonal populations are at risk of extinction because they lack the ability to adapt or escape from changing environments. Twinflower (*Linnaea borealis* L.) has been lost from nearly 50% of its pre-1970 sites. It is a clonal self-incompatible plant and sexual failure has been reported from Canada, Britain and Scandinavia. Sexual failure is due to high levels of within-clone pollination by flies. Seed set occurs naturally in Scottish populations which have some genetic diversity. A non-breeding population in Scotland has been restored to viability by experimental cross-pollination with pollen from a distant source. Conservation action for this species should therefore be directed to the prevention of loss of habitat and restoration of population viability by translocation of compatible mates. Translocating plants into extant, but non-breeding, populations are still a matter of debate and are frequently opposed. However, experimental translocations must now be performed to establish whether intervention can secure the long-term survival of rare clonal plants without the constant need for re-introduction.

921: +.276

The Jersey population of the Agile Frog has been declining in both range and number since the early 1900s. At the present time, there is only one site on the island that supports a natural agile frog population. Since the 1980s, a captive breeding, reintroduction and habitat management programme involving various organisations has been trying to arrest this dramatic decline in agile frog numbers in the wild. All parties involved agreed that without a clearer understanding of the ecology and habitat requirements of the agile frog in Jersey, it was difficult to develop management techniques for the protection and improvement of key habitat areas. The objectives of the study are to (1) estimate the number of adult frogs through a mark - recapture programme; (2) monitor hatching success and recruitment; (3) study the interactions with other species present in the pond (toads, newts, invertebrates and grass snakes) and in the surrounding area (grass snakes, small mammals and birds); (4) determine the frog's overwintering preferences; (5) monitor the captive breeding programme and carry out an investigation of potential reintroduction sites; (6) develop optimal conditions for captive rearing of tadpoles and consider a health monitoring protocol prior to release of captive raised frogs; (7) compare the habitat requirements of the Agile Frog in Jersey and in northern France. Preliminary results of the study obtained from the observations collected during the first fieldwork season are presented here.

922: +.163

Birds species, like plants and other animals are facing an unprecedented decline. About 11% of bird species are threatened with extinction. Captive breeding as a conservation tool can be used as a substitute for wild populations in research and education, to provide demographic and genetic reservoirs for reinforcing or founding wild populations, and as a last resort for species that have no immediate opportunity for survival in nature. Candidates for captive propagation are zoos, private breeders, state agencies, conservation foundations and research centres within or outside of universities. The problems in managing endangered species have motivated conservation biologists to conduct research in many disciplines such as behaviour, physiology, endocrinology, genetics, husbandry, nutrition and veterinary medicine. In addition, an increasing number of techniques for increasing reproductive success, improving genetic management and enhancing reintroduction success have been employed. Breeding success has been improved by improved knowledge of factors that trigger reproduction and stimulate replacement clutches, as well as by

improvements in artificial incubation and artificial insemination. Assuming that the correct social behaviour group is constituted and the animals start to breed, genetic problems are likely to occur in species with only a few remaining individuals. Once numbers are low, genetic variability is reduced and this brings about diminished ability to respond to environmental change. Recent advances in molecular genetics have enabled studies in taxonomy to be carried out in order to determine species, subspecies and population boundaries. They have also contributed to the theoretical development of small population genetics and demographics aimed at improving ex-situ population management. Captive birds are often hand-reared, but since many behaviours are acquired from the parents, or by experience in the wild, artificial rearing by hand could affect the survival potential of released animals. In order to prevent imprinting on humans and other detrimental effects of hand-rearing techniques, parents, foster-parents, puppets or costumes have been used to rear chicks. Finally, recent developments in research on training programmes to find food, to fly, to avoid specific dangers, or to recognise and to avoid predators, appear to have substantially increased release success in reintroduction programmes.

923: +.138

In the 1930-1960s the moose *Alces alces* L. population increased markedly in northern (Skandinavia) and eastern Europe (the European part of the former Soviet Union), and expanded into western and southern Europe. Polish population of moose was growing in the 1960-1970s (Fig. 1), mainly due to spontaneous increase of the local population inhabiting the Biebrza River valley, as well as due to reintroduction of moose into Kampinos Forest (Central Poland) and immigration of animals from the east and north. Since the early 1980s, moose population in Poland and in whole Europe began to decline (Table 1), predominantly because of severe hunting harvest. In this paper, the major migratory routes of moose in Poland have been mapped and the most important refuges (existing at present or in the period of the biggest densities of moose) were localised (Fig. 2). The proposed program of moose restitution includes restricted or banned hunting harvest in the refuges for several years, improvement of migratory corridors to western Poland and selecting areas for refuges there. The aim of the program is to enable migrations of moose to Germany, as the first step towards restitution of the historical range of this species in Central Europe.

924: +.082

Rates of increase, survival and reproduction were studied in two re-introduced populations of mountain ungulates, the Pyrenean chamois (also named isard, *Rupicapra pyrenaica*) and the ibex (*Capra ibex*) in the French Alps. The populations were monitored from 1983 to 1998 (ibex) or 1984 to 1999 (isard) using capture, marking and resighting of individuals. Population rates of increase were estimated during the colonizing phase from: (1) a time series of estimates of population size; (2) projection matrices based on rates of survival and fecundity. Both populations had exponential rates of increase, with annual multiplication rates of 1.28 for isard and 1.30 for ibex. Age of first reproduction was 2 years in both species, with 77% of females breeding at this age in isard and 43% in ibex. From 3 years of age onwards, 90% of isard and 87% of ibex females bred each year. Survival rates of adult females, estimated using capture-recapture models, equalled 0.94 for isard and 0.98 for ibex, whatever the age and year. The projection matrix led to a slightly lower asymptotic multiplication rate than the time series of population size. Despite adult body size of the ibex being about twice that of the isard, no difference was detected in the intrinsic rate of increase between the two species. This supported the hypotheses of homogeneous life-history traits among ungulates, varying little with body size.

925: +.013

Predation is a common problem limiting the success of efforts to reintroduce vertebrates. Naive animals typically suffer high predation rates soon after release despite strong site fidelity in the first few days that would normally reduce predator encounter rates. However, recent theory predicts that low mobility can be associated with high concentrations of odour wastes that are attractive to predators, leading to low survival for individuals that move little. In this paper we test this model for captive-raised *Microtus* voles reintroduced into suitable habitat in western Finland where they are mainly hunted by chemo-sensing predators. Patterns in vole movement behaviour showed a humped relationship with time: animals moved little soon after release, then made exploratory movements from 3 to 6 days, which then subsided. Predation rates were highest in the first 3 days, with no vole mortalities occurring after voles began substantially moving beyond their release sites. Moreover, voles that survived the 3-week study period were more mobile than voles that were killed by scent-hunting predators, during the initial 3 days and during the final 3 days when voles also had lower mobility. These results suggest that the innate fear response of naive animals, which limit their movements in an unfamiliar environment, may be counterproductive when reduced mobility leads to waste accumulation that is attractive to potential predators. Consequently, pre-release conditioning of captive-raised individuals may need to consider methods to overcome initial release-site fidelity in order to enhance long-term survival prospects after reintroduction. 926: +.076

The northern leopard frog (*Rana pipiens*) was once a common and widespread amphibian found throughout central and southern Alberta. During the late 1970s, the leopard frog experienced a dramatic decline in distribution and numbers over much of its historic range in Alberta. As a result, the leopard frog was designated as "Threatened" under Alberta's Wildlife Act in 1996. The Committee on the Status of Endangered Wildlife in Canada (COSEWIC) lists the prairie population of the northern leopard frog as "Special Concern" (COSEWIC 2000). In 1998, the Alberta Fish and Wildlife Division began to explore the feasibility of reintroducing leopard frogs into formerly occupied habitats in the upper Red Deer River and North Saskatchewan River drainage basins. Large areas of unsuitable habitat limit the ability of the leopard frog to disperse back into historic parts of its range. As a result, a pilot reintroduction project for the leopard frog was initiated in 1999 at the Raven Brood Trout Station near Caroline, Alberta. The project involved the captive-rearing of leopard frogs from egg stage of development to metamorphosed frog, in two man-made outdoor ponds. The primary objective of the project is to re-establish leopard frogs in the headwaters of the Red Deer River and the North Saskatchewan River drainages, consequently allowing natural downstream dispersal along these drainages. Over a three-year period, more than 4500 captive-reared leopard frogs have been released into historic habitat in the upper headwaters of the Red Deer River near Caroline, Alberta. In 2001, 750 young frogs were released at a pilot release site in the upper headwaters of the North Saskatchewan River near Rocky Mountain House, Alberta. All captive-reared and released leopard frogs were marked using a Visible Implant Elastomer (VIE) tagging system that allowed unique marking schemes to be used to assess the success at each release site and monitor the dispersal of released frogs. On 19 June 2001, three previously released leopard frogs were found within the study area near Caroline, marking the first occurrence of leopard frogs in that area in nearly 50 years. At least 10 subadult and adult leopard frogs released in previous years were observed or captured within the study area in 2001 and calling activity was recorded. Evidence of the overall success of the project at the first release site may be realized in the summer of 2002, when previously released frogs reach sexual maturity, breed and successfully produce young-of-the-year frogs. During the 2001 field season,

20 potential leopard frog release sites were investigated in the central parkland region of the province and in the upper headwaters of the Red Deer River near Caroline and the North Saskatchewan River near Rocky Mountain House. At each identified site, data were collected on the availability of breeding and summer habitat. In addition, dispersal opportunities into surrounding habitats, including the Red Deer River and North Saskatchewan River drainages, were considered.

927: -.115

We conducted a literature review of coypu (*Wyocastor coypus*) introduction and eradication efforts worldwide. The coypu (also called nutria) has been introduced from its origins in South America to every continent except Australia and Antarctica. While perceived in some regions as a valuable resource, in most regions the animals are considered a pest species. Coypus have caused damage to water control structures, crops, and marsh systems and are considered a disease host. Eradication efforts have met with varying degrees of success. For those efforts to be successful, the coypu populations must be isolated to prevent reintroduction, harsh winters are necessary to reduce their populations, and intensive trapping efforts must be sustained until the last coypu has been removed.

928: +.113

We evaluated the usefulness of microsatellites and recently developed statistical methods for the conservation management of fragmented and reintroduced populations, using the alpine ibex (*Capra ibex*) as a model species. First, we assessed the effects of past reintroduction programmes on genetic diversity and population differentiation considering different population sizes and histories. We show that genetic variability in ibex populations (H-E approximate to 0.13) is among the lowest reported from microsatellites in mammal species, and that the Alpi Marittime-Mercantour population has suffered from a severe genetic bottleneck associated with its reintroduction. Second, using a computer-simulation approach, we provide examples and rough guidelines for translocation programmes concerning the number and origin of individuals for future reintroductions and for the reinforcement of populations with low genetic variability. Finally, we use the ibex microsatellite data to assess the usefulness of several published statistical tests for detecting population bottlenecks and assigning individuals to their population of origin. This study illustrates that microsatellites allow: (i) evaluation of alternative translocation scenarios by simulating different numbers and origins of 'migrants'; (ii) identification of bottlenecked populations (especially using the Wilcoxon signed-ranks test); and (iii) population assignment with a high certainty ($P < 0.001$) of almost 100% of the individuals (or trophies or carcasses) from two distant populations (especially using STRUCTURE or WHICHRUN software).

929: +.033

Mitochondrial DNA (mtDNA) sequences were used to evaluate phylogeographic structure within and among populations of three endangered Hawaiian tree snail species ($n = 86$). The primary focus of this investigation was on setting conservation priorities for *Achatinella mustelina*. Limited data sets for two additional endangered Hawaiian tree snails, *A. livida* and *A. sowerbyana*, were also developed for comparative purposes. Pairwise genetic distance matrices and phylogenetic trees were generated, and an analysis of molecular variance was performed on 675-base pair cytochrome oxidase I gene sequences from multiple populations of Hawaiian tree snails. Sequence data were analysed under distance-based maximum-likelihood, and maximum-parsimony optimality criteria. Within the focal species, *A. mustelina*, numbers of variable and

parsimony informative sites were 90 and 69, respectively. Pairwise intraspecific mtDNA sequence divergence ranged from 0 to 5.3% in *A. mustelina*, from 0 to 1.0% in *A. livida* and from 0 to 1.9% in *A. sowerbyana*. For *A. mustelina*, population genetic structure and mountain topography were strongly correlated. Maximum genetic distances were observed across deep, largely deforested valleys, and steep mountain peaks, independent of geographical distance. However, in certain areas where forest cover is presently fragmented, little mtDNA sequence divergence exists despite large geographical scales (8 km). Genetic data were used to define evolutionarily significant units for conservation purposes including decisions regarding placement of predator exclusion fences, captive propagation, re-introduction and translocation.

930: +.179

River otters (*Lontra canadensis*) were extirpated from much of their historic distribution because of exposure to pollution and urbanization, resulting in expansive reintroduction programmes that continue today for this and other species of otters worldwide. Bioaccumulation of toxins negatively affects fecundity among mustelids, but high vagility and different dispersal distances between genders may permit otter populations to recover from extirpation caused by localized environmental pollution. Without understanding the influence of factors such as social structure and sex-biased dispersal on genetic variation and gene flow among populations, effects of local extirpation and the potential for natural recolonization (i.e. the need for translocations) cannot be assessed. We studied gene flow among seven study areas for river otters (n = 110 otters) inhabiting marine environments in Prince William Sound, Alaska, USA. Using nine DNA microsatellite markers and assignment tests, we calculated immigration rates and dispersal distances and tested for isolation by distance. In addition, we radiotracked 55 individuals in three areas to determine characteristics of dispersal. Gender differences in sociality and spatial relationships resulted in different dispersal distances. Male river otters had greater gene flow among close populations (within 16-30 km) mostly via breeding dispersal, but both genders exhibited an equal, low probability of natal dispersal; and some females dispersed 6090 km. These data, obtained in a coastal environment without anthropogenic barriers to dispersal (e.g. habitat fragmentation or urbanization), may serve as baseline data for predicting dispersal under optimal conditions. Our data may indicate that natural recolonization of coastal river otters following local extirpation could be a slow process because of low dispersal among females, and recolonization may be substantially delayed unless viable populations occurred nearby. Because of significant isolation by distance for male otters and low gene flow for females, translocations should be undertaken with caution to help preserve genetic diversity in this species.

931: -.065

Thirty-three species of landsnail were recorded during surveys of Great Island in 1996-99. Twelve of these species were endemic to Great Island, and another 17 were restricted to the Three Kings group. One previously recorded species, *Cytora kiama* Climo, 1973, is regarded here as a junior synonym of *Cytora solitaria* (Powell, 1935). For more than 300 years up to 1946, sequential anthropic disturbances severely restricted distributions and diminished populations of many landsnail species on Great Island. Some original landsnail species probably became extinct during this period. Conversely, it is possible that some present-day landsnails originated from accidental anthropic translocations from other islands in the Three Kings group and mainland Northland. Since feral goats (*Capra hircus*) were eradicated from the island in 1946, many formerly rare landsnail species have become widespread and abundant, primarily in response to vegetation changes.

932: +.147

We translocated *Margaritifera hembeli* in 2 streams in central Louisiana to investigate the role of stream, habitat (riffle vs pool), and population density in determining the survival, movement, and growth of transplanted mussels. Translocated animals survived well, although 1 translocation site with few resident mussels suffered high mussel mortality from a spate. Translocated animals grew at rates similar to control animals, especially if moved upstream, but moved at greater rates, especially in high-density riffles. Growth rates differed between streams, and were greater in riffles than in pools; pools, where resident mussels are rare, may be suboptimal habitats for growth. Density had variable effects on growth, and growth rates in some cases actually increased with density. Mussels at higher densities may be feeding on bacteria colonizing pseudofeces or have reduced respiration rates, explaining higher growth rates. Our results suggest that translocation is a viable short-term management strategy for endangered margaritiferids threatened by habitat alteration, and that habitat and population density affect mussel survival and growth.

933: +.123

Genetic diversity of the giant panda was examined by DNA fingerprinting method in order to determine genetic distances between two groups, big and small populations. Results obtained suggest that small population may induce the reduction of genetic diversity of the giant panda and result in extinction of the species. These results suggest the need for reintroduction of individuals into small population for preventing the reduction of genetic diversity in giant panda population.

934: +.075

Animal translocation is an important tool in wildlife management and conservation biology. However, translocation success is generally low for many species as released individuals may be particularly prone to death or fail to breed successfully. We translocated 49 European wild rabbit, *Oryctolagus cuniculus*, from Chevreloup (near Paris) to Fay-de-Bretagne (near Nantes, Loire-Atlantique) in January 1996, and studied their survival and movements during the first three weeks after release. All individuals were ear-tagged with colour reflective paper and monitored by the resighting survey method (nocturnal spotlighting). Twenty-nine of them were also radio-equipped. Thus, thanks to the radiotracking survey, we could ascertain the validity of the resighting survey method to estimate survival rates, despite (i) slight differences in survival rate estimates, and (ii) a partial resighting-dependence (catch-happiness in radio-equipped males). During the first two days after release, the mortality rate was 41-51% due either to stress or predation. Concurrently, an intense and early movement activity was displayed by part of the rabbits. Thereafter, the mortality rate was very low and reached the natural one for non-translocated rabbits. The rabbits finally settled down on average at about 225 m from their respective release warrens. Moreover, no individuals actually left the release area, which promotes population founding. Overall, radio-collars and early movements did not influence survival and resighting probabilities. Otherwise, the resighting rate was negatively correlated with body mass.

935: -.099

The Critically Endangered Pre David's deer *Elaphurus davidianus* became extinct in the wild in China in about 1900, and the only surviving animals were held in captivity, at Woburn Abbey in the UK. During 1985-1987, individuals were returned to China, and subsequent growth of the captive population in enclosures at Dafeng Reserve necessitated a trial release of a small group of deer as a prelude to further releases. Seven individuals were released into the unfenced coastal

region of the Dafeng Reserve in 1998. Behaviour, daily activity rhythm, habitat selection, activity range and body condition were recorded for six months after release. The deer exhibited initial changes in behaviour, but returned to their pre-release patterns about four weeks after release, and by six weeks after release their body condition had improved compared to their previous condition in captivity. They left the Reserve and began to forage on farmland, causing conflict with local people. Further releases should be into areas with either a natural or artificial boundary in order to avoid unmanageable levels of conflict between the needs of the deer and those of farmers.

936: +.190

1. After an absence of almost 100 years, the Eurasian lynx *Lynx lynx* is slowly recovering in Germany along the German-Czech border. Additionally, many reintroduction schemes have been discussed, albeit controversially, for various locations. We present a habitat suitability model for lynx in Germany as a basis for further management and conservation efforts aimed at recolonization and population development. 2. We developed a statistical habitat model using logistic regression to quantify the factors that describe lynx home ranges in a fragmented landscape. As no data were available for lynx distribution in Germany, we used data from the Swiss Jura Mountains for model development and validated the habitat model with telemetry data from the Czech Republic and Slovenia. We derived several variables describing land use and fragmentation, also introducing variables that described the connectivity of forested and non-forested semi-natural areas on a larger scale than the map resolution. 3. We obtained a model with only one significant variable that described the connectivity of forested and non-forested semi-natural areas on a scale of about 80 km². This result is biologically meaningful, reflecting the absence of intensive human land use on the scale of an average female lynx home range. Model testing at a cut-off level of $P > 0.5$ correctly classified more than 80% of the Czech and Slovenian telemetry location data of resident lynx. Application of the model to Germany showed that the most suitable habitats for lynx were large-forested low mountain ranges and the large forests in east Germany. 4. Our approach illustrates how information on habitat fragmentation on a large scale can be linked with local data to the potential benefit of lynx conservation in central Europe. Spatially explicit models like ours can form the basis for further assessing the population viability of species of conservation concern in suitable patches.

937: +.119

1. The effects of predation are among the most pervasive in ecology. As parasitoids, parasites, grazers or top carnivores, predators have large influences on the distribution, density, dynamics and evolved traits of other organisms. Effects scale-up to influence community attributes such as species coexistence and ecosystems processes such as production or trophic cascades. 2. Increasingly, however, some of the largest predation issues fall clearly within the scope of applied ecology. They include instances where, due to their ecological attributes and trophic position: (i) predators are valuable to nature conservation, as biocontrol agents, as natural enemies, or as grazers used in rangeland or ecosystem management; (ii) natural or introduced predators are viewed negatively due to effects on conservation, agriculture, forestry, hunting or disease transmission; (iii) predators are affected by human activities such as, resource exploitation, or from exposure to factors such as biomagnified pollutants and disturbance; (iv) predators are controversial because different groups view them as either desirable or undesirable. 3. In all these cases, ecologists have a pivotal role in facilitating appropriate management. For valued predators, this involves developing sufficient ecological understanding to optimize habitat, increase prey abundance or to reinforce, establish or reintroduce desirable species. For predators considered undesirable, management can involve direct control. In other cases, predation and its

consequences can be mitigated by deterrent, exclusion, supplementary feeding, habitat management to favour prey, predator swamping, or by compensating losses financially. These latter strategies are often used where predators are themselves considered too valuable to remove or control.⁴ This collection of seven papers illustrates many of these themes by examining contrasting aspects of the applied ecology of Eurasian lynx; by further probing the interaction between predatory birds and red grouse; by exploring the effects of weather on biocontrol; and by illustrating effects on plant species where grazing or seed predation play a dominant role.⁵ A key lesson from these and other recent papers in the *Journal of Applied Ecology* is that the successful management of predators depends invariably on understanding adequately the exact ecological context in which predator-prey interactions take place and in which problems arise. With predator-related issues growing rather than diminishing, ecologists will need sufficient resources to maintain current research if they are to provide the understanding required to offer and evaluate sound management.

938: +.121

During the last two decades, the State of Connecticut has restored tidal flow to many impounded salt marshes. One of the first of these and the one most extensively studied is Impoundment One in the Barn Island Wildlife Management Area in Stonington, Connecticut. In 1990, twelve years after the re-establishment of tidal flooding, the density of the marsh snail *Melampus bidentatus*, the numerically dominant macroinvertebrate of the high marsh, in Impoundment One was about half that in reference marshes below the breached impoundment dike. By 1999 the densities of *Melampus* above and below the dike were not significantly different, but the shell-free biomass was greater above the dike as a result of the somewhat larger number and size of the snails there. Twenty-one years after the renewal of tidal flooding, three marsh macroinvertebrates (the amphipods *Orchestia grillus* and *Uhorchestia spartinophila* and the mussel *Geukensia demissa*) were significantly less abundant in the previously impounded marsh than in the reference marshes, whereas another amphipod (*Gammarus palustris*) was more abundant above the breached dike where conditions appeared to be somewhat wetter. In 1991 the fish assemblage in a mosquitocontrol ditch in Impoundment One was similar to that in a ditch below the breached dike; however, the common mummichog *Fundulus heteroclitus* appeared to be less abundant in the restoring marsh. By 1999 the number of mummichogs caught in ditches was significantly greater in Impoundment One than in the reference marsh, but the numbers of mummichogs trapped along the tidal creek were comparable above and below the dike. The results obtained in this study and those of other restoring marshes at Barn Island indicate the full recovery of certain animal populations following the reintroduction of tidal flow to impounded marshes may require up to two or more decades. Furthermore, not only do different species recover at different rates on a single marsh, but the time required for the recovery of a particular species may vary widely from marsh to marsh, often independently of other species.

939: +.062

Translocation is an important management strategy in conservation programs for endangered or threatened species, including native cutthroat trout (*Oncorhynchus clarki*) in the western United States. Most subspecies of cutthroat trout have declined to <5% of their historical range, and both historical and translocated populations now persist in small isolated fragments of habitat. Success rates for translocations of fishes are generally <50%, and habitat quality or quantity are frequently cited as the cause of failure. Therefore, we conducted field surveys of stream-scale habitat and measured basin-scale habitat using a Geographic Information System for 27 streams where two subspecies of cutthroat trout were translocated in Colorado and New Mexico, to identify specific

habitat attributes that contribute to the success of translocations. We used polytomous logistic regression to develop models that predict three categories of cutthroat trout translocation success (high, low, absent) from habitat attributes at two spatial scales. Models based on stream-scale habitat attributes indicated that cold summer water temperature, narrow stream width, and lack of deep pools limited translocations of cutthroat trout. Cold summer temperatures are known to delay spawning and prolong egg incubation, which reduces the growth of fry and likely limits their overwinter survival. Furthermore, small streams with few deep pools may lack the space necessary to permit overwinter survival of a sufficient number of individuals to sustain a population. Models based on basin-scale habitat were not as effective as stream-scale habitat models for distinguishing among translocation sites with high, low, or absent population status but indicated that a minimum watershed area of 14.7 km² was useful as a coarse filter for separating sites with high numbers of cutthroat trout from those with low or absent status. Watersheds larger than this are expected to encompass low-elevation habitat that provides warmer summer temperatures and to have relatively wide stream channels of sufficient length to provide an adequate number of deep pools. These results indicate that the appropriate scale of habitat measurement for predicting cutthroat trout translocation success in fragmented watersheds is at the patch rather than landscape scale, which is similar to results for other salmonids and vertebrate taxa in general.

940: +.126

We translocated 80 individuals of *Phrynocephalus guttatus guttatus* into non-occupied isolated sand dune in Southern Kalmykia in June 1998. Observations during the following two years signify to the viability of the population. The demographic structure remained stable since 1999, signifying to the congruence of habitat quality and ecological demands of the lizard species. We evaluated differences in the rate of postnatal development of males and females. In result, the number of sexually active males prevailed over the number of receptive females during the reproductive period, increasing probability of females' pregnancy. Maximum life span of Ph.g. *guttatus* was estimated as up to four years.

941: +.060

Aim Many species find themselves isolated from the predators with which they evolved. This situation commonly occurs with island biota, and is similar to moving from the dangerous inner-city to the suburbs. Economic thinking tells us that we should expect costly antipredator behaviour to be lost if it is no longer beneficial. The loss of antipredator behaviour has important consequences for those seeking to translocate or reintroduce individuals from predator-free islands back to the predator-rich mainland, but we have neither a detailed understanding of the mechanisms of loss nor information on the time course of relaxed selection. **Some antipredator behaviours are experience-dependent: experience with predators is required for their proper performance.** In these cases, antipredator behaviour is lost after only a single generation of isolation, but it should be able to be regained following exposure to predators. Other behaviours may be more 'hard-wired'. The evolutionary loss of antipredator behaviour may occur over as few as several generations, but behaviours may also persist for many thousands of years of predator-free living. **Location** Australia and New Zealand. **Methods** I discuss the results of a series of studies designed to document the mechanisms and time course of relaxed selection for antipredator behaviour in macropodid marsupials. **Controlled studies of visual, acoustic and olfactory predator recognition, as well as field studies of antipredator vigilance focused on several species of kangaroos and wallabies.** **Results** Visual predator recognition may be retained following 9500 years of relaxed selection, but olfactory and acoustic predator recognition may have to be learned. **Insular populations allow humans to approach closer before fleeing than mainland**

animals. Insular species may retain 'group size effects' - the ability to seek safety in numbers - when they are exposed to any predators. Main conclusions I suggest that the presence of any predators may be an important factor in maintaining functional antipredator behaviour. Managers should pay particular attention as to the source and evolutionary history of their population when planning translocations or reintroductions.

942: +.141

Aim We studied dynamics of four populations of New Zealand forest birds for 5-9 years after reintroduction to islands. We primarily aimed to predict whether these populations were viable, and what, if any, management was needed to maintain them. However, the small scale of these islands also provided an opportunity to study density-dependent population growth over a short time frame. **Location** We studied New Zealand robin (toutouwai, *Petroica australis*) and stitchbird (hihi, *Notiomystis cincta*) populations reintroduced to Tiritiri Matangi, a 220-ha offshore island near Auckland, and saddleback (tieke, *Philesturnus carunculatus*) and stitchbird populations reintroduced to Mokoia, a 135-ha island in Lake Rotorua. These islands are free of mammalian predators, but have highly modified habitat following clearing and regeneration. **Methods** We closely monitored each population, individually marking all or most of the birds and in some cases experimentally manipulated population density or food supply. We used model selection procedures to understand factors affecting survival, fecundity and dispersal, and developed stochastic simulation models. **Results** The Tiritiri Matangi robin and Mokoia saddleback populations grew without management and appear to be viable. Both showed strong evidence of density-dependent growth, with fecundity (saddlebacks) and juvenile survival (both populations) declining with increasing density. Neither stitchbird population appears viable without management and supplementation experiments showed reproduction and/or survival to be limited by food supply. The Tiritiri Matangi population appears viable as long as supplementary feeding continues. However, the Mokoia population has a high mortality rate regardless of supplementary feeding, resulting in tenuous viability even with intensive management. Mokoia stitchbirds suffer from infection by *Aspergillus fumigatus*, a pathogenic fungus that is prevalent in highly modified habitats and more abundant on Mokoia than Tiritiri Matangi. **Main conclusions** Some forest birds can thrive in regenerating forest on islands and strong evidence of density dependence can be detected in such populations in as little as 5 years. This allows density-dependent models to be developed, providing guidance when island populations are harvested for further translocations. Other species are limited by food supply in regenerating environments, a problem potentially overcome by management. However, prevalence of *A. fumigatus* may render highly modified environments uninhabitable by some species regardless of management.

943: +.071

Aim Success with eradicating invasive species from islands around New Zealand raises the prospect of reversing the loss of species by restoring biotic communities on modified islands. I seek to identify methods that can be used to clarify restoration targets on Korapuki Island, which was modified by introduced mammals until 1987. **Location** Korapuki, Green and Middle islands, Mercury Islands, north-eastern New Zealand. **Methods** I describe methods of identifying restoration targets by using biogeographical frameworks, and benchmark systems based on neighbouring unmodified islands. Methods that can help identify directions and rates of change are also investigated. **Results** The benchmark islands (Middle and Green) have complex forest systems with a distinctive component of large, flightless invertebrates, dense populations of tuatara *Sphenodon punctatus* (Gray), dense and diverse populations of lizards and dense populations of burrowing seabirds. The restoration island (Korapuki) has simplified forest systems, few large

invertebrates, no *S. punctatus*, a depauperate fauna of lizards and scattered populations of seabirds. These differences are consistent with the recorded effects of rabbits *Oryctolagus cuniculus* (L.) and Pacific rats *Rattus exulans* (Peale) removed from Korapuki Island in 1986-87. Three restoration scenarios are described and restoration targets identified. Time scales for natural succession are likely to be influenced by a long-lived colonizing tree species that now predominate over much of the island. The rate of expansion of reintroduced animals is influenced by the very low productivity of many of the species apparently extirpated by introduced mammals. Main conclusions Ecological restoration of island ecosystems has been likened to reconstituting the ambiguous because of conceptual and practical difficulties. Goals for restoration of island systems are often dependent on value judgements. Biological outcomes or targets can be clarified by the use of unmodified neighbouring islands as benchmarks. However, successional pathways on the restored island may not converge with the benchmarks because of environmental differences between sites.

944: +.256

We develop a stochastic model of population viability which explicitly links demography and genetics in order to examine the consequences for extinction dynamics of different levels of heritable fitness variance within a population. We particularly focus on situations in which a local small population is artificially built with individuals that were taken from several large source populations. Our results suggest that different levels of fitness variability within a population (due to partially recessive deleterious alleles rather than local adaptation) have a large influence on its viability. Moreover, the optimal level of fitness variance for maximizing population persistence is a function of the species life-cycle. Two mechanisms with opposite effects are mainly responsible for the different patterns of extinction obtained depending on the life-cycle, (1) purging of deleterious alleles, (2) demographic stochasticity. For high growth rate or long-lived species, a high fitness variance decreases short-term viability and increases long-term viability. In contrast, for other cases, a high fitness variance increases both short- and long-term viability.

945: +.024

Many species modify their behaviour in response to the scents of their predators, but species or populations living without predators may lose such abilities. This loss has been suggested to be irreversible, and to constitute a significant hurdle in restoring historical ecosystems. Olfactory predator recognition was studied in two macropodid marsupials - the tammar wallaby (*Macropus eugenii*) and the red-necked pademelon (*Thylogale thetis*). Both species are in the 'critical weight range' of Australian native mammals that have been negatively affected by the introduction of novel predators since European settlement. Predator-naïve animals were tested by exposing subjects simultaneously to two feeders with either a predator or a herbivore faecal or urine sample beneath the food tray. The presence of predator olfactory cues beneath the feeder did not affect foraging behaviour or feeder use when compared to control stimuli (herbivore faeces or urine). Previous studies have found that predator-experienced herbivorous marsupials modify their behaviour in the presence of predator scents. In contrast, our studies of predator-naïve individuals found no evidence of such selectivity, suggesting that marsupial herbivores may have to learn to modify their behaviour in response to olfactory cues from predators. This implies that the loss of olfactory predator recognition may not be irreversible. Animals translocated from predator-free areas could potentially be trained to recognise the smells of their predators.

946: -.109

Progressive diebacks of outer canopy branchlets of *Ceanothus crassifolius* were repeatedly observed after rainless periods up to 9 mo in duration in the Santa Monica Mountains of southern California. Mean xylem pressures of branchlets near the end of drought were as low as -11.2 MPa (N = 22) with a mean of about 60 dead branchlets per shrub. Inoculation (N = 15) with three species of fungi previously isolated from the same population of *C. crassifolius* did not promote dieback, suggesting that the observed decline was not fungal induced, as had been proposed. Further, at least 50% of healthy-appearing twigs, without symptoms of dieback, contained isolatable endophytic fungi. We used a centrifugal force method to determine the range of xylem pressure causing cavitation (vulnerability curves) for branchlets (N = 12) and roots (N = 16). We combined vulnerability curves with soil texture data (N = 6) into a water transport model that estimated the critical values (P-Lerit) of leaf xylem pressure associated with the loss of water from soil to foliage. Maximum P-Lerit was between -10 and -11 MPa and within the range of minimum measured xylem pressures of branchlets during drought and dieback. Branchlet dieback correlated with seasonal declines in xylem pressure in concert with declining safety margins from hydraulic failure. Symptoms of dieback were duplicated in the field by partially severing stem xylem that normally supplied branchlets with water. Taken together, these results indicate that loss of hydraulic conductance to foliage was the probable cause of the observed dieback in *C. crassifolius*. Partial dieback of peripheral branchlets, and its attendant reduction in evaporative surface area, may be a last-resort mechanism for whole-plant water conservation and drought survival in this species.

947: +.025

Approximately three million years ago the Isthmus of Panama formed an impenetrable land barrier between the tropical eastern Pacific Ocean and the tropical western Atlantic Ocean. Since this time, isolated geminate species have evolved from once contiguous populations, either side of the barrier. One such organism whose distribution is divided by the Isthmus is the tropical brittlestar *Ophiactis savignyi*, once suggested to be the most common brittlestar in the world. Rather than showing a genetic pattern consistent with a history of isolation, we show that this species has recently dispersed between the Pacific Ocean and the western Atlantic Ocean. This conclusion is based upon a phylogenetic analysis using sequences of the COI mitochondrial DNA gene from these populations. Identical haplotypes between oceans, and a genetic signature of population expansion, provide compelling evidence that the western Atlantic contains at least one cluster of haplotypes recently derived from the Indo-Pacific. Inadvertent human-aided translocation of individuals, presumably in ballast water or fouling communities, is strongly implicated as a mechanism for dispersal between oceans. We believe that cryptic marine invasions are likely to be common and our awareness of them will rapidly increase as systematic and phylogeographic knowledge of marine taxa grow.

948: +.268

The IUCN/SSC Re-introduction Specialist Group: Guidelines for Nonhuman Primate Re-introductions is intended as a guide to re-introduction programmes. The priority has been to develop standards that are of direct, practical assistance to those planning, approving, or implementing reintroductions. The primary audience of these guidelines is the re-introduction practitioner. Because re-introduction projects are often restricted by location, resources, and other limitations, this document is meant as a "best-practice" model, or an ideal code of conduct. Re-introduction managers are strongly encouraged to use this document as their principal guide to primate reintroductions. Each re-introduction project should develop written guidelines that apply specifically to its taxon, region, legal structure, etc. These customised documents should be

updated over time and eventually result in a re-introduction manual for the taxon of interest. They should also directly relate to this existing document, so these guidelines can be regularly updated with new information and techniques. Guidelines for Nonhuman Primate Re-introductions covers the main steps of a re-introduction effort. The steps are listed in a suggested order of execution, although some steps overlap with one another (see "Basic Principles of Reintroductions," below). It is realised that many projects have been operating for some time, so managers of these projects should attempt to integrate the guidelines as soon as possible into their current operating procedures and protocol. Before initiating any re-introduction project, managers must clearly define why that project is needed and conduct a rapid overall assessment to ensure key requirements, such as habitat suitability, can likely be met. The main goal of any re-introduction effort should be to re-establish self-sustaining populations of primates in the wild and to maintain the viability of those populations. Although exceptions to this, such as trial re-introductions of common species and rescue/welfare releases, should also adhere to these guidelines as much as possible, such projects are not considered true re-introductions or conservation approaches and are not specifically covered in these guidelines. Re-introduction practitioners are strongly encouraged to contact the IUCN/SSC Re-introduction Specialist Group (RSG) and present and discuss their re-introduction proposals and results (see Annex III, Page 54). As a result, a network of contacts can be developed and information from various projects shared. Note that details regarding the care of animals held in captivity prior to release, such as enclosure enrichment, are not specifically covered in these guidelines. However, where appropriate, important points regarding these topics will be noted.

949: +.125

Biodiversity provides to the humankind enormous direct economic benefits and an array of indirect essential services through natural ecosystems. Biodiversity is essential for the ecosystem function and stability; several hypotheses are being tested for the relationship between biodiversity and ecosystem function. Biodiversity at the global scale is a balance between the rate of speciation and the rate of extinction. At a regional level it is a balance between the rates of immigration/invasion and that of local/regional extinction. The current rates of extinction are 1000-10000 times higher than the background rate of 10-7 species/species year inferred from fossil record. Today we seem to be losing two to five species per hour from tropical forests alone. This amounts to a loss of 16 m populations per year or 1800 populations per hour. Biodiversity is not uniformly distributed on the earth. There are broad global patterns, and regional and local concentrations of biodiversity. About 44% of vascular plants and 35% of vertebrates are concentrated as endemic species in 25 hotspots, which account for only 1.4% of the global land area. There are several theories to explain the nonuniform distribution of biodiversity. Biodiversity can be assessed at genetic, population, species, ecosystem and landscape levels, at three spatial scales, viz. local, regional, and global. The strategies to conserve biodiversity include establishment of protected area network and corridors with emphasis on appropriate levels of management, reduction of anthropogenic pressure on natural population by cultivating them elsewhere, programmes of augmentation, reintroduction and introduction of target taxa, and in situ techniques such as establishing botanical and zoological gardens, and banks of pollen, seed, tissue culture, DNA, etc.

950: +.221

Although New Zealand's native fauna shares a Gondwana origin with that of Australia, there are major differences between our countries. The near-absence of land mammals and the restricted biodiversity and habitat range of New Zealand, contrast with the species-rich fauna and habitat

variety of Australia. Both countries share an unenviable extinction record, particularly birds in New Zealand and mammals in Australia. Introduced mammals, often interacting with habitat destruction, have frequently been responsible for these losses in New Zealand. In some places, entire vertebrate foraging guilds have disappeared. On the mainland, control of introduced mammals has had limited success but a steadily increasing number of islands have been cleared of alien mammals. This has created new opportunities for translocating threatened species of native vertebrates and invertebrates to pest-free islands. It has also created options for substituting an ecologically similar species for one that is extinct, thus potentially achieving a more comprehensive restoration. Recent progress with island restoration has stimulated a "mainland island" strategy involving simultaneous intensive control of several pest mammals within a limited area that is then used to re-establish viable populations of threatened species. Examples are given to illustrate these conservation actions.

951: +.038

We describe the isolation, development and application of seven microsatellite loci in the eastern wild turkey, *Meleagris gallopavo silvestris*, as well as their amplification and levels of polymorphism in the domestic turkey. The number of alleles per locus ranged from 5 to 15 and average heterozygosity was high for almost all loci. Domestic turkeys showed significantly reduced numbers of alleles per locus and overall heterozygosities when compared to eastern wild turkeys. The high variability in these markers should provide the level of resolution required to continue studies of wild turkey population genetics.

952: -.035

Eight polymorphic microsatellite loci have been characterized for the endangered St Lucia Whiptail Lizard *Cnemidophorus vanzoi*. Endemic to two small islets, Maria Major and Maria Minor, off the coast of St Lucia, Lesser Antilles, the world population is estimated at < 1000 individuals. However, representatives of the systematically complex genus *Cnemidophorus*, containing sexual species and parthenogenetic allopolyploids, are distributed widely in North, Central and South America, and on several islands in the Caribbean Sea. These microsatellite markers are being used to monitor the genetic structure of a population of St Lucia Whiptails, recently founded through translocation, on the nearby Praslin Island.

954: +.179

Artificial breeding for endangered species and subsequent reintroduction are often implemented as conservation strategies, but the reliability of the measures in avoiding the extinction of wild populations is questionable. In this study, we demonstrated reduced genetic variability in a farmed population of the Chinese sucker (*Myxocyprinus asiaticus*) by DNA fingerprinting. Direct parameters (genetic variability, hypervariable loci and heterozygosity) and indirect parameters (band-sharing coefficient and allelic frequency) revealed that artificial breeding of this species caused the reduction of genetic diversity below historic levels, which predicts reduced individual fitness and lower population adaptability than in historic individuals. As a result, conservation efforts, including the introduction of parent fish from natural waters into farmed populations, are needed to improve the genetic structure of farmed breeding stock and to maximize chances for persistence of the whole species after subsequent reintroduction of farmed individuals.

955: +.056

Approximately 440 base pairs (bp) of the mitochondrial 16S ribosomal ribose nucleic acid (rRNA) coding region were sequenced from 13 marron, *Cherax tenuimanus* (Smith), samples from six locations and samples of two additional *Cherax* species from Western Australia. The results indicated that, with the exception of the Margaret River, no variation was found within or between marron populations. In contrast, marron from the Margaret River were found to be polymorphic for two divergent haplotypes (2.76% divergence). These findings were consistent with allozyme data that highlight the general lack of genetic variability within and between populations of this species apart from the Margaret River stocks. The genetic polymorphisms in the Margaret River stocks contrasted with earlier studies and indicated the recent translocation and mixing of genetically differentiated stocks within this river system. The implications of these findings for the conservation and management of genetic diversity within marron are discussed.

956: +.217

The world's fish species are under threat from habitat degradation and over-exploitation. In many instances, attempts to bolster stocks have been made by rearing fish in hatcheries and releasing them into the wild. Fisheries restocking programmes have primarily headed these attempts. However, a substantial number of endangered species recovery programmes also rely on the release of hatchery-reared individuals to ensure long-term population viability. Fisheries scientists have known about the behavioural deficits displayed by hatchery-reared fish and the resultant poor survival rates in the wild for over a century. Whilst there remain considerable gaps in our knowledge about the exact causes of post-release mortality, or their relative contributions, it is clear that significant improvements could be made by rethinking the ways in which hatchery fish are reared, prepared for release and eventually liberated. We emphasize that the focus of fisheries research must now shift from husbandry to improving post-release behavioural performance. In this paper we take a leaf out of the conservation biology literature, paying particular attention to the recent developments in reintroduction biology. Conservation reintroduction techniques including environmental enrichment, life-skills training, and soft release protocols are reviewed and we reflect on their application to fisheries restocking programmes. It emerges that many of the methods examined could be implemented by hatcheries with relative ease and could potentially provide large increases in the probability of survival of hatchery-reared fish. Several of the necessary measures need not be time-consuming or expensive and many could be applied at the hatchery level without any further experimentation.

957: +.132

The reintroduction of anadromous alewives, *Alosa pseudoharengus*, to their historic habitats in the inland waters of the United States and Canada, has prompted concerns about possible interactions with a popular sport fish, white perch, *Morone americana*. Both species are now widely distributed in northeastern North America. Diets of white perch in Lake George, Maine, U. S. A., where alewives were absent, were monitored and compared with those of white perch populations that were sympatric with anadromous alewives in two coastal Maine lakes, Biscay Pond and North Pond. In the presence of introduced alewives, the diet of adult white perch became almost exclusively juvenile alewives by late summer in ponds where both species were present. White perch that were sympatric with alewives were more piscivorous than were Lake George white perch, which primarily consumed Cladocera. Not only were alewives the principal prey item in the diet of white perch in Biscay and North ponds, but adult alewives were largely cannibalistic by August. Thus, success of reintroducing anadromous alewives in waters containing white perch may be negatively impacted by predation as well as cannibalism.

958: **-028**

Many interior populations of cutthroat trout *Oncorhynchus clarki* are at increased risk for extinction because of small population size and the limited length of habitable streams. Further, many of these streams cannot be altered to provide adequate conditions for population persistence. I constructed a stage-based stochastic population matrix model to (1) evaluate reintroduction strategies for streams capable of population restoration and (2) evaluate the feasibility of maintaining populations through periodic supplemental stocking. In general, stocking adults reduced extinction risk more than did stocking comparable numbers of age-0 fish, subadults, or subadults plus adults. Moreover, the greater the numbers of fish stocked, the greater the decrease in extinction risk. When reintroducing populations for restoration, stocking at least 250 adults (10% of the carrying capacity) in a one-time reintroduction event was as effective in achieving population persistence as stocking multiple times over several years. In contrast, the use of age-0 fish or subadults required either repeated stocking over multiple years or adding large numbers of fish relative to the carrying capacity. The persistence of restored populations did not differ substantially between the multiple-year stocking strategies when fish were added during years 1, 2, and 3 or during years 1, 3, and 5. Simulations of supplemental stocking showed that even very small populations were persistent when stocked with as few as 10 adults every 10-20 years. The results of the simulation model indicate that supplementing populations may be an effective conservation strategy to achieve long-term population persistence if no other options for expanding population capacity exist.

959: **+021**

Relocation programs have restored elk (*Cervus elaphus*) to portions of its vast historical range. We examine the consequences of these relocation programs by assessing variation at 10 microsatellite loci in three elk herds, a source herd (Yellowstone National Park), a large herd reintroduced from Yellowstone (Custer State Park) and a bottlenecked herd reintroduced from both Yellowstone and Custer (the Pennsylvania herd). Observed single locus heterozygosities ranged from 0.000 to 0.739. Multi-locus heterozygosities ranged from 0.222 to 0.589. Although significant differences were detected among all three herds, the Yellowstone National Park and Custer State Park herds possessed similar levels of variation and heterozygosity, and the genetic distance between these two herds was small. The Pennsylvania herd, on the other hand, experienced a 61.5% decrease in heterozygosity relative to its source herds, possessed no unique and few rare alleles, and the genetic distances between the Pennsylvania herd and its sources were large. Simulations were performed to identify bottleneck scenarios in agreement with levels of variation in the Pennsylvania herd. Our data confirm that the rate of population growth post-relocation may have important genetic consequences and indicate that theoretical predictions regarding the maintenance of genetic variation during relocation events must be viewed with caution when small numbers of a polygynous species are released.

960: **+135**

The first hypervariable fragment (HVI) of the mitochondrial DNA control region was sequenced in 90 individuals of the European roe deer (*Capreolus capreolus*) from the Alps, central Italy and Spain. Pooling these data with 70 published sequences from several European regions, we were able to identify patterns of divergence within the Italian peninsula, and in Europe in general. The results we obtained can be summarized as follows. First, the genetic structure of European roe deer populations is substantial (Phi(ST) values around 0.6). Second, the divergence between some central Italian populations, the Alpine group (which is genetically close to the French, the Spanish

and the Norwegian samples) and the Eastern European populations seems to reflect Upper Pleistocene subdivisions, possibly related to three southern European refugia. Third, a different group of central Italian individuals probably diverged more recently from the Alpine group, and their attribution to the subspecies *C. c. italicus* does not appear justified. Fourth, the analysis of mitochondrial DNA in the roe deer can be used to identify recently reintroduced animals in the western Alps which clearly cluster within the Eastern European group, thus providing an important tool for conservation and management strategies for this species.

961: -.039

All remaining populations of the wild Asiatic buffalo are known to cross breed with domestic and feral forms living in the vicinity of the handful of reserves in which the species is found. Censuses of these animals done in various places in India and Nepal have been criticized because researchers have used various criteria to differentiate wild buffalo versus feral backcrosses, thus rendering population estimates unreliable. Due to the highly endangered status of the wild buffalo, there is an urgent need for a set of criteria that can be applied more broadly to distinguish wild from feral forms. This paper describes the phenotypic and behavioural characteristics used to census wild buffalo and feral backcrosses in Kosi Tappu Wildlife Reserve, Nepal, which contains the last Nepalese population of the species. It is hoped that other researchers in the region may find these field characteristics useful in identifying wild stocks in South and Southeast Asia, where they are still thought to occur. Ideally, in all cases, detailed genetic studies are needed to plan managerial interventions such as translocation projects. Given the expense of such studies, it is suggested that translocations can be planned using consistent field identification criteria, until such time as more detailed genetic work is done.

962: +.065

The Carpentarian rock-rat (*Zyzomys palatalis*) is a critically endangered endemic rodent known from only four sandstone gorges in the southeast Gulf of Carpentaria, Northern Territory, Australia. These gorges harbour thickets of monsoon rainforest and broadleaf woodland, surrounded by a Eucalypt savanna matrix. The long-term persistence of *Z. palatalis* is threatened by altered fire regimes, grazing by feral animals and stock, weed intrusion, and the stochastic hazards associated with small, fragmented populations. To assess the relative importance of these threats and develop practical management options, a population and habitat simulation model was developed, based on the best existing data. Population viability was predicted to be highly sensitive to the frequency of hot, late dry-season fires. Progressive habitat degradation (due predominantly to intense late dry-season fires) is likely to substantially reduce population size and lead to the probable extinction of the species within the next 100 years. The most effective management strategy to counteract this threat would be regular, controlled, fuel reduction burns in the vegetation around the gorge entrances during the early dry season. Establishing a new population (through translocation of captive-bred individuals) would not appreciably reduce extinction risk, but could provide valuable additional data on the impact of threats, if conducted as an adaptive management experiment. (C) 2002 Published by Elsevier Science Ltd.

963: +.130

New Zealand Robins (*Petroica australis*) were reintroduced to Tiritiri Matangi, a highly modified island undergoing an extensive revegetation program. The island had only 13 ha of fragmented forest likely to be suitable for robins. We wished to determine whether the population was likely to persist until additional habitat became available through maturation of the revegetation and,

therefore, whether it was sensible to reintroduce this species early in the restoration program. We used an information-theoretic approach to model survival, fecundity, sex ratio, and juvenile dispersal for this population, based on data collected in the first 6 years after reintroduction. This involved nominating a limited set of plausible models for each process and then selecting the models that best explained the data based on Akaike's information criterion. We used mark-recapture analysis on survey data to model survival and general linear modeling on fecundity data. The best models were as follows: (1) juvenile survival declined as population size increased, whereas adult survival was constant among years; (2) fecundity was substantially lower for females in their first year after translocation and varied among forest patches, but did not vary among age classes or years; (3) the expected sex ratio of recruits was 50:50; (4) the distribution of recruits depended on the number of existing residents in patches and patch sizes, but not on patch isolation. We used VORTEX to simulate the dynamics of the population based on these models and associated parameter estimates. The population was predicted to have negligible chance of extinction over several decades under current conditions, and this prediction was not sensitive to uncertainty in parameter estimates or model structure. Maturation of the planted matrix should allow the population to expand to several hundred birds over the next few decades, preventing extreme loss of genetic variation. We therefore conclude that the early reintroduction of this species was reasonable, despite the limited habitat available at the time. Our results show that it is critical to obtain data for the first few years after reintroduction if habitat is likely to be limited, because it is otherwise impossible to detect density-dependent processes critical to population viability. Results also show that the first year after reintroduction may be misleading if considered alone.

964: +.186

Grevillea scapigera is one of the world's rarest plant species, currently known from only five plants in the wild. In 1995, 10 plants were selected from the 47 plants known at the time to act as genetically representative founders for translocation into secure sites. Ramets were micropropagated and introduced into one of these secure sites (Corrigin) in 1996, 1997, and 1998. By late 1998, 266 plants had been successfully translocated and were producing large numbers of seeds. With the development of an artificial seed-germination technique and because of an absence of seed germination in situ, seed was collected from these plants and germinated ex situ, and 161 seedlings were returned to the field site in winter 1999. We used the DNA fingerprinting technique of amplified fragment-length polymorphism (AFLP) to (1) assess the genetic fidelity of the clones through the propagation process, (2) contrast genetic variation and average genetic similarities of the F1s to their parents to assess genetic decline, and (3) assign paternity to the reintroduced seeds to assess the reproductive success of each clone. We found that 8 clones, not 10, were present in the translocated population, 54% of all plants were a single clone, and the F1s were on average 22% more inbred and 20% less heterozygous than their parents, largely because 85% of all seeds were the product of only 4 clones. Ultimately, effective population size (N_e) of the founding population was approximately two. Our results highlight the difficulty of maintaining genetic fidelity through a large translocation program. More generally, rapid genetic decline may be a feature of many translocated populations when N_e is small, which may ultimately threaten their long-term survival. Strategies to reverse this genetic decline include equalizing founder numbers, adding new genotypes when discovered, optimizing genetic structure and plant density to promote multiple siring and reduce kinship, promoting natural seed germination in situ rather than artificially germinating seeds ex situ, and creating a metapopulation of numerous translocated populations to restore historical distribution patterns and processes.

965: +.145

Translocations of reptiles and amphibians have been questioned as a conservation tool because they generally have not been successful. However, translocation is the only method by which many species can be restored to parts of their former range, which increases their conservation security. Tuatara (*Sphenodon* spp.), sole surviving members of the reptilian Order Sphenodontia, are restricted to offshore islands of New Zealand. Dispersal into former habitat on the mainland or other islands, following removal of the causes of extinction, is unlikely. Captive rearing of reptile hatchlings from eggs collected in the wild to produce founders for new populations is also a conservation technique that has had mixed success. However, captive incubation and rearing are techniques that allow large numbers of tuatara to be produced to start new populations without detrimental effects on small source populations. We document the first contemporary translocation of *S. guntheri*, providing details on selection of release sites and founders. Release sites were chosen on a rodent-free island that provided a variety of habitats for tuatara as well as abundant food and shelter. The release propagule comprised 18 wild-caught adults and 50 captive-reared juveniles. Four separate release sites were established to separate adults from juveniles during the establishment phase. Five years of monitoring indicate that at least 57% of tuatara survived translocation and that reproduction has occurred on the new island. All tuatara increased in weight and length, demonstrating that tuatara have an indeterminate growth pattern. The 56% of recaptured juveniles represented a cross section of the sizes released. We evaluated the use of head-started juveniles as founders, based on survival and growth data. Because tuatara are long-lived, late-maturing reptiles with slow reproduction, establishment of a self-sustaining population will take decades of monitoring to confirm.

966: +.179

The range of the green and golden bell frog (*Litoria aurea*) has undergone a widespread yet unexplained contraction in southeastern Australia since the mid 1970s, and the species is now listed as endangered in the New South Wales Threatened Species Conservation Act 1995 and as vulnerable in the federal Environmental Protection and Biodiversity Conservation Act 2000. Although the cause of the range contraction is unknown, remedial action is necessary to ensure the long-term viability of remaining populations. This can include habitat creation around existing populations and reintroduction projects. However, the habitat requirements of this species are poorly understood. We examined the habitat at 43 waterbodies on Kooragang Island, Australia, with the aim of producing a set of variables which could differentiate between those occupied by *L. aurea* and those where the species was absent. *L. aurea* was found in 21 waterbodies and breeding was confirmed in four. Aspects of waterbody physiognomy and water chemistry could not explain *L. aurea* distribution. The plant species *Juncus kraussii*, *Schoenoplectus litoralis* and *Sporobolus virginicus* were significant predictors of the presence of *L. aurea*, as was the diversity of vegetation on the banks of waterbodies. The presence of the eastern mosquitofish (*Gambusia holbrooki*) did not influence waterbody occupancy and tadpoles were found co-existing with this introduced fish. The distribution of waterbodies occupied by *L. aurea* was aggregated. A waterbody was more likely to be occupied if neighbouring waterbodies within 50 m were also occupied. Habitat creation projects for this species are most likely to succeed if wetland habitat is created in proximity to an existing population. (C) 2002 Elsevier Science Ltd. All rights reserved.

967: -.067

In 1998 the protected Population of *Perameles gunnii* (eastern barred bandicoot) at Woodlands Historic Park, Victoria, Australia became functionally extinct following removals of individuals for translocation between 1994 and 1996. Population viability analysis and data collected whilst the population was in decline are used to explore the impact that these removals had on the decline

of the *P. gunnii* population at Woodlands. Due to some ambiguities in the life history of *P. gunnii* at Woodlands, two structurally different population models were used. Explicitly including the removal of animals in the analysis indicates that there may be at least a three-fold increase in the risk of quasiextinction due to removals. In some scenarios, over 17% of the trajectories decrease to a level less than or equal to 10 females within the observed time period of the collapse of the population, that is by April 1998. The modelling approach identified a number of critical factors in the decline of the population, such as variation in survival rates. By representing the life history strategy using two alternate models, quantitative statements about the impact that removals had on the population decline at Woodlands are made. While removals probably contributed to the collapse of the population, removals were not the sole cause of population decline. The real reasons for decline remain unknowns however, it is likely to be closely linked to habitat decline, difficult, environmental conditions and predation. If *P. gunnii* are reintroduced to Woodlands again, then the models presented here may help to develop management strategies to establish a self sustaining Population, as well as exploring translocations options. 968: +.053

Logging and poaching have dramatically reduced chimpanzee density and distribution in the Republic of Congo. Most chimpanzee translocations attempted in the past failed because a number of biological and non-biological factors can influence success. Biological considerations include knowledge of behaviour, disease, habitat requirements and genetics. We critically review genetic considerations in pre- and post-release phases of translocations and apply them to a welfare-based chimpanzee release project in the Republic of Congo which aimed to re-establish orphan chimpanzees in the wild with a native chimpanzee population. We analyze genetic diversity and relatedness in released animals and devise a genotyping strategy for monitoring of released individuals and their future offspring. Fifty-nine confiscated chimpanzees from different areas of the Republic of Congo were typed for 20 microsatellites using plucked hair as the DNA source. Genetic diversity was high, with an average expected heterozygosity of 81%, and three to 18 alleles per locus. Between 1996 and 1998, 19 individuals were released, and genetic analysis showed that these are unrelated (mean $r \pm$ jack-knifed SD = -0.014 ± 0.001). Using F(ST) and population admixture analysis, we identified population structure in wild chimpanzees. For long-term genetic monitoring of released and native chimpanzees, we identified a set of six informative markers, which are easy to score using basic techniques.

969: -.034

All existing sea otter (*Enhydra lutris*) populations have suffered at least 1, and in some cases 2, population bottlenecks. The 1st occurred during the 18th and 19th centuries as a result of commercial hunting that eliminated sea otters from much their native range and reduced surviving populations to small remnants. The 2nd bottleneck occurred when small numbers of otters were reintroduced, via translocation, to areas where the species had been eliminated. We examined genetic variation at 7 microsatellite loci and the mitochondrial DNA (mtDNA) control region in 3 remnant populations, Amchitka Island (Aleutian Islands, Alaska), central coastal California, and Prince William Sound (Alaska), and in 2 reintroduced populations, southeast Alaska and Washington, that were founded with transplants from Amchitka, and in the case of southeast Alaska, individuals from Prince William Sound as well. We found no evidence of reduced genetic diversity in translocated populations. Average expected microsatellite heterozygosities (H_e) were similar in all populations (range, 0.40-0.47), and mtDNA haplotype diversities were higher in reintroduced populations (0.51 for both Washington and southeast Alaska) than in remnant

populations (\bar{X}) over bar = 0.35; range, 0.18-0.45). The levels of genetic diversity we observed within sea otter populations were relatively low when compared with other mammals and are thought to be the result of fur trade exploitation.

970: +.129

Tidal flow to salt marshes throughout the northeastern United States is often restricted by roads, dikes, impoundments, and inadequately sized culverts or bridge openings, resulting in altered ecological structure and function. In this study we evaluated the response of vegetation and nekton (fishes and decapod crustaceans) to restoration of full tidal flow to a portion of the Sachuest Point salt marsh, Middletown, Rhode Island. A before, after, control, impact study design was used, including evaluations of the tide-restricted marsh, the same marsh after reintroduction of tidal flow (i.e., tide-restored marsh), and an unrestricted control marsh. Before tidal restoration vegetation of the 3.7-ha tide-restricted marsh was dominated by *Phragmites australis* and was significantly different from the adjacent 6.3-ha *Spartina*-dominated unrestricted control marsh (analysis of similarities randomization test, $p < 0.001$). After one growing season vegetation of the tide-restored marsh had changed from its pre-restoration condition (analysis of similarities randomization test, $p < 0.005$). Although not similar to the unrestricted control marsh, *Spartina patens* and *S. alterniflora* abundance increased and abundance and height of *Phragmites* significantly declined, suggesting a convergence toward typical New England salt marsh vegetation. Before restoration shallow water habitat (creeks and pools) of the unrestricted control marsh supported a greater density of nekton compared with the tide-restricted marsh (analysis of variance, $p < 0.001$), but after one season of restored tidal flow nekton density was equivalent. A similar trend was documented for nekton species richness. Nekton density and species richness from marsh surface samples were similar between the tide-restored marsh and unrestricted control marsh. *Fundulus heteroclitus* and *Palaemonetes pugio* were the numerically dominant fish and decapod species in all sampled habitats. This study provides an example of a quantitative approach for assessing the response of vegetation and nekton to tidal restoration.

971: +.188

Overhunting reduced Eurasian Beaver (*Castor fiber*) populations to c. 1200 animals, in eight isolated populations, around the end of the 19th century. Protection, natural spread and reintroductions led to a powerful recovery in both range and populations during the 20th century, which continues at a rapid pace. The minimum population estimate is 593 000. There are also c. 12 500 North American Beaver (*C. canadensis*) established in Finland and Russian Karelia; however, other populations of *C. canadensis* introduced in Austria, Poland and France appear to be extinct. *Castor fiber* is now established throughout Europe with the exception of the British Isles, Iberia, Italy and the southern Balkans; reintroductions are continuing. Considerable further expansion in range and population, especially in western Europe and the lower Danube basin, can be expected. If current trends continue, *C. fiber* will, within a few decades, be a fairly common mammal in much of Europe. Following initial recolonization, populations typically show a pattern of rapid range extension within a watershed, followed only later by rapid population growth, and a barrier effect of watershed divides, which can be strongly isolating where physical or habitat barriers (such as mountains or intensive farmland) intrude between watersheds. Management of beaver distribution should therefore operate at the watershed scale, except where large human-made dams form significant barriers to spread. The period of rapid population increase, if unchecked, leads to a phase of population decline as marginal habitats are occupied and exhausted. This coincides with a peak in conflicts with human land-use interests. A regulated hunting take of healthy beaver populations is recommended as the optimal management regime in managed

landscapes. Early provision of interpretation and public viewing opportunities has been a feature of several recent reintroductions. This provides a benefit to the local economy through wildlife tourism, and helps foster positive attitudes to beavers.

972: -.053

In 1993 a reintroduction project for the Eurasian otter (*Lutra lutra*) was initiated in northeastern Spain (Girona, Catalonia) to restore extirpated populations. Between 1996 and 2000, 43 otters were captured from southwestern and northern Spain and from Portugal with modified foot-hold traps and transported to Barcelona Zoo. Lesions produced by capture were classified into four categories of increasing severity. Thirty four (79%) animals had category I, three (7%) had category II, five (12%) had category III, and only one (2%) had category IV injuries. During captivity five (11%) animals died, including one from a precapture problem. Radiotrigger devices were implanted i.p. into 36 otters to monitor postrelease movement and survival. At least three radio-implanted otters have bred successfully in Girona province, Catalonia, after release in that area.

973: +.024

The authors monitored postrelease survival rates and dispersal of radiocollared raccoons (*Procyon lotor*) that were trapped as nuisance wildlife in suburban Chicago and translocated to a rural forest preserve (translocated urban); trapped in another wooded area and translocated to the forest preserve (translocated rural); and trapped and released in the forest preserve that served as the release site for the translocations (resident). The authors detected no difference in survival rates among the three treatment groups ($P < 0.05$), although their proximity to the release site and their denning locations differed. Because translocated raccoons survived well, translocation could be an effective way to supplement depleted or re-establish extirpated populations of this species. However, translocating large numbers of raccoons for animal damage control could cause problems for other wildlife and humans near release sites, and translocated animals could serve as vectors for wildlife diseases during zoonotic outbreaks.

974: +.008

The fate of radio-tagged hatchery-reared salmon smolts (*Salmo salar* L.) was investigated in the tailrace of a hydropower station in the Danish River Gudena during 2 years. Seventeen and 27 smolts were tagged and released in late May 1996 and during April 1999, respectively. Out of the total of 44 smolts, only two were recorded to leave the river and enter the estuary. In both years of study, electrofishing was used to sample tagged smolts. In 1996, these attempts were unsuccessful, while in 1999, 19 (70% of total) transmitters were retrieved in the stomachs of pikeperch (*Stizostedion lucioperca* (L.)) and pike (*Esox lucius* L.), and in grey heron (*Ardea cinerea* L.) nests. The present study demonstrates that the physical condition of the watershed, with respect to spawning and rearing, may not be the only crucial determining factors of the success of reintroduction of Atlantic salmon. Hydropower plants not only block the free movement of migratory fish, hence preventing the utilisation of spawning and rearing areas, but also form the basis of areas with increased mortality.

976: +.012

The first record of the trematode *Stichorchis subtriquetrus* is reported from European beaver (*Castor fiber*) in the Czech Republic. Detailed redescription is added and is compared by the

available findings on the morphometric variability of this taxon. The presence of this parasite in the Czech territory where the beaver became extinct some 150-200 years ago is a result of reintroduction of the definitive host. The issue of stichorchosis epizootology of beavers is discussed. As to the ecoso zoological aspects, law protects the beaver and its specific parasites in the Czech Republic.

977: +.132

To examine habitat conditions associated with abundance of *Macrhybopsis hyostoma*, 10 seine-hauls were made at each of 24 sites encompassing the major western tributaries of the Arkansas River. All seine hauls were made in habitats that, within each collection locality, were considered most likely to include the species. Each haul was characterized for mean depth, water velocity, and substratum compaction and particle size. Comparison of use versus availability within intervals of these variables demonstrated nonrandom distribution of the species for each variable measured. At locations where the species occurred, usage curves and electivity indexes indicated that both age-groups preferred moderate current velocities (20-40 cm/s) and substrata with high percentages of pea-sized gravel (60-90%) and moderate levels of compaction. A discriminant function based on stream-reaches of occurrence for the species predicted either absence (90% of the seine hauls) or rarity of the species (10% of the hauls) in stream reaches where *M. hyostoma* or a close relative (*M. tetranema*) had been extirpated. Based on these results, and in the absence of further knowledge on habitat availability and suitability it seems inadvisable to attempt reintroductions of *M. hyostoma* into presently unoccupied streams within its historical range in Oklahoma.

978: +.028

Sanctuaries - centres that care for rescued, orphaned or confiscated animals - hold an uneasy position in the conservation community. Commonly, the problem of captive primates is seen as an unfortunate distraction from the real issue of habitat loss and over-hunting, and sanctuaries are categorized as serving welfare purposes only. Frequently, they struggle for funding and are unable to secure the large grants that are directed towards other conservation initiatives. Sanctuaries also have to face welfare problems created when capacities are exceeded and they lack safe, viable habitat for the species they try to protect. The solutions, discussed in this paper, are integrating care for rescued animals with habitat protection and education. Reintroduction efforts, which would otherwise be of conservation benefit, are constrained by the unresolved issues including disease transfer, competition with wild populations, and the interface with ecotourism activities.

979: -.154

State wildlife agencies have translocated thousands of wild turkeys (*Meleagris gallopavo*) since the 1930s to reestablish this species. Because of threats to the domestic poultry industry and wild birds, screening for selected infectious agents has become routine since the early 1980s. One of the principal sources for Rio Grande wild turkeys (*M. gallopavo intermedia*) for translocation purposes was the Edwards Plateau of Texas (USA). Unfortunately, turkey abundance has declined in the southern Edwards Plateau since the late 1970s. Surprisingly few studies have addressed wild turkeys in this region, perhaps reflecting its status as the heart of Rio Grande turkey range. We surveyed 70 free-living Rio Grande wild turkeys from Bandera and Kerr counties, Texas, for evidence of exposure to *Salmonella typhimurium*, *S. pullorum*, *Mycoplasma gallisepticum*, *M. meleagridis*, *M. synoviae*, *Chlamydophila psittaci*, and the avian influenza, Newcastle disease, turkey corona, and reticuloendotheliosis viruses. Of these, 80% (56) were seropositive for both *M. gallisepticum* and *M. synoviae* on the serum plate antigen test. Ten of these individuals (14% of

total) were positive for *M. synoviae* by hemagglutination inhibition testing. All other serologic tests were negative. Two adult females sampled in Kerr County, whose body mass was significantly less than that of other adult females trapped in the area, tested positive for reticuloendotheliosis virus (REV) proviral DNA on polymerase chain reaction. Reticuloendotheliosis virus was isolated from one of these individuals. The pathogenesis, transmission, and/or population-level influences of *M. gallisepticum*, *M. synoviae*, and REV in Rio Grande wild turkeys deserves further study.

980: +.297

Conservation biologists often must make management decisions based on little empirical information. In Germany biologists are concerned that the recovery and reintroduction of Eurasian lynx (*Lynx lynx*) may fail because the remaining suitable habitat may be insufficient to sustain a viable population. However, no comprehensive study addressing this concern has been made that not only considers distribution of suitable habitat, but also connectivity to other populations. The aims of this study were (1) to quantify the amount and location of potentially suitable lynx habitat in Germany, (2) to estimate the connectivity between patches of suitable habitat, and (3) to evaluate lynx conservation programs. Habitat preferences of lynx were described in a rule-based model based on the availability of forest cover (defined by patch size) and the spatial structure of the habitat. Rules were implemented in a geographic information system to predict locations of suitable habitat. Optimal connections among patches were modeled using a cost-path analysis based on habitat-specific probabilities of lynx crossing patches. Results indicated wide variation in the size of patches of suitable habitat, with 10 areas each sufficiently large to sustain >20 resident lynxes. Overall, a total of 380 lynxes could be sustained by the 10 areas. Uncertainty analyses of model parameters and assumptions revealed little variation in predicted habitat, primarily because results were constrained by the actual distribution of forest habitat. Our analyses suggest that lynx reintroduction programs should emphasize large, connected areas and consider broad-scale habitat connectivity in the landscape. Our approach also demonstrates how biologically plausible rules can be applied in conservation to identify areas in which success is most likely, even when few empirical data are available.

981: +.076

The spatial scale at which anthropogenic disturbance affects an animal population depends on the degree of philopatry and homing of individual organisms within that population. Even in highly vagile species, local populations may comprise ecologically separate entities if most animals display strong and consistent site attachment. We conducted a mark-recapture study on yellow-lipped sea kraits (*Laticauda colubrina*) on two small Fijian islands separated by 5.3 km. These snakes forage over many kilometers in the ocean, but return to land to reproduce, slough, and digest their food. Recovery of marked snakes showed that the populations on these two islands were essentially separate. Relocated snakes returned "home" almost immediately after they were released. Growth rates and mean adult body sizes of male sea snakes also differed between the two islands. This high site fidelity means that activities such as resort development or commercial harvesting for the skin trade are likely to have intense localized effects rather than diffuse broad-scale effects on sea snake populations. Our results also call into question the feasibility of plans to reintroduce snake populations to areas where a species has been eliminated by overexploitation.

982: +.219

A recent recovery in ciril bunting (*Emberiza cirilus*) numbers in the UK has been aided by

deployment of prescriptions for environmentally friendly management of farmland under the Countryside Stewardship Scheme. However, the species' range has not expanded and the population is increasingly under threat from habitat loss due to built development. The UK Biodiversity Action Plan calls for re-establishment of populations outside the current range in order to ensure a wider geographical spread of this species. This study examined territory distribution and foraging patterns of ciril buntings in relation to habitat variables in order to inform the process of site protection and site selection for a possible translocation programme. Ciril bunting territories were positively associated with rough grassland, non-linear scrub and habitat richness, and intensive permanent pasture was avoided. Resampling methods showed that rough grassland was used significantly more than improved pasture as a foraging habitat and that both rough grass and cereals were used more than other arable crops. The results emphasise the importance of protection of unimproved pastures in 'green field' sites and will help quantify the potential carrying capacity of candidate 'receptor' sites. 983: +.241

In 1999, we intensively surveyed all suitable habitat on the Mascarene Island of Rodrigues and mapped 334 territories of the threatened endemic Rodrigues fody (*Foudia flavicans*). In addition, we recorded 58 unpaired males, 85 juveniles, and 100 greybrown-plumaged birds; for a minimum estimated population size of 911 birds. This represents a near 100-fold increase in population size since 1968, which has been achieved in the absence of translocation or taxon-specific management. Birds were generally distributed in direct proportion to the availability of various forest types, but relatively more birds were found in mature, dense forests. Fody density at 10 selected sites, where vegetation surveys were carried out, increased significantly with increasing tree height, canopy cover and tree species diversity. This suggests that habitat management aimed at enhancing Rodrigues fody populations should focus on the protection of existing wooded valleys to allow forest maturation and expansion of afforested areas. (C) 2002 Elsevier Science Ltd. All rights reserved.

984: +.174

Reproductive isolation can function as a mechanism to maintain locally adapted gene complexes while decreasing the heterozygosity in distinct populations. As a result, reproductive behaviour should be considered a fundamental factor influencing reproductive isolation. This is of interest to conservation biology when one desires to regulate gene flow between two populations either by creating opportunities for increased dispersal, by relocation of individuals, or by re-introduction of a species to its natural habitat. Reproductive behaviour can also influence the effective population size and the actual population size through the Allee effect. We investigated the reproductive behaviour of individuals from two isolated populations of the red winged grasshopper, *Oedipoda germanica*, an endangered species in Central Europe. We detail several methods to show how several aspects of the reproductive behaviour of this species interact with the conservation of this species. Foreign males were not disfavoured in mate choice and male body size was also unimportant in mating success. Heterogamic matings were as productive as homogamic matings in terms of total number of eggs per female, egg hatching rate, or nymph survival. Therefore, we suggest that cross-matings of individuals from different populations do not positively influence population size by heterosis effects nor act they negatively in the form of outbreeding depression. We found that female *O. germanica* were able to store viable sperm for extended periods but egg pods showed a decrease in hatching rate when these females were deprived of additional mating opportunities. Multiple mated females laid more eggs than once-mated females. Hence, females

are capable of founding new Populations even after only one mating but their reproductive output may be reduced. Present-day gene flow between populations of *O. germanica* probably does not occur. Consequently, there is an urgent need to pursue habitat management and release programmes that maintain current population sizes of this species. With regard to the reproductive behaviour of the red-winged grasshopper, we suggest that relocation programmes release males and female together and at an early adult stage. Also, because female reproductive output increases with mating activity, the initial release should involve excess females. Because males have it shorter lifespan than females a subsequent release of males at a later time may enhance the overall success of local conservation efforts by resulting in more offspring per female. (C) 2002 Elsevier Science Ltd. All rights reserved.

985: +.080

The objectives of this study were to determine the distribution and abundance of endangered Oregon chub *Oregonichthys crameri*, a small floodplain minnow endemic to the Willamette Valley of western Oregon; to describe the fish communities in current and historic chub habitats; and to establish new populations through introductions. Various sampling gears were used, including seines, minnow traps, dip nets, and a gill net. Oregon chub distribution was found to be restricted in comparison with their historical range, whereas nonnative fishes were widespread in the off-channel habitats preferred by Oregon chub. Oregon chub were absent, or low in abundance, when nonnative fishes were present, and several populations declined or were extirpated when their habitats were invaded by nonnative fishes. Isolated habitats with low connectivity supported larger populations of Oregon chub and were less likely to contain nonnative fish species than were habitats with high connectivity. In habitats that supported abundant Oregon chub populations, chub were often the numerically dominant fish species. Results suggest that increasing the connectivity of floodplain habitats in a system where nonnative fishes are widespread may be detrimental to the conservation and recovery of this species.

986: +.242

The wetlands around the Dongting Lake were inhabited by Pere David's deer before its extinction in the wild. In preparation to restore a wild Pere David's deer populations in the Dongting Lake region, we inspected the Pere David's deer populations in the Tianezhou Reserve, Beijing Milu Park and Dafeng Milu Nature Reserve. We studied the available wetlands in the Yueyang Municipality, Changde Municipality and Yiyang Municipality, and selected Julinyuan of Hanshou County, Changde Municipality and Jichengyuan of the Huarong County, Yueyang Municipality as a potential reintroduction site for Pere David's deer. We studied the vegetations and sampled above-ground biomass of plant in the two sites. We found the natural environments in Julinyuan and Jichengyuan similar to that of the Tianezhou Reserve. There are three Vegetation Type Groups and vascular plant of 75 families, 189 genera and 264 species in Jichengyuan. The habitat available for reintroduction of Pere David's deer in Jichengyuan is 2000 hectare, which can provide the reintroduced deer with 21 158.4 tons of fresh plants, enough to support 1000 Pere David's deers. The natural vegetation rapidly recovered after the lands were abandoned designated for wetland restoration. There are also three Vegetation Type Groups and vascular plants of 75 families, 189 genera and more than 200 species in Julinyuan. The habitat available for reintroduction of Pere David's deer in Julinyuan is 1703.1 hectare, which can provide reintroduced deer with 18 859.0 tons of fresh plants, enough to support 850 Pere David's deers. Judged by the climate, food resources and environmental carrying capacity, Julinyuan and Jichengyuan are both suitable for reintroduction of Pere David's deer. We also discuss the human-assisted survival strategies for Pere David's deer, such as guarantee living space, diseases

prevention, habitat restoration, and population and habitat monitoring.

987: +.055

Antirrhinum subbaeticum is an endangered species inhabiting fragmented limestone cliffs. In the last 3 years, a drastic population decline has been observed in three of four known populations and the estimated number of surviving individuals is now close to 400. A RAPID study was conducted to evaluate the levels of genetic variation present in this species to improve conservation guidelines. Thirty-nine polymorphic products identified 66.1% of the samples by unique RAPID multilocus profiles. A cluster analysis grouped the samples into two broad groups corresponding to northern or southern provenances. AMOVA analysis showed that only 17.7% of the genetic diversity was partitioned within populations. These results are in contrast to data available for other *Antirrhinum* species. This genetic structure could be explained by the predominant selfing behaviour exhibited by *A. subbaeticum* as opposed to the allogamy of other congeners. Genetic diversity within populations does not seem to be strongly related to population size and historical factors could be responsible for the very low levels of genetic diversity found in one population. Given the low genetic diversity within populations, it is suggested that an extensive sampling of individuals be made for recovering appropriate levels of the gene pool for ex situ preservation. However, translocation of individuals to the genetically weakened Bogarra population from other sources is not recommended.

988: +.238

We have studied the exotic parrot fauna of Broward County, Florida since July 1999. During this period, 31 species of parrots were observed, with 20 of these not previously known to occur in the county. Twenty-four species (77%) were documented by still or video photographs. Three species are newly reported for Florida but only one of these was photographed. Breeding of 14 species was confirmed during our study. We summarize the population status, distribution, and verifiable evidence of occurrence for all parrots that have been reported in Broward County, including seven species observed prior to, but not during, our study. Populations of Red-crowned Parrots in Broward County may be suitable for reintroduction programs into Mexico, should such an effort be undertaken. Increased monitoring of parrots and other exotic birds in Florida is encouraged.

989: +.086

The Hine's emerald dragonfly (*Somatochlora hineana*) may be the United States' most endangered species of dragonfly. *S. hineana* currently inhabits Wisconsin, Michigan, Illinois, and Missouri. It is a very site-specific species, living in calcareous wetlands with slow flowing water where larvae can spend up to four years growing and developing. Human alterations of the species' limited habitat, such as filling in and fragmenting wetlands with development of roads and ditches, have contributed to the dragonfly's status. The species is federally listed as endangered, and a recovery plan was completed and approved by the U.S. Fish and Wildlife Service in September 2001. Conservation efforts include the management of extant populations, research, searches for additional populations, an education program, a reintroduction program, and tracking of the recovery progress.

990: +.070

Capsule The first co-ordinated Red Kite survey across Britain since the reintroduction programme began in 1989, yields 430 breeding pairs. Aims To estimate the current size and extent of the

British breeding population. Methods A complete census of the populations in the East Midlands, Yorkshire, central and north Scotland was undertaken, while in Wales and the Chilterns, populations were surveyed using a stratified sample of tetrads. Breeding and territorial pairs were identified. Results The survey indicated that there were 430 breeding pairs in Britain (95% CIs, 372-490). There were 259 breeding pairs in Wales (95% CIs, 200-318) and 109 (95% CIs, 96-124) in the Chilterns. Elsewhere, 16 breeding pairs were located in the East Midlands, three in Yorkshire, seven in central Scotland and 33 in north Scotland. An additional three pairs were recorded in southern England, away from the main population centres. Conclusion The 2000 survey provides a baseline against which to measure future changes in Red Kite populations in Britain, using standard, repeatable methods.

991: +.192

Australian mammals have one of the world's worst records of recent extinctions. A number of studies have demonstrated that red foxes (*Vulpes vulpes*) have a profound effect on the population biology of some species. However, not all species exposed to fox predation have declined. We studied the antipredator behaviour of a species that has not declined - the red-necked pademelon (*Thylogale thetis*), and contrasted it with previous studies on a species that has declined - the tammam wallaby (*Macropus eugenii*), to try to understand behavioural factors associated with survival. We focused on two antipredator behaviours: predator recognition and the way in which antipredator vigilance is influenced by the presence of conspecifics. We found that predator-naïve pademelons responded to the sight of certain predators, suggesting that they had some degree of innate recognition ability. However, pademelons responded similarly to a broad range of acoustic stimuli, including dingo howls, wedge-tailed eagle calls, foot-thumps - a predator-elicited sound - and a control sound, suggesting that they did not specifically recognize predator vocalizations. Unlike a number of other macropodid marsupials, including tammars, pademelons did not modify time allocated to antipredator vigilance as group size increased. Taken together, these results suggest that red-necked pademelons independently assessed and managed their predation risk whereas tammars relied more on conspecifics to assess and manage risk. We suggest that these factors may have been important determinants of species survival. More generally, we suggest that a fundamental understanding of antipredator behaviour can enlighten conservation efforts.

992: +.156

While wild populations continue to decrease, the number of orphaned primates, sanctuaries, and attempts to reintroduce primates back to the natural environment are increasing. An umbrella organization called the Pan-African Sanctuary Alliance (PASA) was formed in 2000 and recently the IUCN Reintroduction Specialist Group developed a set of specific policy guidelines for primates (2002). Data presented in this report are based upon questionnaire responses by managers from 17 African facilities that have become members of PASA (membership in PASA is defined by attendance at an annual PASA workshop). These PASA facilities house over 500 great apes. (There may be other facilities not represented here simply because their managers did not attend a PASA workshop.) The majority of the apes arrived at the sanctuaries when they were less than 4 years old and half were confiscated. Over 40% were found awaiting sale, and 30% had been previously kept as pets. Common ailments upon arrival included internal parasites, behavioral abnormalities, and malnutrition; 20% of the total sanctuary population died prematurely. Most sanctuaries use a combination of enclosures surrounded by electric fencing and cages to accommodate the apes. Sanctuaries actively participate in conservation education, habitat protection, tourism, scientific data collection, local development, and reintroduction. The median total facility operating cost was US\$65,000 per annum. The median facility cost per ape was

US\$2,222 per annum. Most funding comes from overseas nongovernmental agencies. Discussion focuses on evaluating the present status of sanctuaries, the problems facing them, and their potential role in African conservation issues. (C) 2002 Wiley-Liss, Inc.

993: -.125

A male and female Harpy Eagle (*Harpia harpyja*), both reintroduced captive-bred subadults, were observed on Barro Colorado Island (BCI), Panama for 89 and 205 days, respectively, between June 1999 and August 2000. The male captured 25 individuals from nine different mammalian species and the female captured 46 individuals from 8 different mammalian and one reptilian species during the period of observation. Fifty-two percent of captures by the male were of two-toed (*Choloepus hoffmanni*) and three-toed (*Bradypus variegatus*) sloths. Fifty-four percent of captures by the female were of sloths. On average, the male made a capture every 3.6 days with a daily average consumption of 888 g. The female made a capture on average every 4.4 days with a daily average consumption of 812 g. The eagles attacked solitary arboreal prey species from 1-50 m distance, sometimes with several calculated attempts from within 5 m. Social arboreal prey species were most often attacked by surprise from less than 30 m, and terrestrial prey species were attacked by surprise from less than 10 m. The female eagle was observed to capture solitary arboreal prey significantly more during sunny weather and the dry season. She was also observed to capture social arboreal prey significantly more during cloudy weather and the wet season. Capture success rates of observed predations for the male and female eagle were 38% and 49%, respectively.

994: +.063

Wild rabbit (*Oryctolagus cuniculus*) restocking is a common practice in management in France. However rabbits generally experience heavy mortality after release, which jeopardizes restocking efficiency. Release success is full only when introduced individuals produce offspring. We present a controlled release that is appraised through survival and genetic data to evaluate the subsequent breeding contribution of introduced rabbits. Preliminary genetic analyses with 9 microsatellite markers led to choose a dense population of rabbits in Lot (southwestern France) to restock a small population in Vendee (northwestern France). Both populations had comparable polymorphism and allelic variability, and unfortunately only a few specific alleles at low frequency. We translocated 55 rabbits from Lot to Vendee in late July 1999, and by radiotracking 35 rabbits, we assessed a 49% survival in December 1999, resulting in 20 introduced rabbits still alive when the breeding season began. Concurrent spotlight census indicated a resident breeding population size of about 45 individuals. Thus, there were 31% of introduced rabbits within the breeding population. Then, the population was genetically sampled by live trapping, and thereafter by hunting. We distinguished two age groups of individuals: breeders and offspring. Genotypes of young individuals ($n = 20$) were compared with that of adults originating from either the resident population ($n = 29$) or the source population. Assignment of offspring to each parental population indicated a low breeding contribution of introduced individuals as not any young fully originated from the source population, whereas only 32% of them resulted from crosses between both populations.

995: +.209

Traditionally the distribution of the Arabian oryx in the Kingdom of Saudi Arabia has been closely associated with that of the major sand deserts, notably the Great Nafud in the north and the Rub' al Khali in the south. Due to a successful captive breeding programme the Arabian oryx was

reintroduced in the 'Uruq Barn Ma'arid Protected Area, on the western edge of the Rub' al Khali during 1995, thereby re-establishing the southern population in the Kingdom of Saudi Arabia. Population viability analysis is used to demonstrate the re-establishment of the northern oryx population, the vulnerability of certain populations and to suggest a management approach that should enhance the survival of the free-living populations in the Kingdom of Saudi Arabia. Population models predict that the 'Uruq Bani Ma'arid population could be subject to extinction ($P_{\text{survival}} = 0.38$) when modeled in isolation. Associated with this is a low heterozygosity. The proposed release strategy of oryxes into a northern protected area results in maximum population growth during the first 20-years and continued positive population growth during the 100-year modeling period. The latter free-living population is, however, also subject to extinction due to its relatively small size. By managing all of the Arabian oryx populations in the Kingdom of Saudi Arabia as a single metapopulation, survival of the free-living populations are enhanced, without negatively affecting the other populations.

996: +.091

Nekton (fishes and decapod crustaceans) is an abundant and productive faunal component of salt marshes, yet nekton responses to tidal manipulations of New England salt marshes remain unclear. This study examined nekton use of a tidally restricted salt marsh in Narragansett, Rhode Island relative to an unrestricted marsh during summer. In addition, a before-after-control-impact design was used to examine early responses of nekton to the reintroduction of natural tidal flushing. Species richness and densities of *Cyprinodon variegatus*, *Lucania parva*, *Menidia beryllina*, and *Palaemonetes pugio* were higher in the restricted marsh compared with the unrestricted marsh. The unrestricted marsh supported higher densities of *Menidia menidia* and *Fundulus majalis*. Mean lengths of *Carcinus maenas* and *P. pugio* were greater in the restricted marsh. Tidal restoration resulted in increased tidal flushing, salinity, and water depth in the restricted marsh. Densities of *Fundulus heteroclitus*, *F. majalis*, and *Callinectes sapidus* were higher after 2 years of restoration. Density of *L. parva* decreased after restoration, probably in response to a loss of macroalgal habitat. Species richness also decreased after 2 years, from 20.9 species when the marsh was restricted to 13.0 species. Total nekton density did not change with restoration, but shifts in community composition were evident. In this study restoration induced rapid changes in the composition, density, size, and distribution of nekton species, but additional monitoring is necessary to quantify longer-term effects of salt marsh restoration on nekton.

997: +.233

Populations of the marble trout (*Salmo marmoratus*) have declined critically due to introgression by brown trout (*Salmo trutta*) strains. In order to define strategies for long-term conservation, we examined the genetic structure of the 8 known pure populations using 15 microsatellite loci. The analyses reveal extraordinarily strong genetic differentiation among populations separated by < 15 km, and extremely low levels of intrapopulation genetic variability. As natural recolonization seems highly unlikely, appropriate management and conservation strategies should comprise the reintroduction of pure populations from mixed stocks (translocation) to avoid further loss of genetic diversity.

998: +.033

The European beaver (*Castor fiber*) once was a common species in Europe. Due to hunting and increased intolerance, the species disappeared from most countries of its former range. In Belgium, the last beaver was killed in 1848. During the last decade many countries have carried

out reintroduction and translocation programmes to restore the range of the beaver in Europe. In spite of these and many other initiatives, the beaver is still threatened: it only inhabits a limited part of its former range and its populations are small and scattered. As an assignment of the department Nature of the Ministry of the Flemish Community research has been started to assess the chances and risks for a successful reintroduction of beavers in the basin of the Schelde and the Dijle. Suitable habitat was mapped, the coherence of these areas were investigated, bottlenecks for the return of the beaver were assessed and the need and feasibility of a reintroduction were evaluated. In this article, the methods and results of this study are discussed. Within the research area are enough suitable areas for a viable, coherent population of at least 40 beaver families. It is to be expected that there are also many suitable habitats in the adjacent basins outside the study area. There are no large bottlenecks for the development of a population: the largest problem is the city of Leuven, as an obstacle for dispersal. The risks of nuisance due to digging, gnawed trees and the building of dams are considered small. It is expected that at certain locations, beavers will build up a high load of cadmium and other heavy metals. The chances of a natural recolonization of Flanders by dispersal from adjacent populations in the basin of the Maas and reproduction of resident beavers in the Laan and the Dijle are estimated to be small. It is concluded that a viable beaver population can only develop when at least 20-30 individuals are reintroduced. The choice of a genetically mixed group is possibly the best option.

999: -.046

The island endemic Madagascar Fish-Eagle (*Haliaeetus vociferoides*) is one of the most endangered birds of prey. Certain populations in west-central Madagascar sometimes exhibit a third, and sometimes a fourth, adult involved in breeding activities at a nest. We applied DNA fingerprinting to assess relatedness among 17 individuals at four nests. In all nests with young, a subordinate rather than the dominant male sired the offspring. Within-nest relatedness comparisons showed that some dominant males had an apparent first-order relationship with the female. Between-nest relatedness comparisons showed that some adults had an apparent first-order relative at another nest in the study area. Findings that subordinate males contribute to breeding, and that adults in an area may be related, may require conservation measures such as translocation to assure the species' survival.

1000: +.202

The lake sturgeon (*Acipenser fulvescens*) is a species of cultural significance to the Menominee Nation, a Native American tribe indigenous to northeast Wisconsin. Lake sturgeon in the Lake Winnebago system historically migrated up the Wolf River to spawn at Keshena Falls, within the current boundaries of the Menominee Reservation where, each spring, the Menominee people gathered at Keshena Falls to harvest lake sturgeon. The construction of two dams on the Wolf River downstream of Keshena Falls in the late nineteenth and early twentieth centuries contributed to extirpation of this species on the Menominee Reservation. The general public has had the opportunity to harvest lake sturgeon from Lake Winnebago during a winter spear fishery since 1932. Those who participate in this fishery feel as strongly about the lake sturgeon resource as do the Menominee people. Cooperation among multiple resource management agencies and the public was necessary to address the interests of both groups and at the same time ensure protection of the Winnebago system lake sturgeon population. In 1993, tribal, state, and federal representatives developed a plan to reintroduce lake sturgeon to the Menominee Reservation. The planning process was designed to involve all the various, often competing, tribal and non-tribal interests in a constructive effort to develop and implement a Menominee Reservation sturgeon rehabilitation plan that all parties could accept and endorse. The core planning group was the

Menominee Reservation Lake Sturgeon Enhancement Committee which worked with the various sturgeon 'publics' to identify common sturgeon restoration goals, objectives and management strategies, and which has worked together since that time in the effort to re-establish viable lake sturgeon populations in Menominee Reservation waters. Since 1994, over 30 000 hatchery-raised lake sturgeon have been stocked in reservation lakes, and 87 Wolf River lake sturgeon have been radio-tagged and relocated upstream to reservation waters of the river. Enough mature lake sturgeon were present in this river reach in 2001 to permit spawning there for the first time in 50 years. The success of the co-management effort has been encouraging and participants are committed to the goal of establishing self-sustaining lake sturgeon populations in reservation waters.

1001: +.043

Restoration of the crested ibis, *Nipponia nippon*. J. Appl. Anim. Res., 22: 193-200. In China, the crested ibis *Nipponia nippon* was thought to have become extinct until seven birds were rediscovered in 1981. After its rediscovery, various projects for the conservation of the species in the wild and for captive breeding were begun with the goal of managing the population. A total number of this species increased to more than 200 birds including about 100 in the wild and 130 in captivity by 2000. Despite captive breeding inbreeding depression has not been observed. In the course of research, however, various factors were influencing the rate of increase of the crested ibis population. The factors include: habitat loss, the increased human population within the species range, environmental pollution resulting from the use of agro-chemicals in particular pesticides and also predators such as snakes and birds. The fate of the crested ibis probably depends largely upon the life style of humankind.

1002: -.065

Alien species invasions have already caused substantial ecological and economic damage and will likely have even greater negative consequences in the future. Thus, it is imperative to improve our basic ecological understanding of these invasions and enhance our ability to reverse or mitigate their often devastating effects. Invasions by fire-promoting alien grasses have played a particularly important role in the destruction, of tropical dry forests and are a major reason why these ecosystems are now among the most endangered in the world. We investigated how light availability (full sun and 50% shade), alien grass control (bulldoze, herbicide, plastic mulch, and trim treatments), and native species additions (outplanting and direct-seeding) affected the establishment of native plants and the suppression of a dominant invasive bunchgrass (fountain grass, *Pennisetum setaceum*) within a highly degraded fenced dry forest remnant on the island of Hawaii. The percent cover of native species increased in all light, grass control, and species addition treatments throughout the 20 mo of the experiment, and was greatest in the shade, bulldoze, and outplant treatments. Although fountain grass cover also increased over time in all grass control treatments, the three more aggressive techniques all significantly reduced grass cover relative to the more moderate trim treatment. In addition, there was a significant overall negative correlation between the final cover of fountain grass and native species, suggesting that these native species may successfully compete with fountain grass for water and/or nutrients. Outplant survival and the number of individuals established from direct-seeding differed significantly among the grass control treatments, and in each case, the response was highly species specific. Photosynthetic rates of established outplanted individuals and fountain grass did not differ significantly across most experimental environments, indicating that the local dominance of fountain grass may not be due to superior physiological attributes-The results of this experiment highlight the importance of investigating species- and treatment-specific responses before

attempting larger-scale restoration projects, particularly when using rare and endangered species. This study also suggests that relatively simple techniques may be used to simultaneously establish populations of vigorous understory native species and suppress alien grasses at relatively large spatial scales, and that remnant or newly created favorable microsites may be exploited to facilitate the establishment of rarer native overstory species.

1003: +.183

The successful recovery of critically endangered flora will rely increasingly on its translocation to secure sites where the amelioration of threats has been successful or where current threats such as weeds are absent. Translocations are both costly and time consuming and in many cases involve very small numbers of plants from critically endangered populations. Consequently it is important that effective, efficient methodologies are developed for the process and for monitoring success. Equally critical, as part of the same monitoring program, is the need to develop protocols for determining and predicting translocation success. Of the 28 Acacia species listed as threatened (Declared Rare Flora) 12 are critically endangered and all occur in agricultural areas where there has been extensive land clearing and habitat degradation. The Department of Conservation and Land Management has carried out 15 experimental translocations of critically endangered taxa as part of approved Interim Recovery Plans, including *Acacia aprica* and *Acacia cochlocarpa* subsp. *cochlocarpa*. Preliminary data are presented on the current status and success of experimental translocations of these two taxa of Acacia. Artificial watering and mulch had little effect on enhancing survival or growth of either taxon. Protection from grazing appears to be essential in ensuring translocation success. Continued monitoring is required to evaluate translocation success satisfactorily.

1004: +.121

The European bison, extirpated from the Carpathian Mountains over 200 years ago, was reintroduced to the Bieszczady Mountains in the 1960/1970s in two small, isolated herds, and is now threatened by high inbreeding and low genetic variability. A new program of re-establishing viable populations in the Carpathians is based on the genetic analysis of formerly released animals, using the European Bison Pedigree Book. Calculating founder contributions, founder genome survival, founder genome equivalent, inbreeding coefficient and mean kinship allows the identification of under-represented or missing founders. Since genetic variability is much higher among bison in captivity and, in Poland, the Lowland-Caucasian line is represented only in those free-ranging herds, the reintroduction will be based on animals from foreign breeding centres. Bison will be released into existing herds, and planned new introduction sites, to facilitate natural gene exchange in the future. The same approach will be recommended for planned introductions in the Slovakian and Romanian Carpathians. (C) 2002 Elsevier Science Ltd. All rights reserved.

1005: +.103

The pattern of dispersal of burrowing bettongs (*Bettongia lesueur*) was studied in a population reintroduced to a peninsula protected from exotic predators at Heirisson Prong in Shark Bay, Western Australia. The reintroduced population was growing strongly in numbers and expanding in area during the study. Young were first marked in the pouch and subsequently monitored by trapping and radio-telemetry after independence to establish their movements relative to those of their mothers. *B. lesueur* on Heirisson Prong dispersed between the ages of 170 and 250 days, coinciding with the period from weaning to sexual maturity. Dispersal was male-biased. Young males dispersed significantly further than young females with mean dispersal distances of 4600 m

and 1100 m respectively. Male *B. lesueur* also frequented significantly more warrens than females, being located at a mean of 0.37 warrens per daily radio-tracking fix compared with a mean of 0.24 per fix for females. Scarring from intra-specific aggression occurred in male bettongs only. Males may disperse to the periphery of the population to escape aggressive interactions with established adult males and visit more warrens to increase mating opportunities. Dispersal in females may be related to resource quality or inbreeding avoidance.

1006: -.046

Crocodylus siamensis, the Siamese crocodile, is a critically endangered species of freshwater crocodile previously distributed throughout much of SE Asia. Recovery plans call for reintroductions to the wild using founder individuals currently in captivity, mostly in commercial crocodile farms: On many farms *C. siamensis* has been intentionally hybridised with either Cuban crocodiles, *C. rhombifer*, or the estuarine crocodile, *C. porosus*, and hybrids may be difficult to distinguish morphologically. We report on the combined use of microsatellite and mtDNA genetic markers to determine the species status of potential founder individuals for reintroduction of *C. siamensis*. Genetic markers were used to characterise 103 captive and wild-caught individuals of *C. siamensis*; *C. rhombifer* and *C. porosus* in Vietnam and to distinguish purebred versus hybrid individuals. Although the microsatellite loci used had some overlap of allele sizes among species, assignment tests allowed differentiation. Four hybrids were identified, two of which had not been recognised morphologically as hybrids, and one of these was thought to be a *C. siamensis* suitable for reintroduction. Nineteen of the identified purebred *C. siamensis* were subsequently released into Cat Tien National Park in southern Vietnam. *J. Exp. Zool.* (C) 2002 Wiley-Liss, Inc.

1007: -.015

Empirical support for the genetic management strategies employed by captive breeding and reintroduction programs is scarce. We evaluated the genetic management plan for the highly endangered black-footed ferret (*Mustela nigripes*) developed by the American Zoo and Aquarium Associations (AZA) as a part of the species survival plan (SSP). We contrasted data collected from five microsatellite loci to predictions from a pedigree-based kinship matrix analysis of the captive black-footed ferret population. We compared genetic diversity among captive populations managed for continued captive breeding or reintroduction, and among wild-born individuals from two reintroduced populations. Microsatellite data gave an accurate but only moderately precise estimate of heterozygosity. Genetic diversity was similar in captive populations maintained for breeding and release, and it appears that the recovery program will achieve its goal of maintaining 80% of the genetic diversity of the founder population over 25 years. Wild-born individuals from reintroduced populations maintained genetic diversity and avoided close inbreeding. We detected small but measurable genetic differentiation between the reintroduced populations. The model of random mating predicted only slightly lower levels of heterozygosity retention compared to the SSP strategy. The random mating strategy may be a viable alternative for managing large, stable, captive populations such as that of the black-footed ferret. (C) 2003 Wiley-Liss, Inc.

1008: +.186

Nine bilbies were reintroduced to a 14-km² reserve free of rabbits, cats and foxes in South Australia in April 2000. The survival, growth and ecology of the population were studied for 17 months after release by means of radio-tracking and trapping. Reproduction was continuous over the study period, with juveniles successfully recruited into the population. Home-range size of female bilbies averaged 0.18 km² and was significantly smaller than home ranges of males,

which averaged 3.16 km²). Wild-born subadults had smaller home ranges than adults. While male home ranges, and male and female home ranges overlapped considerably, females appeared to maintain areas discrete from other adult females. Bilbies showed a significant preference for dune habitat. As swale habitat appears too hard for burrow construction and males moved greater distances from diurnal burrows than females, males are likely to access food reserves that are under-used by females. Both males and females reused at least 30% of their burrows, and females displayed long-term site fidelity. The release was considered successful and suggests that despite historical damage from rabbits and stock, bilbies are able to successfully recolonise parts of their former range in arid South Australia once rabbits, cats and foxes are removed.

1009: +.032

Wild boar *Sus scrofa* has been extinct in Britain for several centuries. Recently, however, some conservationists have argued that it should be reintroduced. Here, we report that two populations of free-living wild boar are already present in Britain, in the south of England, ranging over areas of approximately 15 km² in the county of Dorset and 175 km² in the counties of Kent and East Sussex. Presence of the animals was indicated initially by unsolicited reports to the Department of Environment Food and Rural Affairs, and was confirmed by searching the relevant areas for field signs such as tracks, faeces, nests and rooted areas. Six carcasses of road-killed or shot animals were available for inspection from the Kent/East Sussex area and had the morphological characteristics of wild boar. Breeding was confirmed in the Kent/East Sussex area and is suspected in the Dorset population. A simple population dynamics model, based on an estimated initial population of 100 animals, suggests a growth rate, r , of between 0.016 and 0.267 for the Kent/East Sussex population. We conclude that the Kent/East Sussex population is likely to prove viable unless actively persecuted, and discuss the social, agricultural, ecological and conservational implications.

1010: +.040

The Eagle Owl has been considered extinct in Hesse, western Germany, since 1910. Reasons for its disappearance were mainly persecution by shooting, but also by egg collecting and 'trophy hunting' etc. As late as 1925 a pair of Eagle Owls was shot at Creuzburg near the border between Thuringia and Hesse. The main reasons for the reappearance of the Eagle Owl in Hesse are reintroduction programmes in adjacent regions like Lower Saxony and Northrhine-Westphalia. Through these successful programmes the Eagle Owl also reappeared in Hesse and bred for the first time successfully in 1977 in the district of Limburg-Weilburg. Since then numbers of breeding pairs increased slowly, but by 1985 had reached only four pairs. In the early 1990s a rapid growth started and in 1993 a total of 43 Eagle Owl territories were occupied with an average reproductive output of 1.93 young per pair. During the mid-1990s there was a decline in reproductive success in Hesse, the number of fledglings per pair dropped to 1.0-1.2. An exception was the Hessian Weserbergland with a rate of usually 2.0 young per pair. In the year 2000 the rate increased to 1.4-1.6 young per pair overall and the total population grew up to 58-60 pairs. Although shooting has been eliminated and pesticide contamination is of minor importance, many Eagle Owls are killed by collisions with wires, vehicles and by electrocution. Inbreeding depression - seriously discussed especially for the reintroduction project - did not play a role among captive-breeding Eagle Owls nor among the released birds. On the contrary the reintroduced Eagle Owls showed a high fitness, which was evident in a higher reproductive rate in the initial stage compared to other federal states (e.g. Baden-Wuerttemberg, Bavaria and Thuringia). Competition for nest sites with other birds does not occur in Eagle Owls, because it is the dominant, prevailing species. I predict that the number of Eagle Owls in Hesse will increase further because there are still vacant

potential breeding habitats. Eagle Owls show very high flexibility and are now by far less prone to disturbance than the founder population, plus they occupy more and more secondary breeding habitats.

1011: +.103

The Eagle Owl became extinct in Schleswig-Holstein in about 1850 as a direct result of human persecution. In 1981 the state government of Schleswig-Holstein decided to attempt to re-introduce the Eagle Owl as a characteristic species within the state. The species protection programme "Re-introduction of the Eagle Owl in Schleswig-Holstein" was carried out successfully by the State Society for Owl Protection in Schleswig-Holstein. In the period 1983 to 2002, 681 young Eagle Owls, reared in captivity, were released into the wild from release aviaries. Since 1984, 650 successful breeding attempts have been recorded in the wild in Schleswig-Holstein, producing 1314 young. Unsuccessful breeding attempts were recorded in a further 172 cases. The Eagle Owl is now an established part of the Schleswig-Holstein avifauna with 100 pairs breeding annually. The Eagle Owl has mainly colonised areas with a rich landscape structure including woods, rivers, lakes and meadows. These diverse habitats are particularly favourable, supplying the species with breeding sites and sufficient food. Observations have shown that the Eagle Owl has little or no detrimental effect on the populations of the rare breeding species such as White-tailed Eagle, Black Stork, Peregrine, Raven and Common Buzzard. However, the Goshawk has been displaced from traditional breeding territories by the Eagle Owl, which led to regional declines in breeding numbers. The re-establishment in Schleswig-Holstein has led to re-colonisation of the neighbouring country of Denmark by the Eagle Owl where 25-30 pairs now breed.

1013: -.115

Until recently, eastern woodrats (*Neotoma floridana*, Ord) at Pine Hills, Union County, were believed to be the only extant population in Illinois. During 1994, additional populations in adjacent Jackson County were discovered at Fountain Bluff, Horseshoe Bluff, and Little Grand Canyon. Genetic variation among Illinois woodrat populations was estimated based on microsatellite DNA at 6 loci. The four populations were separated by 2-14 km, yet all exhibited significant genetic differentiation. Fountain Bluff was the most geographically isolated population and had the lowest genetic heterozygosity. A sample of individuals from a more contiguous population in Missouri exhibited the highest heterozygosity. Populations were monitored by mark-recapture live-trapping for 39 months at Pine Hills and 19 months at Fountain Bluff. Although the Fountain Bluff population was smaller than the Pine Hills population, seasonal demographics and reproductive output were similar. Natural dispersal from all 4 populations was limited by fragmented habitat, natural barriers, and anthropogenic barriers. Reintroductions of woodrats may be necessary for the species to repopulate formerly occupied sites throughout southern Illinois.

1014: +.171

The irregular distribution of the White-tailed Eagle in Europe is considered to be a relict of an earlier pan-European range. It was due to intense human persecution in Western Europe in the last millennium. Although populations in northern Europe have recovered, there is no such change in the rest of the continent. Most ornithologists regard this eagle as a northern species living in wild places but changes in attitudes towards large raptors gives hope of successful re-colonisation in more inhabited lands. Migrants are becoming commoner in winter to the south of the breeding areas but experience suggests long distance natural recovery is unlikely. Sea eagles exhibit a slow

rate of range expansion, even in productive breeding populations. The re-introduced Scottish population has reached 21 breeding pairs and the techniques for re-introduction are now well proven and successful. In order to restore the white-tailed eagle to large parts of its original range, it is recommended that a program of new translocations is carried out in western and southern Europe.

1015: +.011

The last two pairs of White-tailed Sea Eagle were extinguished from Israel in 1957 following the drainage of the Hula swamp and the massive and uncontrolled use of Thallium sulphate. These were probably the last breeding pairs of the species in this area of the Middle East: Lebanon, Israel, Syria and Iraq. Since the extinction, only wintering, or migrating, White-tailed Sea Eagles (less than seven per year) have been observed in Israel. In 1991, a re-introduction program was started to restore the White-tailed Sea Eagle population in Israel, and hopefully in the Middle East. The source is captive bred White-tailed Sea Eagles from Israel and European zoos. Captives are released by hacking: chicks are placed in an artificial nest for acclimatization until the age of fledging ([approximately]80 d) and then released. Since 1992, 21 White-tailed Sea Eagles have been released. Nineteen by hacking: 12 in the Hula Nature Reserve and 7 in Beit Shean valley; 2 two-year old birds were released after long acclimatization in the Hula valley. Eight losses of released birds (38%) have been recorded, three in the Hula valley and five in Beit Shean valley: one drowned in a small fish tank, one was poisoned in Jordan; three males and a female were predated shortly after release and two were electrocuted. Since the releases started, White-tailed Sea Eagles have occupied the Hula Valley and the adjacent Golan Heights and Upper Galilee. A male released in 1992 and female in 1993 formed a pair in 1996 and bred from 1998 in a two-meter wide nest, 30 m above the ground in a Eucalyptus tree but as yet without success. The diet of the released birds varied from livestock carcasses to all vertebrates classes except Amphibia, apparently according to local availability.

1016: +.147

Archaeology, placenames and documentary evidence clearly reveals that the Sea Eagle was once a common and widespread bird in the British Isles. Habitat loss and persecution reduced it to west and north coast strongholds in the 19th century leading to its ultimate extinction as a breeding bird by 1916. The localities of both Golden and Sea Eagle clutches taken in the past indicate that the two species occupied separate habitats, but some overlap did occur in certain freshwater systems inland, and on larger, mountainous islands. Once the Sea Eagle disappeared Golden Eagles spread to occupy some of its former territories on the coast. Although the smaller of the two is the more aggressive, the Sea Eagle seems to be experiencing little difficulty in re-establishing, some Golden Eagles being ousted completely but others managing to live alongside their larger cousin. There are also areas available to Sea Eagles that are without Golden Eagles altogether. Thus the prospects are good for the continued growth and expansion of the reintroduced population.

1019: +.190

Current Status: The Quino checkerspot butterfly (*Euphydryas editha quino*), is federally listed as endangered. This taxon occurs in San Diego and Riverside Counties and several localities in Baja California Norte, Mexico. Although no long-term empirical monitoring of populations has been conducted, some conclusions may be drawn regarding the species' overall status. The Quino checkerspot butterfly has apparently undergone a limited increase in abundance and distribution following its disappearance during the prolonged 1980's drought. However, current species

abundance and distribution remain far below the pre-drought 1970's levels, and there is no evidence that the long-term decline due to human impacts has slowed (see section I.C.5 below, Metapopulation Resilience). Although large portions of occupied habitat are under public ownership, few, if any, known population distributions (preliminarily delineated in this document as occurrence complexes, further defined below) are entirely protected. There are no populations currently known to be resilient. Destruction and degradation of occupied habitat continues throughout the range of the Quino checkerspot butterfly, and some level of ongoing degradation exists in all occupied habitat.

Habitat Requirements and Limiting Factors: The Quino checkerspot butterfly is found in association with topographically diverse open woody canopy landscapes containing low to moderate levels of nonnative vegetation compared to disturbed habitat. Vegetation types that support the Quino checkerspot butterfly include coastal sage scrub, open chaparral, juniper woodland, and native grassland. Soil and climatic conditions, as well as other ecological and physical factors, affect the suitability of habitat within the species' range. Urban and agricultural development, invasion of nonnative species, habitat fragmentation and degradation, and other human-caused disturbances have resulted in substantial losses of habitat and declines in habitat suitability throughout the species' historic range.

Conservation needs include protection and management of landscape connectivity (habitat patches and intervening dispersal areas); habitat restoration and enhancement; and establishment of a formal Quino checkerspot butterfly captive breeding program. The recovery strategy focuses on landscape-level protection of metapopulations that experience marked fluctuations in density and geographic distribution on a scale of 5 to 10 years. This recovery plan identifies six recovery units (Northwest Riverside, Southwest Riverside, South Riverside, South Riverside/North San Diego, Southwest San Diego, and Southeast San Diego). Recovery units are the major units for managing recovery efforts. Most recovery units contain one or more existing core (relatively large) occurrence complexes. A number of factors were considered in identifying recovery units, primarily biological and genetic factors, political boundaries, and ongoing conservation efforts. In some instances, recovery unit boundaries were modified to maximize efficiency of reserves, encompass areas of common threats, or accommodate logistic concerns. Recovery units may include areas of apparently suitable networks of habitat patches and dispersal areas that are not known to be occupied, when biological evidence warrants.

Biologically, Quino checkerspot butterfly recovery units include areas within which gene flow is currently possible.

Recovery Priority: 6C, per criteria published in the Federal Register (U.S. Fish and Wildlife Service 1983a, 1983b). The priority is based on designation as a subspecies with a high degree of threat, a moderate to low potential for recovery, and existing conflict between the species' conservation and development.

Objectives: The overall objective of this recovery plan is to reclassify the Quino checkerspot butterfly from endangered to threatened status and ensure the species' long-term conservation. Interim goals include: (1) protect and manage habitat supporting known current population distributions (occurrence complexes) and landscape connectivity between them; (2) maintain or create resilient populations; and (3) conduct research necessary to refine recovery criteria.

Reclassification to threatened status is appropriate when a taxon is no longer in danger of extinction throughout a significant portion of its range. Because data upon which to base reclassification decisions are incomplete, downlisting criteria in this recovery plan are necessarily preliminary. There are insufficient data on which to base delisting criteria at this time.

Recovery Criteria: The Quino checkerspot butterfly could be downlisted to threatened when the following criteria are met: 1) Permanently protect the habitat within occurrence complexes (estimated occupied areas based on habitat within 1 kilometer (0.6 mile) of recent butterfly occurrences; see section I.D below, Distribution and Habitat Considerations), a configuration designed to support resilient populations. One or more occurrence complexes may belong to a single greater population distribution, an occurrence complex may contain more than one whole or partial population distributions. When population distributions are determined, they will replace the occurrence complex as the protected

unit. There are currently 46 described occurrence complexes. 2) Conduct research including: determine the current short-term and potential long-term distributions of populations and associated habitat; conduct preliminary modeling of metapopulation dynamics for core occurrence complexes identified in section I.D below (Distribution and Habitat Considerations). 3) Permanently provide for and implement management of occurrence complexes (or population distributions when delineated) to restore or enhance habitat quality and population resilience. Management should be implemented as described in Recovery Action 1 (section II.C below, Recovery Action Narrative). 4) The protected, managed (conserved) population segments within core occurrence complexes (or population distributions when delineated) must demonstrate evidence of resilience. Evidence of resilience is demonstrated if a decrease in the number of occupied habitat patches over a 10- to 20-year period within an occurrence complex (or population distribution when delineated) is followed by increases of equal or greater magnitude. Monitoring must be initiated in the third of three years of favorable climate (total annual January and February precipitation within one standard error of the average total for those months over the past 30 years, based on local or proxy climate data). Populations that do not demonstrate resilience after 20 years should be augmented and monitoring reinitiated. 5) One additional population should be documented or introduced within the Lake Matthews population site (formerly occupied, not known to be currently occupied) in the Northwest Riverside Recovery Unit. At least one of the extant populations outside of current recovery units (e.g. the San Vicente Reservoir occurrence complex) must meet resilience specifications above unless an additional population is established or documented within 10 kilometers (6 miles) of the ocean (a more stable marine climate influence should minimize susceptibility to drought and reduce probability of extirpation). 6) Establish and maintain a captive propagation program for purposes of maintenance of representative refugia populations, research, and reintroduction and augmentation of wild populations as appropriate. 7) Initiate and implement a cooperative outreach program targeting areas where Quino checkerspot butterfly populations are concentrated in western Riverside and southern San Diego Counties. At present there is insufficient information about the biology of the species to establish criteria and timeframes for delisting. Research needs for development of delisting criteria are described under Recovery Action 6 below.

1020: +.160

The eastern Gulf Slope streams draining the Apalachicola Region are defined as streams from the Escambia to the Suwannee River systems. Occurring in southeast Alabama, west-central and southwest Georgia, and north Florida, these river systems collectively form one of the largest drainage areas in the eastern Gulf Coastal Plain. Historically, these rivers were known for their rich freshwater mussel populations. However, the fat threeridge (*Amblema neislerii*), shinyrayed pocketbook (*Lampsilis subangulata*), Gulf moccasinshell (*Medionidus penicillatus*), Ochlockonee moccasinshell (*Medionidus simpsonianus*), oval pigtoe (*Pleurobema pyriforme*), Chipola slabshell (*Elliptio chipolaensis*), and purple bankclimber (*Elliptoideus sloatianus*) mussels have all undergone significant reduction in total range and abundance. Current Status: The fat threeridge, shinyrayed pocketbook, Gulf moccasinshell, Ochlockonee moccasinshell, and oval pigtoe were federally listed as endangered species; and the Chipola slabshell and purple bankclimber were federally listed as threatened species under the Endangered Species Act of 1973, as amended, on March 16, 1998 (63 FR 12664). These mussel species are vulnerable to extinction due to significant habitat loss, range restriction, and population fragmentation and size reduction. Only one (purple bankclimber) of the species remains in the Chattahoochee River main stem, having recently (2000) been rediscovered after a nearly 150-year absence from collection records. There is little evidence of recent recruitment documented during status surveys for these species except the fat threeridge. The restricted distribution of these seven species also makes localized

subpopulations susceptible to adverse habitat and water quality alterations, toxic chemical spills, and the deleterious effects of genetic isolation. **Recovery Goal:** Restore viable populations of the fat threeridge, shinyrayed pocketbook, Gulf moccasinshell, Ochlockonee moccasinshell, oval pigtoe, Chipola slabshell, and purple bankclimber within a significant portion of their historical ranges, and eliminate or reduce threats to their continued survival, so that their protection under the Endangered Species Act is no longer required. **Recovery Strategy:** Because of the extent of their decline and the continuing threats to their habitats, securing the viability of existing subpopulations of the seven species and their habitats is the most important and urgent recovery objective. The most efficient means of accomplishing this objective is by applying knowledge of the distribution and habitat needs of these species towards reducing and preventing threats to the existing populations and their habitats through existing regulatory mechanisms, habitat restoration programs, and partnerships with various stakeholders. That knowledge will grow as research outlined in this plan, about the species' life history, threats, and management techniques for habitat restoration, is completed. As the viability of existing subpopulations and their habitats is secured, the next objective is to increase the number of subpopulations and extend their range. This objective is necessary in order to reach our recovery goal for these mussels. Increases can occur in two basic ways, by either finding a previously unknown subpopulation, or artificially reestablishing a new subpopulation. Reestablishing new subpopulations will require close coordination and concurrence of the State(s) and other partners with interests at any potential reintroduction sites. Due to the low numbers of animals in most extant subpopulations, the propagation of laboratory- or hatchery-reared progeny is the most likely means of providing animals for new subpopulations. Priorities for recovery via artificial propagation are: (1) develop propagation technology; (2) augment and expand the ranges of extant subpopulations to ensure their viability; and (3) reestablish viable populations in other streams within their historical range that have suitable habitat and water quality. As these elements of our recovery strategy are implemented, we will also periodically monitor subpopulations and habitats in order to measure progress towards recovery and to support possible modifications to the recovery plan. Because these mussels are affected by land and water uses that occur upstream in their watersheds, an outreach program is proposed to educate the public about watershed conservation generally, and the role of mussels in their ecosystem specifically. The last element of our recovery strategy is to periodically evaluate the effectiveness of recovery plan implementation. This is always a necessary component of recovery plans, but is an especially important one in this plan because we have much to learn still about these species and we anticipate that recovery will take more than 15 years to accomplish. **Recovery Criteria:** The Service will consider the fat threeridge, shinyrayed pocketbook, Gulf moccasinshell, Ochlockonee moccasinshell, and oval pigtoe for reclassification to threatened status when each species has: (1) shown an increase in its current range to reflect occupation of at least 50 percent of the total historical habitat; (2) at least three viable subpopulations in each of the watersheds (listed in Table 8) that currently supports the species (e.g., Econfina Creek, lower Flint River); and (3) at least ten viable subpopulations in the large river basins (i.e., Apalachicola- Chattahoochee-Flint, Ochlockonee, Suwannee Rivers) within the historical range of the species, for at least 3 generations. The Service will consider delisting the five endangered mussels, the Chipola slabshell, and purple bankclimber when biennial monitoring shows that an increase of the current number of subpopulations/sites and extent of occurrence is enough to ensure population viability, reduce isolation among populations, and increase the potential for genetic exchange. Specific increases in subpopulations and river miles needed to delist all 7 mussels from threatened status are currently unknown and will be determined by tasks outlined in this recovery plan. To downlist and delist these seven mussels, all necessary subpopulations must be viable and secure, and all current and foreseeable threats must be identified and reduced as addressed under the Listing/Recovery Factor Criteria.

1021: **-.051**

The Peary caribou (*Rangifer tarandus pearyi*) was recognized as 'Threatened' by the Committee on the Status of Endangered Wildlife in Canada in 1979 and 'Endangered' in 1991. It is the only member of the deer family (Cervidae) found on the Queen Elizabeth Islands (QEI) of the Canadian High Arctic. The Peary caribou is a significant part of the region's biodiversity and a socially important and economically valuable part of Arctic Canada's natural heritage. Recent microsatellite DNA findings indicate that Peary caribou on the QEI are distinct from caribou on the other Arctic Islands beyond the QEI, including Banks Island. This fact must be kept in mind if any translocation of caribou to the QEI is proposed. The subspecies is too gross a level at which to recognize the considerable diversity that exists between Peary caribou on the QEI and divergent caribou on other Canadian Arctic Islands. The Committee on the Status of Endangered Wildlife in Canada should take this considerable diversity among these caribou at below the subspecies classification to mind when assigning conservation divisions (units) to caribou on the Canadian Arctic Islands. In summer 1961, the first and only nearly range-wide aerial survey of Peary caribou yielded a population estimate on the QEI of 25 845, including about 20% calves. There was a strong preference for range on the western QEI (WEQI), where 94% (24 363) of the estimated caribou occurred on only 24% (ca. 97 000 km²) of the collective island-landmass. By summer 1973, the overall number of Peary caribou on the QEI had decreased markedly and was estimated at about 7000 animals. The following winter and spring (1973-74), the Peary caribou population declined 49% on the WQEI. The estimated number dropping to 3000, with no calves seen by us in summer 1974. Based on estimates from several aerial surveys conducted on the WQEI from 1985 to 1987, the number of Peary caribou on the QEI as a whole was judged to be 3300-3600 or only about 13-14% of the 1961 estimate. After a partial recovery in the late 1980s and early 1990s, Peary caribou on the WQEI declined drastically between 1994 and 1997 and were estimated at an all-time known low of about 1100 animals by summer 1997. The number of Peary caribou on the QEI in summer 1997 was likely no more than 2000-2400 or only 8-9% of the 1961 estimate. The four known major die-offs of Peary caribou on the WQEI between 1973 and 1997 occurred during winter and spring periods (1 Sep-21 Jun) with significantly greater (P<0.005) total snowfall, when compared to the long-term mean obtained from 55 caribou-years (1 Jul-30 Jun), 1947/48-2001/02, of weather records from Resolute Airport on Cornwallis Island. Of ecological significance is that the die-offs occurred when the caribou were at low mean overall densities and involved similar high annual rates of loss among muskoxen (*Ovibos moschatus*). All of the available evidence indicates that Peary caribou (and muskoxen) on the QEI experienced die-offs from prolonged, undernutrition (starvation) caused by relative unavailability of forage-the forage was there but it was inaccessible to the caribou due to snow and/or ice cover. We cannot control the severe weather that greatly restricts the forage supply but we should try to reduce the losses of Peary caribou from other sources-humans, predators and competitors.

1022: **+.032**

Currently, river otters (*Lontra canadensis*) range throughout Canada and northern parts of the United States, which constitutes half their historical range. River otters are a threatened species in South Dakota, although their current status and distribution are relatively unknown. We attempted to determine the status and distribution of river otters in South Dakota. To conduct river otter surveys, 14 rivers and 3 creeks were selected throughout South Dakota based on stream size (orders three to seven), water gradient, and water permanence. At each river or creek, line transects and shorelines (below high water mark) were surveyed for river otter sign. In addition, reports were collected from the Natural Heritage Database and landowners, and observation report forms were mailed to state conservation officers collecting their observations. Thirty-four verified

and three unverified sightings were recorded during our research. Eighty-nine percent of the sightings were reported in eastern South Dakota, particularly along the Big Sioux River. There may be a small population of river otters residing in the Big Sioux River watershed, which is possibly the result of reintroduction efforts by the Flandreau Santee Sioux Tribe. From our survey efforts, we found no indication of a remnant river otter population in South Dakota, though a small population of reintroduced river otters may reside in the eastern third of South Dakota. Because river otter populations do not likely exist in other areas of the state, efforts should be taken to restore this native animal to South Dakota's river systems.

1023: +.068

We report a case of successful reproduction in wild-released orphan chimpanzees. Using non-invasive genetic analysis, we determined the paternity of an infant born to a female chimpanzee released by HELP (Habitat Ecologique et Liberte des Primates) Congo into the Conkouati-Douli National Park, Republic of Congo. The sire was a released male, thus demonstrating successful reproduction in both male and female released chimpanzees. These results provide evidence that release into the wild may be a viable response to the plight of orphan chimpanzees in Africa, and we discuss further applications of non-invasive genetic tagging to release programs.

1024: -.066

Dasyurid marsupials are distributed throughout the major terrestrial environments of Australia, but since European settlement have suffered local and regional extinctions, range reductions and population decline. In this paper we examine the conservation status of small dasyurids (<500 g) and the threats they face. We also evaluate recovery procedures for threatened taxa and assess their success. Twenty-four percent of smaller dasyurids are classified as vulnerable, endangered or data deficient. Large body size and occupancy of one or two habitat types are correlated strongly with endangerment; species currently considered as 'low risk, near threatened' group closely with vulnerable and endangered species, indicating a risk of further declines. The processes contributing most to declines include habitat loss and fragmentation, altered fire regimes and predation. As of April 2001, no Recovery Plans had been adopted by the Commonwealth Government for any small dasyurid species. There is much information on the reproduction and development of smaller dasyurids, making them suitable for captive breeding. However, captive breeding programs have been limited, the dibbler *Parantechinus apicalis* being the only species bred systematically for reintroductions. There is a need for integration between captive breeding programs and recovery planning, as well as for more information on the population viability and metapopulation structures of small dasyurids, genetic diversity of populations and inbreeding depression. We suggest a program of survey, research, management and education to improve conservation outcomes for all small dasyurids.

1025: +.073

The genetic diversity of re-established population of endangered species *Allium angulosum* L. was tested as a one part of rescue program. Founder individuals were picked in Chropyne - Zarici area (North Moravia, Czech Republic) and new population was set in Protected Landscape Area Litovelske Pomoravi (North Moravia, Czech Republic). The task was whether the newly founded population was made by representative individuals to cover (include) the genetic variability of source (mother) population. Items were tested with variability assay of six isozyme systems (G-6-PDH, AAT, PGM, EST, ACP, PGI) using discontinuous polyacrylamide gel electrophoresis (PAGE). The method stated relatively sufficient level of variability on condition that new

population would be raised to prevent genetic changes. Application of more tests checking the genetic diversity within population could be useful during reintroduction and management of endangered plant species.

1026: +.155

The aim of this work was to assess density, biomass and species composition of earthworm communities within four translocated grasslands at Runway 2, Manchester Airport. Results from this study also evaluated the availability of earthworms as a food source for displaced, protected vertebrate species. The sites studied differed in topography and method/type of soil/turf transfer. Earthworms were extracted by digging and hand sorting of soil from replicated 0.1 m² plots, followed by vermifuge application. Monitoring from 1998-2001 produced nine species of earthworm representing all three ecological groupings. Throughout, areas supplied with turf contained significantly ($P < 0.05$) more earthworms with greater mass than adjacent areas supplied with soil only. Areas of hummocks and adjacent wet hollows, both covered with the same translocated turf, differed in species composition. Data are presented for mean earthworm community density and mass over the sampling period. Across all sites, figures for density and mass (in 2001), ranged from 50-427 m⁻² and 12-128 g m⁻² respectively. In all sampled areas, density and mass of earthworms has either increased or remained relatively stable, suggesting each translocation method to be successful after 4 years.

1027: +.189

The ecological communities of Quail Island (Otamahua) in Lyttelton Harbour, Banks Peninsula, New Zealand, are being restored to a more natural condition. Invertebrates were collected from the island and identified to produce an inventory. Banks Peninsula endemic species currently known from Quail Island include: five spider species *Misgolas borealis*, *Migas saxatilis*, *Maniho ngaitahu*, *Pahora kaituna* and *Stanwellia* sp., a tenebrionid beetle *Mimopeus granulatus*, a cockroach *Celatoblatta* sp., a ground weta *Hemiandrus* sp., a cicada *Kikihia* sp., a silverfish *Heterolepisma* sp., a millipede *Icosidesmus schenkeli* and a snail *Charopa pseudocoma*. A rare native aphid, *Aphis cottieri*, was found on *Muehlenbeckia complexa* and the populations represent some of the largest known for this aphid. Species absent from Quail Island but found close by in Orton Bradley Park include a tree weta (*Anostostomatidae*) *Hemideina femorata* and five ground beetle (*Carabidae*) species. Insects proposed for introduction are listed and habitat requirements are discussed.

1028: +.300

This Strategy provides a response to the key threats to native fish populations in the Murray-Darling Basin. These range from flow regulation, habitat degradation, lowered water quality, manmade barriers to fish movement, the introduction of alien fish species, fisheries exploitation, the spread of diseases and translocation and stocking of fish. Native fish populations in the Basin's rivers have declined under these threats with experts estimating that current levels are about 10 per cent compared to pre-European settlement. The vision of this Strategy is to ensure that the Basin sustains viable fish populations and communities throughout its rivers. The goal of this Strategy is to rehabilitate native fish communities in the Basin back to 60 per cent of their estimated pre-European settlement levels after 50 years of implementation. In the absence of targets that underpin accountability arrangements, the best expert advice recommends the following as examples of indications of the level of implementation needed by 2013: * an overall increase of aquatic structural habitat values of 20 per cent; and * functional processes and river floodplain

links re-established for 80 per cent of remaining wetland habitats through improved flow management. This Strategy has been developed and will be implemented within the context of the Murray-Darling Basin Commission's Integrated Catchment Management Policy. This policy reflects a commitment by the community and governments to do all that needs to be done to manage and use the resources of the Basin in an ecologically sustainable manner. A substantial reallocation of funding will be needed by governments and the community to implement this Strategy. This partnership approach depends on the commitment of individual landholders, Indigenous communities, Landcare groups, catchment management organisations, waterway managers, urban and rural community groups, local, State and Australian Government agencies, as well as the Murray-Darling Basin Commission. The Strategy will address its goal and targets through strategic actions designed to achieve 13 objectives directed at improving the status of native fish populations in the Basin. These objectives are to: 1. repair and protect key components of aquatic and riparian habitats; 2. rehabilitate and protect the natural functioning of wetlands and floodplain habitats; 3. improve key aspects of water quality that affect native fish; 4. modify flow regulation practices; 5. provide adequate passage for native fish; 6. devise and implement recovery plans for threatened native fish species; 7. create and implement management plans for other native fish species and communities; 8. control and manage alien fish species; 9. protect native fish from threats of disease and parasites; 10. manage fisheries in a sustainable manner; 11. protect native fish from the adverse effects of translocation and stocking; 12. ensure native fish populations are not threatened from aquaculture; and 13. ensure community and partner ownership and support for native fish management. These 13 objectives will be achieved by implementing six driving actions that include management, research and investigation, and community engagement interventions: * rehabilitating fish habitat - helping to achieve objectives 1-8; * protecting fish habitat - helping to achieve objectives 1-8; * managing riverine structures - helping to achieve objectives 4-8; * controlling alien fish species - helping to achieve objectives 6-9; * protecting threatened native fish species - helping to achieve objectives 6 and 10; and * managing fish translocation and stocking - helping to achieve objectives 9-12. All of the driving actions include a community engagement component designed to achieve objective 13. The establishment of effective fish passages through major barriers and the implementation of engineering and operational solutions to thermal pollution are the core actions for managing riverine structures. Alien fish species will be managed through integrated pest management approaches that use a combination of actions to reduce populations and stop the spread of alien fish species. The Strategy urges immediate investment in the development and implementation of species' recovery plans for threatened or endangered native fish species. The establishment of Habitat Management Areas will help such recovery plans. A consistent, coordinated and firm Basin-wide approach is needed for managing fish translocation and stocking. The implementation of the driving actions will not see an immediate return on investment. While the rehabilitation of fish habitat and the management of riverine structures should result in changes within the next 10 to 15 years to native fish communities, the other driving actions are likely to take considerably longer before benefits become obvious. However, if this investment is delayed it will prove more costly to rehabilitate the Basin's native fish communities in the future. A key feature of the driving actions, especially for rehabilitation of fish habitat, will be the establishment of Riverine Management Zones that reflect the ecological functioning of the Basin's rivers as well as management capabilities. Management plans will be developed for each Zone and will be prioritised for investment according to both their feasibility and importance. Plans will be integrated with other planning processes. Within Riverine Management Zones there may be demonstration reaches, varying from a few kilometres in length to larger sections of about 100 kilometres. The demonstration reaches will integrate all land and water programs to form comprehensive rehabilitation exercises on important and visible river reaches. The key purpose of a demonstration reach is to show the community the cumulative benefits of using a number of actions for rehabilitating native fish populations and communities.

Riverine Management Zones may also include Habitat Management Areas that aim to protect remnant areas of healthy fish habitat. The Habitat Management Areas can range from those with limited human access to multiple-use areas, such as those which allow sustainable recreational angling. Experts have agreed that the actions such as habitat restoration and improved environmental flows detailed in the Strategy must be acted upon in an integrated way, if they are to be effective. If undertaken singly, the capacity of these interventions to recover the native fish populations of the Basin beyond 25 per cent of their pre-European level is questionable. The targeting of investment in the actions of developing a system of Habitat Management Areas and managing other alien fish species will also ensure a greater level of success with this approach. This Strategy will be monitored against accountability indicators in conjunction with the Sustainable Rivers Audit process. Its progress will be reviewed annually, with major external reviews of the Strategy conducted in the fifth and tenth year of its operation. In 2013, development of the 2013-23 Native Fish Strategy will ensure Basin-wide approaches to native fish management into the foreseeable future. The successful implementation of this Strategy relies on knowledge generation and exchange. This will be achieved by research and investigation to fill gaps in our knowledge and understanding about fish and river ecology, and through a comprehensive communication strategy that focuses on partner consultation and engagement. An agreed, fully funded Native Fish Strategy will provide benefits beyond just those for native fish:

- * There are obvious and significant economic advantages to the recreational fishing and tourism industries through having healthy fish populations and healthy rivers;
- * Healthy fish populations would signal a return of cultural values and the notion of community 'connectedness' to the River;
- * Indigenous people across the Basin have always had a strong spiritual and physical connection to the environment, and healthy fish populations and river systems will ensure the continuation of this connection;
- * The holistic and integrated approach promoted in the Strategy will lead to enhanced biodiversity conservation generally, and highlight the contribution of improved native fish populations to river ecosystems;
- * The aesthetic value of an improved, functioning river system cannot be overstated - for example, carp-free wetlands and intact riparian vegetation;
- * Improved river health will enhance all recreational activities, particularly for those Australians who live in the vicinity of the Basin's rivers and wetlands.

All available evidence indicates that on a Basin-wide scale, native fish populations and communities are not in good shape. However, we are not starting from scratch- there have been some success stories to date. There are a number of examples where the sort of 'interventions' mentioned in the Strategy have led to increased native fish populations. For example:

- * Resnagging has been conducted at 14 sites on the River Murray with the addition of over 300 large river red gum snags. The resnagging was conducted on a scientific basis which allowed the testing of different snag pile locations and configurations. Structured monitoring has been undertaken which shows that a range of native fish species use the new snags, in the same proportions as would have been expected in natural snag piles. The snags were favoured by native species such as Murray cod, trout cod and golden perch, but were not heavily used by carp. Different locations were more successful than others, indicating designs to maximise environmental benefit. Similarly, different locations were used by different species. A cost benefit analysis of resnagging was also conducted.
- * Torrumbarry was the first fishway built in Australia that was directly based on experiments on the swimming ability of native fish. In 1990 it was the highest fishway at the time, at 6.5 metres. It opened up 350 km of river, to Yarrawonga Weir upstream. From the moment it was opened, native fish used it; in the first two years the fishway passed over 20 000 native fish from seven species. Above the weir, numbers of silver perch increased and juvenile golden perch were seen for the first time in decades. Tagged golden perch moved all the way to Yarrawonga Weir and also entered the Goulburn River. Shortheaded lampreys, a very uncommon native species, used the fishway-these fish migrate from the sea and have swum over 1600 km to reach Torrumbarry.
- * Before Googong Dam was constructed on the Queanbeyan River in 1978, there was a small population of the threatened Macquarie perch in the

river. After the dam was built, a fish monitoring program revealed that Macquarie perch were present in the reservoir, but were not breeding. It is believed that the filling of the reservoir flooded all available Macquarie perch spawning sites, and the population was unable to access the spawning habitats in the river above the reservoir because of a natural barrier posed by a waterfall. Fifty-seven adult Macquarie perch were netted from the reservoir and transported upstream, past the waterfall, and released at two sites on the Queanbeyan River. There is now a thriving population of Macquarie perch, with regular breeding occurring. * In the lower Murray, there are several local areas where anglers have reported increased catch rates for the larger species (such as Murray cod), while at the same time carp populations seem to be in decline

1029: +.073

Translocation of animals to re-establish extirpated populations or to maintain declining ones has often been carried out without genetic information on source or target populations, or adequate consideration of the potential effects of mixing genetic stocks. We consider the conservation status of the fisher (*Martes pennanti*) and evaluate the potential genetic consequences of past and future translocations on this medium-sized carnivore by examining population variation in mitochondrial control-region sequences. We sampled populations throughout the fisher's range in North America including five populations unaffected by translocations and two western populations that had received long-distance translocations. Twelve haplotypes showed little sequence divergence. Haplotype frequencies differed significantly among subspecies and between populations within subspecies. Analysis of molecular variance (AMOVA) and neighbour-joining analyses of haplotype relationships revealed population subdivision similar to current subspecies designations, but which may reflect an isolation-by-distance pattern. Populations in Oregon and in Montana and Idaho received several translocations and each showed greater similarity to the populations where translocations originated than to adjacent populations. Additional sequences obtained from museum specimens collected prior to any translocations suggest historical gene flow among populations in British Columbia, Washington, Oregon, and California. Anthropogenic impacts in that region have greatly reduced and isolated extant populations in Oregon and California. Future translocations may be necessary to recover populations in Washington and portions of Oregon and California; our results indicate that British Columbia would be the most appropriate source population.

1031: +.158

Current Species Status: The Karner blue butterfly, *Lycaeides melissa samuelis* Nabokov (Lepidoptera: Lycaenidae), formerly occurred in a band extending across 12 states from Minnesota to Maine and in the province of Ontario, Canada, and now only occurs in the seven states of Minnesota, Wisconsin, Indiana, Michigan, New York, New Hampshire, and Ohio. Wisconsin and Michigan support the greatest number of Karner blue butterflies and butterfly sites. The majority of the populations in the remaining states are small and several are at risk of extinction from habitat degradation or loss. Based on the decline of the Karner blue across its historic range, it was listed as endangered in 1992. Since listing, two populations have been extirpated and are being reintroduced to Concord, New Hampshire, and West Gary, Indiana. A third population is being reintroduced to Ohio. Habitat Requirements and Limiting Factors: The Karner blue butterfly is dependent on wild lupine, *Lupinus perennis* L. (Fabaceae), its only known larval food plant, and on nectar plants. These plants historically occurred in savanna and barrens habitats typified by dry sandy soils, and now occur in remnants of these habitats, as well as other locations such as roadsides, military bases, and some forest lands. The primary limiting factors are loss of habitat through development, and canopy closure (succession) without a concomitant restoration of

habitat. A shifting geographic mosaic that provides a balance between closed and open-canopy habitats is essential for the maintenance of large viable populations of Karner blue butterflies. Recovery Objectives: The objective of this recovery plan is to restore viable metapopulations of Karner blues across the species extant range so that it can be reclassified from endangered to threatened. The long-range goal is to remove it from the Federal list of Endangered and Threatened Wildlife and Plants. Recovery Criteria: The reclassification criteria will be met when a minimum of 27 metapopulations [19 viable metapopulations (supporting 3,000 butterflies each), and 8 large viable metapopulations (supporting 6,000 butterflies each)] are established within at least 13 recovery units across the butterfly's range and are being managed consistent with the recovery objectives outlined in this plan. Delisting will be considered when a minimum of 29 metapopulations (13 viable and 16 large viable metapopulations) have been established within at least 13 recovery units and are being managed consistent with the plan. Actions Needed: 1. Protect and manage Karner blue and its habitat to perpetuate viable metapopulations. 2. Evaluate and implement translocation where appropriate. 3. Develop rangewide and regional management guidelines. 4. Develop and implement information and education program. 5. Collect important ecological data on Karner blue and associated habitats. 6. Review and track recovery progress (includes re-evaluation of recovery goals for Wisconsin).

1032: +.070

Baseline data on health of free-ranging wildlife is essential to evaluate impacts of habitat transformation and wildlife translocation, rehabilitation, and reintroduction programs. Health information on many species, especially great apes, is extremely limited. Between 1996 and 1998, 84 free-ranging orangutans captured for translocation, underwent a complete health evaluation. Analogous data were gathered from 60 semi-captive orangutans in Malaysia. Baseline hematology and serology; vitamin, mineral and pesticide levels; and results of health evaluations, including physical examination, provide a baseline for future monitoring. Free-ranging and semicaptive orangutans shared exposure to 11 of 47 viruses. The semi-captive orangutans had significantly higher prevalence of antibodies to adenovirus ($P < 0.0005$) and rota (SA 11) virus ($P < 0.008$). More free-ranging than semi-captive animals had antibodies to Japanese encephalitis virus ($P < 0.08$) and foamy virus ($P = 0.05$). Exposure to parainfluenza and langkat viruses was detected exclusively in semi-captive animals and exposure to sinbis virus was only found in free-ranging orangutans. There was evidence of exposure to respiratory syncytial virus, coxsackie virus, dengue virus, and zika virus in both groups. Ebstein-Barr virus was ubiquitous in both groups. Prevalence of antibodies against mumps virus changed from 0% in 1996 to 45% in 1998. No antibodies were detected to many important zoonotic viral pathogens, including herpesvirus and hepatitis virus. Prevalence of *Balantidium coli* and *Plasmodium pitheci* infections and exposure to mycobacterium was higher in the semi-captive animals. Differences in exposure to pathogens between the groups may be due to environmental factors including differences in exposures to other species, habitat quality, nutritional status, and other potential stressors. Differences in health parameters between captive and free-ranging orangutans need to be considered when planning conservation areas, translocation procedures, and rehabilitation protocols. Because survival of the orangutan is linked to animal and ecosystem health, results of this study will assist wildlife conservation programs by providing baseline health information.

1033: +.165

This 589-page book is meant to be an introduction to the subject of mammal invasions and their threat to biodiversity and ecological integrity around the world. It represents a companion volume to *Introduced Birds of the World*. The book provides a brief description of 337 mammalian species

that have been introduced, reintroduced or translocated into new environments, with a summary of the history of introductions, habits, behaviour, distribution and influence for each. The history includes date of introduction, person or agency responsible, location of release, and the fate of the introduction. The book is organized by Order, Family and Genus, with species placed alphabetically under each genus. The text is illustrated with distributional maps for several of the animals and with line drawings for a small number. A lengthy list of references is included at the end of the book, as well as an index to common names and an index to scientific names. The text is written in English. Users of the book will include students of ecological systems management and biological conservation and practitioners in those fields.

1034: +.318

The development of new scientific techniques has led to significant advances in our understanding of biodiversity and the threats facing animal populations. Zoos have been at the forefront of the application of these techniques, ranging from cytogenetics to the analysis of small-population biology, with the aim of improving animal management and facilitating in situ conservation. Many of the key applications of genetic analysis are discussed; for example, assessing species diversity, utilizing studbook data, understanding genetic diseases and the related implications for captive-breeding and reintroduction, together with the latest technological developments. The increasing power of genetic analysis will offer fundamental insights into aspects of biology that are of direct concern to zoos.

1035: +.345

This paper reviews the occurrence and quality of reintroductions of plants and animals, and the use of reintroduction as a tool in conservation biology. The Re-introduction Specialist Group (RSG) of the IUCN/Species Survival Commission (SSC) was created in 1988 and the activities of the Group are described. Illustrations of innovative processes and practices, developed within improved frameworks of policies and legislation, including the Convention on Biological Diversity, show that reintroduction has become a more rigorous discipline with the potential to contribute to community-restoration programmes. The activities of the RSG have contributed to this achievement.

1037: +.063

The last lowland locality of *Gentiana verna* in the Czech Republic is a calcareous grassland near Rovna at Strakonice in South Bohemia. This locality was the subject of a recovery programme that included support of the remaining population by micropropagation. The plants were inoculated with arbuscular mycorrhizal fungi (AMF) after their transfer to ex vitro and the effect of AMF on their establishment and survival was studied. Although the conventional method of inoculation of *G. verna* using spores or colonized root segments as an inoculum source resulted in no or negligible root colonization, the transplantation of gentians to the locality Rovna was successful and the plants became colonized with AMF very rapidly in the field. Successful mycorrhization of gentians under experimental conditions occurred only via the extraradical mycelial network established by neighbouring mycorrhizal plant species (nurse plant effect). Different nurse plant species formed different morphological types of mycorrhiza when inoculated with the same fungal isolate. Gentians always had the Paris type of root colonization with intracellular hyphal loops and swellings. Intercellular hyphae, arbuscules and vesicles were not observed. No evidence for a positive growth response was found in *G. verna*.

1038: -.037

Previous work suggests that submergence of *Lycaena dispar* larvae during overwintering may play a significant role in this butterfly's population dynamics. Since potential re-introduction sites in eastern England are prone to regular seasonal flooding, we further studied the species' submergence tolerance with a view to formulating management protocols conducive to larval survivorship under periodic flood conditions. Simulated flooding regimes using captive-reared larvae showed that enforced submergence has a twofold effect: firstly, a direct increase in mortality after 28 days under water and, secondly, a longer term, post-diapause increase in mortality; manifest either as an inability of larvae to resume feeding, or a failure to complete development. Additionally, there was a marked difference in the response of "early" and "late" diapause larvae; the latter generally succumbing after shorter periods under water, and suffering higher total mortalities. Behavioural investigations suggest that, if afforded the opportunity, diapausing larvae can evade submergence by climbing onto the exposed sections of partially flooded host plants. Significantly, survival on partially flooded plants was found to be comparable to that on unflooded controls. Further re-introductions of *L. dispar* in the U.K. will probably necessitate a direct translocation of wild Dutch stock. As the flood tolerance of this source population remains largely undetermined, and given that re-introduction site hydrology will be generally unamenable to conservation-oriented manipulation, it is recommended that restoration management be directed towards creating structural diversity in the vegetation of overwintering habitats, thereby providing potential "flood refugia" for hibernating larvae.

1039: +.149

This paper presents data obtained on the biology of the Marquesan Imperial-Pigeon, or Upe, a critically endangered species that is very poorly studied, during a reintroduction procedure of the species from Nuku Hiva to Ua Huka Island, which was initiated as a conservation priority to create a second population. Our data show that in the study area, the Upe preferentially used the plant species of the emergent tree stratum and some of the native tree species of the intermediate stratum. The species' diet includes fruit and grain but also flowers, leaves and insects. Data collected on nest sites, social interactions, courtship, vocalisations and measurements, including sex and age determination, are also presented.

1040: +.056

The leaf beetles *Cryptocephalus coryli*, *C. decemmaculatus* and *C. nitidulus* are of conservation concern and are included on the UK Biodiversity Action Plan. The distinctiveness of the disjunct remaining populations of these beetles was compared to that of more continuously distributed *Cryptocephalus* species. This was carried out with a view to defining evolutionary significant units (ESUs) in the rare species. A portion of the cytochrome b gene, an intergenic spacer and partial tRNA was analysed from 93 specimens of *Cryptocephalus* beetle (Coleoptera: Chrysomelidae). Considerable sequence divergence was apparent in all the species, even at an intersite scale when the distances between sampled localities were very small (< 1 km). Intrapopulation, intersite and interpopulation divergence observed in the rare species was reflected in the species that have a more continuous distribution, implying that dispersal ability in these species is poor and gene flow can be impeded by relatively trivial barriers to dispersal. The evidence suggests that the disjunct populations of the rare *Cryptocephalus* species can, tentatively, be considered as ESUs. This has important implications for management strategies and reintroductions.

In a Zoo-FISH study chicken autosomal chromosome paints 1 to 9 (GGA1-GGA9) were hybridized to metaphase spreads of nine diverse birds belonging to primitive and modern orders. This comparative approach allows tracing of chromosomal rearrangements that occurred during bird evolution. Striking homologies in the chromosomes of the different species were noted, indicating a high degree of evolutionary conservation in avian karyotypes. In two species, the quail and the goose, all chicken paints specifically labeled their corresponding chromosomes. In three pheasant species as well as in the American rhea and blackbird, GGA4 hybridized to chromosome 4 and additionally to a single pair of microchromosomes. Furthermore, in the pheasants fission of the ancestral galliform chromosome 2 could be documented. Hybridization of various chicken probes to two different chromosomes or to only the short or long chromosome arm of one chromosome pair in the species representing the orders Passeriformes, Strigiformes, and Columbiformes revealed translocations and chromosome fissions during species radiation. Thus comparative analysis with chicken chromosome-specific painting probes proves to be a rapid and comprehensive approach to elucidate the chromosomal relationships of the extant birds.

The Delmarva fox squirrel, *Sciurus niger cinereus*, is a federally listed endangered subspecies whose range has been reduced by 90%. In an attempt to increase both population size and range, translocation sites were established beginning in the 1960's by moving squirrels from the natural range to sites outside the current range. Although translocations have served as the primary component of the DFS recovery program, there has been very little post-release examination of the genetics of the translocation sites. In this study, we developed ten microsatellite loci, screened the three polymorphic loci, and sequenced a 330 bp fragment of the mitochondrial control region in order to assess levels of genetic variation in natural and translocated regions of Delmarva fox squirrels and to compare them to Southeastern fox squirrels (*S. n. niger*). Although we found low levels of microsatellite polymorphism, there were no differences in heterozygosity between natural and translocated regions, or between Delmarva and Southeastern fox squirrels. We found high levels of polymorphism in the mitochondrial control region. Our patterns of haplotype diversity suggest incomplete lineage sorting of the two subspecies. In general, our data suggest that the current levels of genetic variation in the translocated sites are representative of those found in the natural population, and we encourage the continued use of translocations as a major component of Delmarva fox squirrel recovery.

1043: -.009

Silene hifacensis is a narrowly endemic plant, restricted to a few small populations on limestone cliffs in the Spanish province of Alicante and on the Balearic island of Ibiza. The species was collected to extinction in its original mainland location by the early 20th century. Attempts have been made to reintroduce *S. hifacensis* to this area but conservation efforts are limited by a lack of information on the geographic structure of genetic variation in the species. We used nuclear (allozyme) and chloroplast DNA (cpDNA) PCR/RFLP markers to investigate the structure of genetic variation in 2 mainland and 6 Ibizan populations. Levels of allozyme variation were low, with a mean of 2 alleles per polymorphic locus. Mean (over polymorphic loci) total allozyme diversity (H_{tot}) was 0.203 and mean within-population diversity (H_{pop}) was 0.085. Most diversity was explained by the between-population diversity component ($G(\text{pop})$, $\text{reg} = 57\%$). Both mainland populations showed allozyme fixation. Three composite cpDNA haplotypes were identified. The first is unique to a mainland population that is also allozymically distinct from all the other populations. The second haplotype is found in the other mainland population and one

Ibizan population: these two populations are allozymically identical. The remaining Ibizan populations contain the third haplotype. The geographic distribution of allozymes and cpDNA haplotypes is discussed in terms of population history, dispersal and, speculatively, in terms of the possibility that there has been undocumented translocation of material between populations.

1044: +.058

Until recently, the dusky Canada goose (*Branta canadensis occidentalis*) was managed as one breeding population from the Copper River Delta (CRD), Alaska. Population numbers on the CRD have declined precipitously over the last three decades, due in part to changes in habitat. In 1981, a pair of Canada geese, presumably *B. c. occidentalis*, was reported nesting on Middleton Island (MID), in the Gulf of Alaska. Numbers of Canada geese on the island increased in the decade subsequent to a translocation of geese from CRD to MID, but it is unclear whether the increase is attributable to the translocation effort. We used genetic data derived from three classes of genetic markers to clarify relationships of Canada geese breeding in south-coastal Alaska. Geese were sampled from 5 populations: CRD, MID, Anchorage (ANC), Admiralty Island (ADM) in southeastern Alaska, and Green Island (GRN) in Prince William Sound (PWS). Mitochondrial DNA analyses demonstrate Canada geese from MID are nearly monomorphic for a unique haplotype fixed on GRN but not found in CRD or any other breeding population. Furthermore, nuclear markers consistently cluster MID with GRN to the exclusion of CRD. We suggest the current population on MID is not derived from birds translocated from CRD, but rather that MID was most likely colonised by birds inhabiting other island habitats within the PWS. Furthermore, since geese from the CRD share mtDNA haplotypes with geese from other breeding locales, they apparently share recent common ancestry and/or gene flow with populations representing other subspecies. Our genetic data raise questions about the validity of current management units of Canada geese.

1045: +.119

Dry, sandy scrub habitats of the Florida peninsula represent naturally fragmented remnants of xeric ecosystems that were widespread during the Pliocene and early Pleistocene. This habitat is characterized by high endemism, and distribution of genetic and evolutionary diversity among scrub "islands" is of compelling interest because Florida scrub is rapidly disappearing under human development. We compare range-wide diversity in mitochondrial cytochrome b sequences for three scrub-associated lizards with contrasting levels of habitat specificity. All species show strong geographic partitioning of genetic diversity, supporting the hypothesis that scrub fauna is highly restricted by vicariant separations. The mole skink (*Eumeces egregius*), the least habitat specific, has the lowest phylogeographic structure among the lizards ($\phi(st) = 0.631$). The mtDNA genealogy for *E. egregius* is not entirely concordant with the five recognized subspecies and supports a link between populations in central Florida (*E. e. lividus*) and the Florida Keys (*E. e. egregius*) rather than a previously proposed affiliation between northern and southern populations. The Florida scrub lizard (*Sceloporus woodi*) is the most habitat specific of the lizards and has the strongest phylogeographic structure ($\phi(st) = 0.876$). The sand skink (*Neoseps reynoldsi*) falls between the mole skink and scrub lizard in terms of habitat specificity and phylogeographic structure ($\phi(st) = 0.667$). For all three species, networks of mtDNA haplotypes coalesce on two central ridges that contain the oldest scrub. The geographic structure and deep evolutionary lineages observed in these species have strong implications for conservation, including strategies for translocation, reserve design, and management of landscape connectivity.

1046: +.110

Pleistocene fragmentation of the Great Bahama Bank resulted in one large and several small populations of rock iguanas (*Cyclura cyclura*). We explore patterns of genetic variation within and among these island populations using mitochondrial sequence data (partial ND4 to tRNA(Leu)) in combination with eight polymorphic microsatellite loci (2 to 10 alleles). Genetic data support two phylogeographically distinct groups, Andros Island and the Exuma cays. This result conflicts with current subspecific taxonomy in which three subspecies are described. Analyses of allelic data indicate that most island populations are currently demographically independent. Pairwise F_{st} values between eight island populations range from 0.18 to 0.63, and 6 of 135 individuals are misassigned in an assignment test. Population-genetic diversity is characterized using standard measures such as number of alleles and heterozygosity (H) in addition to a normalized Shannon-Weaver index of diversity (D). We find genetic diversity in the Andros Island population comparable to that in other non-piscine animals (avg. # of alleles = 5, avg. H = 0.56, avg. D = 0.66) while in the Exuma cays populations these measures are much lower (avg. # of alleles = 2.75-1.625, avg. H = 0.43-0.17, avg. D = 0.45-0.18). These data are used to discuss conservation management strategies, including prioritization and translocation.

1047: +.251

Underpinning the conservation management of *Austropotamobius pallipes* in the UK is the process of monitoring and reporting crayfish distribution. Should the current trend in the decline of *A. pallipes* continue, the species could be virtually extinct in mainland Britain within 30 years (SIBLEY, 2003). Conversely, if the increase in the distribution of non-indigenous crayfish species (NICS) continues at its current rate, the distribution (by 10 km squares) of these species could double within 15 years. These forward projections are based on a number of possibly unreliable assumptions; they illustrate however the magnitude of the challenge facing those concerned with the conservation of *A. pallipes* in the UK at this time. Recent work in crayfish conservation management in the UK has yielded guidance in several areas including monitoring, habitat enhancement and a re-introduction protocol for *A. pallipes* (KEMP and HILEY, 2003). Similarly, scientific research continues to inform our understanding of the movement and behaviour of NICS and explores new methods for the potential management of these species. In addition, the protection afforded to *A. pallipes* by current legislation is key to the long-term survival prospects of the species, albeit with a probable fragmented distribution, across the British Isles and continental Europe. Legal provisions in the UK derive in part from European instructions (e.g. EC Habitats and Species Directive) and also from national legislation (e.g. Salmon and Freshwater Fisheries Act (1975) and the Wildlife and Countryside Act (1981)). Also, a raft of "quasi-legislation" exists which requires responsible organisations in the UK to implement the white-clawed crayfish biodiversity action plan (BAP). Altogether these provisions constitute a considerable volume of legal protection for crayfish and provide the legal framework on which UK management policy and practice are based.

1048: +.183

When looking at the various national surveys performed in Metropolitan France since 1977 by the Conseil superieur de la peche, crayfish species distribution shows that native species (*Austropotamobius pallipes*, *Astacus astacus*, *Austropotamobius torrentium*) are either rare, or in decline; while the introduced species (*Orconectes limosus*, *Pacifastacus leniusculus*, *Procambarus clarkii*, *Astacus leptodactylus*), are increasing. The ban of live introduced species transport, except for *A. leptodactylus*, didn't stop this process with a peculiar acceleration of *P. leniusculus* propagation these last five years, certainly responsible for plague (*Aphanomyces astaci*) renewed outbreaks. The other measures in favor of native species, such as fishing limitations and

reintroduction plans, have not reversed the trend. So, it seems necessary to develop a conservation policy based on habitat preservation and on the respect of certain prophylactic rules which are to be determined. That can only be considered on watersheds of small area, easily controlled if local authorities are involved. The 55 French habitat decrees, and the 154 Natura 2000 zones with their management plans, seem to be a promising way to implement this type of actions in France. The case of Corsica, recently colonized by *O. limosus*, would require special measures to prevent the island from invasion by *P. leniusculus* and *P. clarkii* in the future.

1049: +.002

Before 1994, the California condor (*Gymnogyps californianus*) captive program relied upon egg removal, double clutching, and hand rearing for the rapid increase of the captive population and subsequent reintroduction. Problems encountered with the first hand-reared released birds resulted in modification of the captive condor program to initiate parent rearing whenever possible. From 1994 through 1999, we examined incubation behavior in eight captive pairs of California condors at the San Diego Wild Animal Park using time-lapsed, dawn-to-dusk video recordings. Known pedigrees were the basis for pair formation rather than free choice. For males and females, we calculated the percent of time spent incubating, frequency of nest box entry with distinction between entries into a vacant or occupied nest box, egg manipulation, number of incubation bouts, nudge mate, egg pull, and aggressive interactions. There were no sex differences in the percent of time spent in incubation. Males entered occupied nest boxes significantly more often than females and such entries frequently resulted in aggression. Females had a higher mean rate of aggression than did males, but the difference was not significant. Because some pairs had higher combined rates of male/female aggression than others we categorized pairs as "compatible" or "incompatible" based on the results of paired sign tests. Incompatible pairs had a significantly greater proportion of entry into occupied nests, rates of nudge mate, and egg pull than the compatible pairs. Observed differences found within particular pairs in their daily time spent on nest and rates of aggression suggest that some of the forced pairs were less cooperative in their parental care duties. As more birds become available for captive propagation, there will be greater flexibility in establishing cooperative condor pairs and potentially increasing the number of parent-reared birds for release.

1050: +.175

Stocks of anadromous American shad *Alosa sapidissima*, blueback herring *A. aestivalis*, and alewife *A. pseudoharengus* are being restored to the Susquehanna River in Maryland, Pennsylvania, and New York. This river once supported extensive American shad and herring fisheries that were lost with construction of four large hydroelectric dams in the lower 90 km during 1904-1931. Fish reintroduction and project evaluation activities have been undertaken over a 3-decade period by numerous state, federal, and utility company partners. These included the culture and release of over 150 million marked larval and fingerling American shad and trap and transport of over 200,000 prespawning adults to suitable spawning waters above blockages. The American shad population returning to the lowermost dam on the Susquehanna grew from only a few hundred to over 150,000 fish in the past 16 years. Survival of out-migrating juvenile American shad through hydroelectric turbines has been evaluated and, where necessary, improved with project operational changes during peak movement periods. Settlement agreements reached with each of the utility companies led to construction of large-capacity fish elevators and ladders at the four lower river dams during 1991-2000. As a result, over 750 km of historic spawning habitat for anadromous fishes has been reopened for the first time in almost a century.

1051: +.160

Among fishes of the family Clupeidae (which includes the shads), about 29 species are diadromous, most of them anadromous, though one is amphidromous and two are catadromous. The origin and evolution of diadromy in shads remains largely unexamined, and how often it has evolved is unknown. The implications of diadromy, nine of which follow, for the ecology, evolution, and biogeography of shads are diverse. (1) Diadromy suppresses evolutionary divergence and increase, in species diversity through facilitation of gene flow among populations that are otherwise isolated in separate river systems. (2) This gene flow is hindered, and so divergence and diversity are fostered, when diadromous shads are able to undertake accurate homing to natal habitats. (3) Diadromy facilitates dispersal and the acquisition of broad geographical ranges, because even where there is some homing, straying is likely. (4) Diadromy enables species to be among the first that invade newly available habitats (as with the retreat of glaciers) and also facilitates restoration of fish populations to habitats following short-term perturbation. (5) Diadromy appears, in general, to hinder successful human translocation of species to novel areas, probably as a result of highly evolved navigational powers that relate to solar or geomagnetic guidance mechanisms, though the only instance in which an anadromous shad translocation has been attempted was successful, and the species has continued to spread. (6) Diadromous migrations pose special problems for conservation, in relation to the need for fishes to have both upstream and downstream access during their life cycles. (7) There is latitudinal variation in the frequency of diadromy, with anadromous fishes tending to be more common at higher latitudes, but explanations of this variation that point to parallel gradients in marine productivity seem more elegant than real and are, at best, partial. (8) Diadromy has a significant and distinctive role in stream fish community assembly; gradients of upstream-downstream diversity in strongly diadromous fish communities that superficially appear to conform to the River Continuum Concept have an altogether different explanation: diversity is an outcome of differential upstream penetration by fish species migrating into rivers from the sea. (9) Diadromy has implications for the application of indices of biological integrity (IBI) to the extent that without the acquisition of extensive data sets of local origin and the elaboration of models of distribution, IBIs are largely inapplicable to fish communities that include a significant proportion of diadromous fishes.

1052: +.106

Vulture Reintroduction Projects in the Alps. In the last century all four European vulture species nested in the Alps, albeit with different status, sometimes based upon unreliable historical data. Proposals for the reintroduction of the Bearded Vulture had already been put forward in the 1920's but the plan finally became operative with a program of reintroductions using the 'hacking' technique starting in 1986 in the High Tauern in Austria. Following on from this, the reintroduction program was extended to four different Alpine sectors and the use of various release points. Altogether more than 100 individuals have been released with a current population of about 70 Bearded Vultures. The first successful breeding occurred in 1997 since when there has been a gradual increase in the number of pairs formed and young birds fledging. The Eastern Alps play regular host to Griffon Vultures coming from the Balkans. These over-summer particularly in the High Tauern range in Austria and the mountainous areas of Friuli and Slovenia. This phenomenon seems to be declining in recent decades in parallel with the decline in Griffon Vulture populations in south-eastern Europe and especially those of the Kvarner Archipelago (Croatia), which holds the northernmost colonies and from where, at least in recent years, most of the birds originate. Steps to help the species were proposed from the 1970's onwards. The main focus of efforts for this species have been interventions aimed at helping the species maintain and

consolidate its presence in the Alpine area, as well as contributing to the protection of the northern Adriatic colonies. To this end a project was undertaken in the Friulan Pre-Alps with the release of 60 birds between 1992 and 1998 and the establishment of a feeding site. The initiative has brought about the creation of nesting colonies in the area with about 60 Griffon Vultures present. It also acts as a focal point for Croatian birds which can number more than 50 birds during the summer months. The possibility to stop over at secure sites with a reliable food supply has reduced mortality rates for these birds (particularly the juveniles), allowing the expansion of the feeding range of the Croatian colonies and providing a fundamental contribution to the strategy for the conservation of the species in Eastern Central Europe. Griffon Vultures from other areas (France and Spain) have also been observed at the site and the colonies and feeding site acts as a magnet, drawing in other raptors including species which are rare in Italy. After the success of the project in the Cevennes, three further Griffon reintroduction projects have been launched in Provence (France) with the aim of bringing the species back to southern France and the French Alps, In these areas the reintroduction of the Black Vulture is also being planned.

1053: +.356

Conservation and reintroductions: poor planning, many projects. By examining the INFS (Istituto Nazionale per la Fauna Selvatica) mail archives, scientific literature, the main popular nature magazines, and bulletins from the most relevant nature conservation associations, it has been possible to assess the extent of raptor reintroduction projects proposed or in progress in Italy between 1995 and 2001. In total, 115 news events have been recorded, referring to 23 projects involving 8 different raptor species. These results suggest that there are many reintroduction programs, carried out by many different organizations and concerning a wide range of species, some of them characterizing a favourable conservation outcome. In Italy, reintroductions are therefore perceived as ordinary tools for raptor conservation and are often promoted at the local level, without consideration of the wider perspectives and critical evaluation parameters (i.e., actual effectiveness of the action, priority level, risks assessment of impacts on natural populations, etc.). Such a situation requires the development of a more formal reintroduction policy for raptors and other wildlife in Italy. In order to change the current approach to reintroductions, and for improving the quality level of the reintroduction efforts, it is suggested that only those projects that are explicitly supported by international and national action plans should be undertaken in the future; and moreover, each reintroduction program should be submitted for scientific and technical approval.

1054: -.040

In 2001 the California Department of Fish and Game requested that I conduct an independent review of the causes of mortality of California Condors and to specifically review the data on lead in the environment in California and the magnitude of the lead exposure hazard to condors. The scope of this study has included the compilation of data on mortality, movements of birds in the field, feeding, monitoring efforts, blood sampling, and the lead exposure data for other species within the condor range in California. This review also examines the potential sources of lead in the environment in California, and assesses the magnitude of the exposure risk of lead to California Condors. The California Condor Recovery Program has overcome many hurdles in the effort to increase the condor population and return birds to successful independent survival in the wild. Captive propagation to increase numbers has been accomplished at three facilities (San Diego Wild Animal Park, Los Angeles Zoo, and the Peregrine Fund World Center for Birds of Prey, Boise Idaho) with the hatching and rearing of more than 250 chicks over the past 20 years. Reintroduced California Condors now occupy most of the range within California that they used

during the period 1940-1987. Range expansion into Monterey County has occurred with reintroductions near Big Sur. The wild-hatched condors AC8 and AC9, which were trapped in 1986-7 and held in captivity for 14 years, were reintroduced in 2000 and 2001, and they use the traditional foraging areas of the Sierra foothills. Condors have suffered a high mortality rate in the wild. During the 1970s and 1980s approximately half of the known population disappeared from the wild, with many of the carcasses never found. During that period, at least 3 condors died of lethal exposure to lead. All remaining condors were trapped and kept in captivity until a reintroduction program was begun in the early 1990s. Since 1995, more than 140 condors have been released in California and Arizona, and 44 are free-flying in California at the current time. Four condors have died of lead poisoning since 1997 (1 in California, 3 in Arizona), and 26 condors have received emergency chelation treatment to reduce toxic lead levels (8 in California, and 18 in Arizona). AC8 nearly died in November 2002, when she ingested metallic lead near Hopper Mountain NWR. Expert veterinary care prevented her death, and several other potential lead mortalities since 2000. AC8 was released back to the wild in late December 2002, but she was shot and killed on the Tejon Ranch in early February 2003. Field biologists have systematically monitored lead exposure in condors since 1997. In California, every bird has had detectable lead in blood samples. 62% of the blood samples taken in Southern California have shown higher than background lead exposure (blood levels greater than 20 $\mu\text{g}/\text{dl}$ blood). 13 of 87 samples (15%) have exceeded 60 $\mu\text{g}/\text{dl}$, indicating the condors were clinically affected by lead poisoning, and 6 birds have had blood lead levels greater than 100 $\mu\text{g}/\text{dl}$, indicating acute toxic exposure and requiring emergency veterinary intervention. The half-time for excretion of lead from condor blood is about 13 days, demonstrating that condors will quickly deplete lead if kept in a clean environment. The high number of condors with above background blood levels suggests that the birds are frequently exposed to lead in the wild. Metallic lead fragments have been positively identified in the digestive systems of two condors in California since 1984. Two additional condors (AC3 and 132) had metal fragments in their gut at death, but chemical analysis was not performed to confirm lead. Three other condors with high blood lead levels had X-ray identification of dense particles, also not confirmed by recovery and testing, making a total of seven condors in California suspected of having lead fragments in their digestive systems. In Arizona, seven condors have either had lead pellets recovered from their gizzards, or have been diagnosed by radiography. Six of these 14 birds died of lead poisoning, and the others were successfully treated for acute toxicity. Lead exposure and intoxication continue to be a very critical problem for both the California and Arizona populations. Seventeen of the 35 dead condors examined by pathologists have not been tested for lead exposure. High-resolution lead and copper analysis techniques should be conducted on feathers that were growing at the time of death of the archived condors to determine the extent of lead and copper exposure in all condors that have died and been recovered since 1982. Experimental studies with lead intoxication of other species of raptors indicate that condors are not more sensitive to lead intoxication than most species of birds. Turkey Vultures, however, are very resistant to the effects of lead, and are not a good surrogate species to compare with condors. Condors and Turkey Vultures also apparently have very different responses to ingested copper. Copper levels in the livers of condors analyzed at necropsy have all exceeded 20 ppm (21-181 ppm), although the significance of copper residue levels is unknown. Copper levels should be studied in feathers, to determine whether a relationship exists with lead exposure. Potential sources of lead within the condor range include residual atmospheric lead deposition from leaded gasoline exhaust, lead in the soil from natural deposits, from disposal of lead containing items, and lead ammunition on rifle ranges. Current industrial air emissions of lead in California are small, totally only 9301 pounds in 2001, and most emission sources are outside of the condor range and not in the prevailing wind pattern. Hunting within the condor range is extensive, and the number of game animals taken by hunters in 2001 was estimated at 106,049 for the eight counties within the condor range. This review estimates the

number of large animal carcasses and field-dressed visceral remains (gut-piles) left in the field at more than 30,000 annually. This includes the gut piles of 8,180 deer, 17,249 wild pigs, and the carcasses of 10,816 coyotes, plus unrecovered carcasses of deer and pigs crippled by hunters and depredation permit holders. The number of ground squirrels shot within the condor range is unknown, but almost certainly represents a significant source of carrion with the potential to contain lead fragments that could be ingested by both condors and other scavenging birds and mammals. The risk of lead exposure to condors is high, because of the amount of carrion left in the field. Direct observations of condors feeding on hunter-shot carrion are few, even with intense radio telemetry and visual surveillance, and every effort should be made to document and organize the field observation data to quantify the exposure hazard from hunter-shot carrion. Every effort should be made to educate hunters and depredation permittees of this potential problem, and to encourage or require the use of commercially available lead-free and "lead-safe" rifle and shotgun ammunition. Field and captive management efforts by the condor program have been highly professional and the overall program is very successful. The field program has concentrated on a feeding program to prevent exposure to lead, monitoring the birds to determine movements, capture of birds to keep radio transmitters functional and to collect blood samples to monitor for lead exposure, and emergency intervention to prevent the debilitation or death of birds exposed to lead. The program has become very labor intensive, but the efforts to prevent lead exposure have not been successful. If a reduction in condor lead exposure can be accomplished, the Condor Recovery Program shows every promise of successfully rebuilding a stable wild population.

1. After re-introduction in 1991 of Eurasian otters *Lutra lutra* (L.) to the River Lee catchment (England), changes in range were assessed from spraint collections in the periods 1991-1994, 1995-1997 and 1998-2000. Diet, assessed from concerted spraint sampling within the first two periods, was compared between 1992-1994 and 1996-1997, with dietary preferences assessed for the initial phase using available fish stock data for that period. 2. In 1991-1994, range encompassed much of the catchment, but reduced in 1995-1997 to a small area around the initial release site, when the otters were joined/replaced by natural immigrants presumed to come from a contiguous catchment. Range expanded in 1998-2000 to upper reaches of the catchment's major tributaries. 3. Fish, mainly cyprinids, were the major prey taken in 1992-1994 and 1996-1997. In 1996-1997, fish abundant near the initial release site became more prominent, in particular chub *Leuciscus cephalus*, and (upstream) species characteristic of the initial range decreased in importance. 4. Despite confirmed and unconfirmed sightings of females with cubs, it remains unclear whether the presence and apparent expansion of otters in the Lee catchment is the result of the reintroduction or of natural immigration/recolonization. 1060: +.278

The aim of this study was to evaluate the recovery and survival of four species of unionid mussels [pimpleback, *Quadrula pustulosa pustulosa* (I. Lea, 1831); spike, *Elliptio dilatata* (Rafinesque, 1820); Higgins eye, *Lampsilis higginsii* (I. Lea, 1857); and pocketbook, *Lampsilis cardium* (Rafinesque, 1820)] that were experimentally relocated to in situ refugia in the St Croix River of Minnesota and Wisconsin, USA. In 1996, 150 mussels of each of the first three species (450 total) were relocated to three 5 x 5 m study grids (Site A), one near Lakeland, Minnesota, which served as a source-site control, and two in the experimental refuge 48 km upstream, near Franconia, Minnesota. In a second relocation in 1997, *L. cardium* was substituted for *L. higginsii* and 150 mussels of this and each of the other two species (450 total), were relocated to two study grids (Site B). The source site control was near Sunrise, Minnesota and the experimental refuge was 14

km downstream near Almelund, Minnesota. Mussel recovery, survival and substratum characteristics were evaluated annually at Site A for 2 years and for 3 years at Site B. Mean annual recovery of all three species ranged from 90 to 100% at Site A, and from 34 to 70% at site B. The mean annual survival of recaptured mussels ranged from 85 to 100% at Site A, and from 88 to 100% at Site B. The textural characteristics of the substratum differed significantly between the control and the two refuge locations at the beginning of the study, but did not differ from this initial status among subsequent years at Site A. At Site B, there was a significant shift in textural characteristics from large to smaller fractions over the four years. The relatively high survival of mussels during this study demonstrates the importance of proper handling and transport protocols when relocating mussels and the selection of suitable relocation habitat with stable substratum. When established correctly, in situ refugia may be a viable tool for preserving unionid mussels.

1061: +.146

Kokako (*Callaeas cinerea wilsoni*) population recovery on the North Island of New Zealand depends primarily on control of key introduced mammal pests, especially ship rats (*Rattus rattus*) and brushtail possums (*Trichosurus vulpecula*). Recovery can still occur if pest control is pulsed (x years 'on'; y years 'off') because kokako sub-adults and adults are generally long-lived, although chick production is high only during 'on' years. Pulsing effort means that conservation resources can be extended to other sites or problems during 'off' years; that toxin input at any one site is reduced; and that project staff do not burn out by repeatedly working at a site. Mathematical modelling supports empirical evidence that pests need not be controlled every year in order to maintain or greatly increase kokako populations. It predicts that the total number of years during which there is pest control is the main factor determining population size. Three years of pest control in each 10 should be sufficient to at least maintain a population with 20 females when mean parameters apply, but pulsed control should still be effective with very pessimistic parameters. In the safest strategies, control should occur in minimum pulses of 2-3 years to avoid single poor years when few breeding attempts are made. Very small populations should first be increased to at least 20 females by translocation or continuous pest control. This will greatly reduce the probability of chance extinction, and increase the efficiency of subsequent pest control. The model will apply best to closed kokako populations below carrying capacity, in which pests are controlled over the entire block. Empirical data on the effects of habitat carrying capacity on kokako dispersal, and on the importance of stoats as predators of adult females are required to further strengthen the model. 1062: +.095

The western barred bandicoot was reintroduced to the Australian mainland in 1995 after an absence of at least 60 years. The new population was derived from 14 animals, reintroduced to Heirisson Prong from Dorre Island in Shark Bay, Western Australia. Introduced predators (the European red fox and the feral cat) were controlled at the reintroduction site, but European rabbits were not. A large fenced area of natural vegetation within the reintroduction site was used as a secure refuge from mammalian predators. Bandicoots were released from this predator refuge to the 12 km² conservation site. Dispersal from the point of free release was minimal. The reintroduced population has persisted for 4 years and increased, with at least 175 bandicoots recruited to the population in this time. The recapture rate of marked bandicoots was low, suggesting that adult mortality was high. Reproductive output at Heirisson Prong appeared greater than that of the two surviving wild populations on Bernier and Dorre Islands. Litter size was similar, but there was an extended annual breeding season at the reintroduction site. Body condition of reintroduced and wild bandicoots were similar, although there was some indication

that reintroduced males may have been in poorer condition than their island counterparts. The litter size of bandicoots increased with a decrease in rabbit abundance, however, bandicoots were able to reproduce, maintain condition, and sustain recruitment to allow the population to increase despite the presence of rabbits. Two fox incursions occurred during the 4-year period of establishment, and feral cats were present on occasion in low numbers. Feral cats may be responsible for a lower rate of population increase than that observed on predator-free Dorre Island. Ongoing predator control is essential for any mainland reintroduction of bandicoots. (C) 2002 Elsevier Science Ltd. All rights reserved.

1063: +.170

The behavioral development of reintroduced, captive-born animals and their wild-born offspring is understudied, limiting the scientific understanding and, therefore, utility of reintroduction as a conservation tool. Several reintroduction programs have shown that survival rates of captive-born animals are lower than those of their wild-born offspring. However, whether these differences are because of increased behavioral competency of wild-born animals or age-related factors is unknown. This study compared behavior of captive-born golden lion tamarins to that of their age-matched first- and second-generation descendents. Subjects included 134 golden lion tamarins living in and around the Poco das Antas Biological Reserve in Brazil. Overall, captive-born animals were deficient in locomotor and foraging skills as compared with their wild-born offspring, and some of these deficiencies persisted after two years in the wild. Locomotor and foraging differences were also observed between generations of wild-born animals, suggesting that behavioral change continued past the first generation. Recommendations for future reintroductions with this and other species include: (1) increased exposure to complex environments prior to release; (2) intensive post-release support; (3) introduction of naive animals with experienced conspecifics when possible; (4) comparisons of reintroduced and wild populations when possible; and (5) short-term management plans aimed at the survival of captive-born individuals combined with long-term plans focused on maximizing natural adaptive processes.

1064: +.134

Maritime ringlet butterflies (*Coenonympha tullia nipisiquit* McDunnough) are rare, endangered salt marsh butterflies with larvae that survive periodic tidal submergence. Only six disjunct populations are known to exist. First-instar larvae were released and monitored in seven microhabitats within a salt marsh in Bathurst, New Brunswick, Canada. From resighting data, microhabitat-specific daily death rates were estimated with maximum likelihood. The survival of the larvae released in groups was compared by calculating minimum number of larvae known to be alive (MNKA). Death rates were low in microhabitats with the larval host plant, salt meadow cordgrass (*Spartina patens* (Aiton) Muhl.) and the major nectar source, sea lavender (*Limonium carolinianum* (Walter) Britton), a habitat with a moderate frequency of flooding. Because microhabitats have a large effect on the survival rate of young larvae, use of microhabitat profiles in salt marshes as habitat-quality indices is recommended in critical-habitat assessment and reintroduction efforts.

1065: +.479

Declines in the number and range of prairie grouse (*Tympanuchus* spp.) in North America have prompted numerous translocation efforts to establish additional populations, but overall success of translocations has been low. Because success of a translocation is ultimately determined by the quantity and quality of habitat at the translocation site, evaluating habitat prior to translocation

should be a critical consideration. I used landscape characteristics surrounding 75 greater prairie chicken (*T. cupido*) leks and 75 unused points to develop a habitat model identifying suitability of landscapes for greater prairie chickens in Wisconsin. Presence of leks was positively associated with amount of grassland and wetland in the landscape and negatively associated with forest cover and distance from nearest known lek. The model correctly identified 94% of sample leks and unused points. I applied the model to digital landcover data of the entire state of Wisconsin to create a spatially explicit map predicting suitability of unoccupied landscapes for translocation of greater prairie chickens. Sites identified as suitable for greater prairie chickens agreed with results of other prairie chicken habitat models and landscapes identified as having high priority for conservation of grassland birds in Wisconsin. The most suitable landscapes had substantial public ownership but would likely require fine-grained management to meet all habitat requirements of greater prairie chickens. Landscape-level habitat models combined with accurate digital data provide an efficient means of objectively assessing habitat for prairie chicken translocation.

1066: +.064

Recent studies illustrate the emerging field of restoration genetics, which is a synthesis of restoration ecology and population genetics. The translocation of organisms during the restoration of native ecosystems has provoked new questions concerning the consequences of sampling protocols and of intraspecific hybridization between locally adapted and transplanted genotypes. Studies are now underway to determine both the extent of local adaptation among focal populations and the potential risks of introducing foreign genotypes, including founder effects, genetic swamping and outbreeding depression. Data are needed to delineate 'seed transfer zones', or regions within which plants can be moved with little or no consequences for population fitness. Here, we address the revival of transplant and common garden studies, the use of novel molecular markers to predict population genetic consequences of translocation, and their combined power for determining appropriate seed transfer zones in restoration planning for native plant populations.

1067: -.165

Desert bighorn sheep (*Ovis canadensis*) are known for their climbing skills in rugged and steep terrain. Occasionally sheep die from climbing accidents. Between 1979 and 1995, the Arizona Game and Fish Department reintroduced desert bighorn sheep to areas within their historic distribution: northwest, southwest, southeast, and central Arizona. Because at least half of reintroduced sheep ($n = 412$) were fitted with radiocollars and monitored monthly, we documented mortalities by climbing accidents. None of 54 mortalities in the southeastern region and 53 mortalities in the southwestern region was identified as climbing accidents. However, climbing accidents caused 5 of 42 sheep mortalities in the northwestern region and 4 out of 54 mortalities in the central region. Most climbing accidents (7 out of 9) happened <9 months after sheep were translocated. Our data suggest that translocated desert bighorn sheep can be vulnerable to climbing accidents due to lack of familiarity with local terrain. Differential vulnerability between regions might be related to differences in substrate, ruggedness of terrain, or both at release sites. Additionally, sheep translocated from less rugged terrain might be more likely to fall in new areas than sheep translocated from more rugged terrain.

1068: +.214

We translocated five colonies of the highly social and co-operatively breeding Black-eared Miner *Manorina melanotis*, an endangered Australian honeyeater. Two colonies were released immediately (hard release) and two colonies were housed in aviaries for up to a week on-site and

then supplied with food for a further week following release (soft release). A fifth colony was released using a combination of methods. All four hard and soft released colonies contained dependent fledglings at the time of release. This appears to be the first translocation of a cooperative species where intact colonies containing multiple breeding females, each with a suite of helpers have been translocated successfully. Both hard and soft release treatments appeared equally successful during an initial monitoring period of up to two months. All four colonies maintained social cohesion, and displayed high levels of survival and site fidelity. Both hard release and one soft release colony attempted to breed within 600 m of their release site within eight weeks of release. The other soft release colony bred 12 months later. We believe the inclusion of dependent young in each translocated colony provided a focus for translocated colonies that promoted site faithfulness and colony cohesion. Results of long-term monitoring remain inconclusive and it is recommended that monitoring be repeated during several future breeding events. Given our findings, we recommend that when translocating highly social species every effort is made to translocate the entire group, hard release techniques be applied and stimuli that enhance group cohesion and site faithfulness (the presence of dependent young) be exploited.

1069: +.119

The state of Washington and four Native American tribes on the east Olympic Peninsula cooperatively conducted single translocations of 17 Roosevelt elk into the Dosewallips drainage in 1995 and 24 elk into the Skokomish drainage in 1997, in attempts to augment the small resident herds. Three of the elk translocated into the Dosewallips and 12 of those translocated into the Skokomish were fitted with radio-collars and monitored for 3 yr post-translocation for survival and movement. Survival of elk translocated into the Dosewallips could not be calculated due to insufficient sample size, but survival of elk translocated into the Skokomish averaged 0.65 +/- 0.04 for the first 2 yr and was 0.80 the third year post-translocation. This compares with survival of 0.91 +/- 0.02 for 43 resident elk from six herds in the east Olympics from 1993-2000. Of the elk translocated into the Dosewallips, 41% remained with the resident herd for at least 1 yr, while only 4% of the translocated elk remained with the Skokomish herd for 1 yr. All radio-collared elk translocated into the Skokomish dispersed singly or in small groups an average of 20 km in the general direction of the source herd. The population in the Dosewallips herd increased from 26 to 46 within 1 yr of the translocation, and has remained stable at the higher level. The Skokomish herd increased from 17 to 25 after the translocation, but subsequently declined to 15.

1070: -.070

The reintroduction of wild boar from central Europe after World War II has contributed substantially to the range expansion of this species in Italy, where indiscriminate hunting in earlier times resulted in extreme demographic reduction. However, the genetic impact of such processes is not well-understood. In this study, 105 individuals from Italian and Hungarian wild boar populations were characterized for nine autosomal microsatellite loci. The Hungarian samples, and two central Italian samples from protected areas (parks) where reintroduction is not documented, were assumed to be representative of the genetic composition of the source and the target populations in the reintroduction process, respectively. Animals hunted in the wild in the Florence area of Tuscany (Italy) were then studied to identify the effects of reintroduction. The results we obtained can be summarized as follows: (i) none of the populations analysed shows genetic evidence of demographic decline; (ii) the three parental populations from Italy and Hungary are genetically distinct; however, the low level of divergence appears in conflict with the naming of the Italian and the European subspecies (*Sus scrofa majori* and *Sus scrofa scrofa*, respectively); in addition, the Italian groups appear to be as divergent from each other as they are from the

Hungarian population; (iii) most of the individuals hunted near Florence are genetically intermediate between the parental groups, suggesting that hybridization has occurred in this area, the average introgression of Hungarian genotypes is 13%, but approximate to 45% of the genetic pool of these individuals can not be directly attributed to any of the parental populations we analysed; (iv) analysis of microsatellite loci, though in a limited number, is an important tool for estimating the genetic effect of reintroduction in the wild boar, and therefore for the development of conservation and management strategies for this species.

1071: +.022

As part of a project to restore the American peregrine falcon (*Falco peregrinus anatum*) in Kentucky, cliff habitat, we initiated a series of pre-release evaluations designed to promote efficient allocation of project resources and to provide empirical support for decision-making. Pre-release evaluations included development of a demographic model examining the relative influence of first-year mortality, rate of philopatry, and founder cohort size on population persistence for 20 years. Using VORTEX, we simulated reintroductions in which 6-96 peregrine falcons were released annually for 3 consecutive years under conditions of first-year mortality and rate of philopatry that were 0.45-0.65 and 0.03-0.15, respectively. We used logistic regression to conduct sensitivity analysis. We compared standardized regression coefficients (b_n/SE_n) to quantify and rank the magnitude of effect on model outcomes at year 20 associated with changes in input parameter values. Founder cohort size accounted for the most variability, ($b/SE=9.85$) in the probability of persistence at year 20. First-year mortality and rate of philopatry affected the persistence of reintroduced peregrine falcon populations to a lesser extent ($b/SE=4.86$ and -0.11 , respectively). High first-year mortality (0.65) precluded population reestablishment regardless of founder cohort size. Similarly, releasing <48 peregrine falcons annually for 3 consecutive years resulted in high extinction probability ($gtoreq0.8$) and low population size at year 20 (<0.6), regardless of variation in first-year mortality and rate of philopatry. To address the influence of high first-year mortality on population recovery, we recommend a formal assessment of risk of predation or other sources of mortality at potential release sites. However, program financial resources should be allocated largely to maximizing founder cohort size because, given identification and avoidance of potential release habitats where first-year mortality, likely would be high (i.e., $gtoreq0.65$), successful restoration of peregrine falcons in Kentucky cliff habitat will be predicated on maximizing the number of peregrine falcons released.

1072: +.187

This paper presents brief overview of the historical development of the Beaver (*Castor fiber*) population in Germany. Thanks to conservation legislation and undertaken protection measures the post-war population of subspecies *C. f. albicus* (Matsche, 1970) survived from extinction. That population has grown up afterwards to approximately 3,500 animals. Also reintroduction projects are described. The most successful one was carried out in Bavaria, southern Germany, with several subspecies involved (*C. f. fiber*, *C. f. vistulanus*, *C. f. galliae*). Currently the Beaver population in Bavaria is estimated at 2,500 to 2,800 animals. The total stock of Beavers (ca. 6,000) is the result of comprehensive management based on systematic research. Number of Beavers continues to grow up, but populations in suboptimal habitats cause now increasing conflicts with water supplies, agriculture and forestry. Ecological adaptations of Beavers admit them to live in areas developed and populated by humans.

1073: +.392

Captive breeding and release programs, widely used to supplement populations of declining species, minimize juvenile mortality to achieve rapid population growth. However, raising animals in benign environments may promote traits that are adaptive in captivity but maladaptive in nature. In chinook salmon, hatchery rearing relaxes natural selection favoring large eggs, allowing fecundity selection to drive exceptionally rapid evolution of small eggs. Trends toward small eggs are also evident in natural populations heavily supplemented by hatcheries, but not in minimally supplemented populations. Unintentional selection in captivity can lead to rapid changes in critical life-history traits that may reduce the success of supplementation or reintroduction programs.

1074: +.051

Exterminated at the beginning of the 19th century, the beaver was reintroduced along the upper Rhine with animals captured in the Rhone valley: 22 animals released on the river Muehlbach (1973) and the river Moder (1993-95) in Alsace, thus as 4 animals on the river Rench (1979) in Baden. Method and results of the monitoring realized at 1998-2002 on both riversides of the upper Rhine are presented. The presence of beavers is attested in 28 localities in Alsace and 5 in Baden. Current population size is estimated at 90-110 individuals divided in two subpopulations that are mostly localized near both release areas in Alsace. However, three decades after the first releases in Alsace, the species has not yet reoccupied many suitable habitats like drainage channels, residual parts of the old Rhine and most part of the Floodplains in Baden. Several limiting factors are supposed to be responsible for this situation as deaths caused by non-selective process of destroying against muskrat and coypou, or by road traffic. Propositions are made for improvement of the habitats just as strengthening and monitoring of the net of beaver subpopulations established in the French and the German part of the Floodplain of the upper Rhine.

1075: +.080

Predation is an important selective pressure in natural ecosystems. Among non-human primates, relatively little is known about how predators hunt primate prey and how primates acquire adaptive responses to counteract predation. In this study we took advantage of the recent reintroduction of radio-tagged harpy eagles (*Harpia harpyja*) to Barro Colorado Island (BCI), Panama to explore how mantled howler monkeys (*Alouatta palliata*), one of their primary prey, acquire anti-predator defences. Based on the observation that harpies follow their prey prior to attack, and often call during this pursuit period, we broadcast harpy eagle calls to howlers on BCI as well as to a nearby control population with no harpy predation. Although harpies have been extinct from this area for 50-100 years, results indicate that BCI howlers rapidly acquired an adaptive anti-predator response to harpy calls, while showing no response to other avian vocalizations; howlers maintained this response several months after the removal of the eagles. These results not only show that non-human primates can rapidly acquire an alarm response to a newly introduced predator, but that they can detect and identify predators on the basis of acoustic cues alone. These findings have significant implications both for the role of learning mechanisms in the evolution of prey defence and for conservation strategies, suggesting that the use of 'probing' approaches, such as auditory playbacks, may highly enhance an a priori assessment of the impact of species reintroduction.

1077: +.133

We studied habitat use and movements of a repatriated population of federally endangered Wyoming toads (*Bufo baxteri*) after the breeding season at Mortensen Lake, Albany County, Wyoming, USA. We followed 8 adult toads using telemetry (n = 68 relocations) during periods of

activity and observed 59 post-metamorphic juvenile toads ($n = 59$ locations). Adult toads used habitat with a greater mean vegetation canopy cover (mean = 52.6%) than juveniles (mean = 39.20%). We found adults farther from the shoreline (mean = 1.32 m) than juveniles (mean = 1.04 m). Substrates used by toads had a mean surface temperature of 20.31 degreesC for adults and 23.05 degreesC for juveniles. We found most adult and juvenile toads on saturated substrates. All adult toads sampled did not move outside of a 30 x 500 m area along the east-to-south shore where they were captured. Toads were active diurnally through the end of October. We found toads torpid at night. We compared our results to a similar study of the historic population and found that adult toads of the current population used denser vegetation than those of the historic population. Unlike many bufonids, terrestrial stages of the Wyoming toad appear to depend on saturated substrates. The best logistic regression predictors of adult and juvenile toad presence were surface temperature and distance to shore. Survey transects within the moist margin of the lake (! 10 m from water) and after substrates have reached temperatures greater than or equal to 20 degreesC will likely yield more detections.

1078: +.241

1. The UK Biodiversity Action Plan (UKBAP) identifies invertebrate species in danger of national extinction. For many of these species, targets for recovery specify the number of populations that should exist by a specific future date but offer no procedure to plan strategically to achieve the target for any species. 2. Here we describe techniques based upon geographic information systems (GIS) that produce conservation strategy maps (CSM) to assist with achieving recovery targets based on all available and relevant information. 3. The heath fritillary *Mellicta athalia* is a UKBAP species used here to illustrate the use of CSM. A phase 1 habitat survey was used to identify habitat polygons across the county of Kent, UK. These were systematically filtered using relevant habitat, botanical and autecological data to identify seven types of polygon, including those with extant colonies or in the vicinity of extant colonies, areas managed for conservation but without colonies, and polygons that had the appropriate habitat structure and may therefore be suitable for reintroduction. 4. Five clusters of polygons of interest were found across the study area. The CSM of two of them are illustrated here: the Blean Wood complex, which contains the existing colonies of heath fritillary in Kent, and the Orlestone Forest complex, which offers opportunities for reintroduction. 5. Synthesis and applications. Although the CSM concept is illustrated here for the UK, we suggest that CSM could be part of species conservation programmes throughout the world. CSM are dynamic and should be stored in electronic format, preferably on the world-wide web, so that they can be easily viewed and updated. CSM can be used to illustrate opportunities and to develop strategies with scientists and non-scientists, enabling the engagement of all communities in a conservation programme. CSM for different years can be presented to illustrate the progress of a plan or to provide continuous feedback on how a field scenario develops.

1079: +.019

A total of 21 acidified Norwegian rivers are now being limed to re-establish or restore Atlantic salmon, *Salmo salar* L., stocks. Natural reproduction of Atlantic salmon was evident 1 year after the first year of liming in all rivers that had lost their native stocks ($n=9$) except for one river. The density of fry (age 0+) developed significantly more rapidly in rivers that supported remnant stocks than in rivers that had lost their stocks, based on data 5 years after treatment. Nine of the study rivers were supplied with hatchery-reared salmon, mainly unfed fry. Of the rivers with lost stocks, those which were supplied with fish had significantly higher densities than those that were not enhanced. On the other hand, rivers with remnant stocks that were supplied with fish had significantly lower densities of salmon fry than those that did not undergo such mitigation

measures. In 2001, all limed rivers yielded 41.9 t of salmon.

1080: +.008

Mammalian carnivores are increasingly the focus of reintroduction attempts in areas from which they have been extirpated by historic persecution. We used static and dynamic spatial models to evaluate whether a proposed wolf reintroduction to the southern Rocky Mountain region (U.S.A) would advance recovery by increasing species distribution beyond what might be expected through natural range expansion. We used multiple logistic regression to develop a resource-selection function relating wolf distribution in the Greater Yellowstone region with regional-scale habitat variables. We also used a spatially explicit population model to predict wolf distribution and viability at several potential reintroduction sites within the region under current conditions and under two contrasting predictions of future landscape change. Areas of the southern Rocky Mountains with resource-selection-function values similar to those of currently inhabited areas in Yellowstone could potentially support >1000 wolves, 40% within protected areas and 47% on unprotected public lands. The dynamic model predicted similar distribution under current conditions but suggested that development trends over 25 years may result in the loss of one of four potential regional subpopulations and increased isolation of the remaining areas. The reduction in carrying capacity due to landscape change ranged from 49% to 66%, depending on assumptions about road development on public lands. Although much of the wolf population occurs outside core protected areas, these areas remain the key to the persistence of subpopulations. Although the dynamic model's sensitivity to dispersal parameters made it difficult to predict the probability of natural recolonization from distant sources, it suggested that an active reintroduction to two sites within the region may be necessary to ensure low extinction probability. Social carnivores such as the wolf, which often require larger territories than solitary species of similar size, may be more vulnerable to environmental stochasticity and landscape fragmentation than their vagility and fecundity would suggest.

1081: +.041

During October-December 1989-1991, biologists from the Vermont Fish and Wildlife Department and the USDA Forest Service reintroduced 115 (88 male, 27 female) American Martens (*Martes americana*) into the southern half of the Green Mountain National Forest. During the years of release, brief radio-contact was made with 9 of the 13 (8 male, 5 female) radio-collared animals, and several of these may have established residency. Results of winter track count surveys suggested the presence of at least four Martens in 1990. During winter 1994-1995, Trailmaster(R) cameras and boxed camera systems detected Martens at two, and Fishers (*Martes pennanti*) at 11, of 20 sites. During winter 1997-1998, Fishers were detected at 37 of 47 boxed camera sites, but no Martens were detected. During summer 1997 and 1998, no Marten photos were recorded at 285 pressure-plate camera stations in a larger area that included all Marten release sites. Although post-release monitoring may have been insufficient to definitively confirm Marten presence, results from the 1997 and 1998 camera surveys indicate that a viable population of Martens was not established in southern Vermont, perhaps due to competition with Fishers.

1082: +.043

With gray wolves restored to Yellowstone National Park, this ecosystem once again supports the full native array of large ungulates and their attendant large carnivores. We consider the possible ecological implications of wolf restoration in the context of another national park, Isle Royale, where wolves restored themselves a half-century ago. At Isle Royale, where resident mammals are

relatively few, wolves completely eliminated coyotes and went on to influence moose population dynamics, which had implications for forest growth and composition. At Yellowstone, we predict that wolf restoration will have similar effects to a degree, reducing elk-and coyote density. As at Isle Royale, Yellowstone plant communities will be affected, as will mesocarnivores, but to what degree is as yet undetermined. At Yellowstone, ecosystem response to the arrival of the wolf will take decades to unfold, and we argue that comprehensive ecological research and monitoring should be an essential long-term component of the management of Yellowstone National Park.

1083: -.030

Wild dogs have been eradicated from most of South Africa. However, a large number of smaller isolated reserves offer the potential for metapopulation conservation management of this species through continued translocations among reserves. Wild dogs were released into the Pilanesberg National Park (500 km²), South Africa, in June 1999 from a combination of wild captured and captive-bred individuals. The reserve has lions but no spotted hyaenas. We document post-release spatial use, prey selection and breeding biology. Dogs used a very small area (13.4 km²) for their first denning period, and then ranged more widely, but avoided the central parts of the park. Movement patterns and den site locations suggested that dogs avoided the presence of lions. Major prey species were kudu (50 %), impala (32 %) and waterbuck (14 %). Large prey, including adult male kudu (250 kg) and waterbuck (260 kg) were taken regularly through use of the boundary fence as an aid to capture. Wild dogs have bred three times since introduction, indicating that reserves as small as 200 km² may be suitable for introduction of wild dogs, and metapopulation management strategies may be a viable option as long as sympatric large predator populations are absent or managed appropriately.

1084: +.070

The cooperation between international organisations for conservation of species and local wildlife rescue centers is not ideal at present. But the right to exist of the latter is undeniable and their position and contribution to conservation activities should be improved and intensified. Basic approaches were two workshops held by the Humane Society of the United States/International (HSUS/HSI) and the university of San Jose, Costa Rica, with together more than 200 participants (representatives from different governments and rescue centers, biologists and veterinarians) from North-, Central- and South America. Aims were to improve the rescue centers in animal husbandry, disease controlling, techniques of reintroduction to the wild and environmental education. Rescue centers which are specialized on certain taxa, like 'Profelidae', could contribute to projects of zoos and breeding centers by sharing their experiences. International trade with wild animals is directed and controlled by CITES. But what about national wild animal trade? Surveys in Costa Rica have shown, that in 24[degree] of the households, wild animals are (most illegally) kept. In the city of Santa Cruz de la Sierra (Bolivia), this percentage is almost doubled (47 [degree]). Due to bad terms of keeping, mortality, and, thus, sales are high. This shows once more, that an intact environment does not guarantee for intact animal populations. Education and ex situ conservation are important parts for all conservation projects and could be carried out by specialized wildlife rescue centers.

1085: +.248

Historically, Kuwait is the home for 28 mammalian, over 300 bird, and 40 reptilian species. Expanding human population and technology are increasingly altering Kuwait's natural habitat. Such alterations have led to the disappearance of many native wildlife species. Currently, eight

mammalian species have been eradicated locally but are available elsewhere in the Arabian Peninsula. I have developed a priority system for reintroduction efforts for these species or other wildlife species in the area. This system will help decision makers in efforts to conserve Kuwait's wildlife biodiversity. The application of this system requires the accumulation of basic information about species. The most important of such information is related to the historic range and major extinction factors for each of the local species. (C) 2003 Elsevier Science Ltd.

1086: +.078

We analysed the mitochondrial DNA (mtDNA) from two historical samples of eastern North American wolves: the last wolf reported to have been killed in northern New York State (ca. 1890s) and a wolf killed in Maine in the 1880s. These wolves represent eastern wolves, presently classified as the gray wolf (*Canis lupus*) subspecies *Canis lupus lycaon*, which were present well before the expansion of western coyotes (*Canis latrans*) into these regions. We show the absence of gray wolf mtDNA in these wolves. They both contain New World mtDNA, supporting previous findings of a North American evolution of the eastern timber wolf (originally classified as *Canis lycaon*) and red wolf (*Canis rufus*) independently of the gray wolf, which originated in Eurasia. The presence of a second wolf species in North America has important implications for the conservation and management of wolves. In the upper Great Lakes region, wolves of both species may exist in sympatry or interbreed with each other, which impacts the accuracy of estimates of numbers of wolves of each species within this geographic region. Furthermore, the historical distribution of the eastern timber wolf (*C. lycaon*), as revealed by these skin samples, has important implications for the reintroduction of wolves into the northeastern U.S. states, such as New York and Maine.

1087: +.052

We monitored the survival, dispersal, and home-range establishment of captive-bred, reintroduced puaiohi *Myadestes palmeri*, a critically endangered thrush endemic to the island of Kauai. Fourteen captive-bred, juvenile birds were released from hawktowers in January-February 1999 and monitored for 8-10 weeks using radiotelemetry. All 14 birds (100%) survived to 56 days post-release. Two birds (14.3%) dispersed greater than 3 km from release site within 1 day of release. The remaining birds settled within 1 week and established either temporary home-ranges (mean area = 7.9 +/- 12.0 ha, range 0.4-31.9) or breeding home-ranges (mean area 1.2 +/- 0.34 ha, range 0.8-1.6). Temporary home ranges were abandoned by the beginning of the breeding season, and ultimately 6 of the 14 birds (43%) established breeding home ranges in the release area. The high survival rate bodes well for establishing additional populations through captive breeding and release; however, the 57% dispersal rate out of the target area means that several releases of birds may be necessary in order to repopulate a given drainage. Furthermore, observed dispersal and gene flow between the reintroduced and wild populations have important implications for management of the captive flock. Published by Elsevier Science Ltd.

1089: +.047

British red squirrel populations have been subject to landscape management practices resulting in large-scale fragmentation and defragmentation of habitat, as well as numerous historical introductions of closely related subspecies. This unique population history allowed us to examine: (1) the morphological changes to a rare native species probably caused by hybridization with introduced subspecies; (2) the impact of landscape management, specifically reforestation, on the spread of these morphological changes across the north of England. British red squirrels represent

a peripheral population of *Sciurus vulgaris*, which is regarded as a separate subspecies (*S. v. leucourus*) to populations found on the European continent. British populations are in danger of extinction because of the introduction of the North American grey squirrel *S. carolinensis*. Repeated translocation of continental European *S. vulgaris* individuals to Britain over 150 years may be responsible for an alteration of the morphological characteristics of populations compared to the original subspecies description. The majority of examined populations possessed the coat colour characteristics associated with continental European subspecies. Only populations in the western region of Cumbria possessed coat colour characteristics similar to the described subspecies *S. v. leucourus*. Changes to landscape connectivity in Britain during the 1980s greatly altered dispersal patterns, resulting in an increase of gene flow from populations in the north-east of England and the Borders into Cumbria. The morphological characteristics of the Cumbrian population also changed over this period, from traits similar to the British subspecies before 1980, to traits similar to the continental European subspecies after 1980. This study demonstrates the threat landscape management practices and the introduction of closely related subspecies can present to rare peripheral populations.

1090: -.066

1. Interactions between captive-reared and wild salmonids are frequent because hatcheries annually rear millions of fish for release in conservation programmes while many thousands of domesticated fish escape from fish farms. However, the outcome of competition between captive-reared and wild fish is not clear: wild fish may be smaller and less aggressive than hatchery fish, but they have more local experience and a prior residence advantage. Moreover, it is important to know whether any competitive differences are genetic (due to the process of domestication) or due to the rearing environment. 2. We therefore examined the factors influencing competition for feeding territories in juvenile Atlantic salmon. We studied the effect of domestication by using three independent stocks of both domesticated and wild-origin fish, all of which were reared in a common hatchery environment. We also used fish from the same wild stocks that had been living in the wild. Territorial contests were staged in stream tank compartments between pairs of fish differing in origin or rearing environment; the relative importance of body size and prior residence was also assessed. 3. All three stocks of domesticated fish were generally dominant over wild-origin fish when both had been raised in a common hatchery environment. If the wild-origin fish were given a 2-day period of prior residence on the territory this asymmetry in dominance was reversed. However, domesticated fish did not gain any additional advantage from being prior residents. The relative body size of the two contestants had a negligible effect on contest outcomes. 4. Truly wild fish (i.e. those of wild origin that had also grown up in the wild) were generally dominant over domesticated or wild-origin fish that had been hatchery-reared. Differences in body size between contestants had no effect on the outcome. 5. Synthesis and applications. These results show that, while juvenile farmed Atlantic salmon are inherently more aggressive than wild-origin fish, the hatchery environment reduces their ability to compete for territories with wild resident fish. Rearing salmon in conventional hatcheries for later release into the wild where natural populations already exist may not be a prudent conservation measure; it is preferable to plant eggs or first-feeding fry rather than attempt to 'help' the fish by rearing them through the early life stages.

1091: +.225

Using microsatellite analysis, we investigated the reproductive success and genetic structure of a translocated colony of the Bahamian iguana (*Cyclura cychlura inornata*) 10-yr post introduction. We investigated the reproductive success of the founder males to determine if all were

contributing equally to the descendant gene pool. We compared the genetic diversity in the founder population with that in the incipient, translocated population to determine if the number of translocated individuals was sufficient to retain the genetic diversity derived from the source population. In 1999, the estimated population size for the translocated colony was between 75 and 90 individuals. Blood was taken from 35 iguanas (16 males, 18 females, and 1 juvenile) of mixed age, including the four original translocated males and three of the four original translocated females. Of the eight polymorphic microsatellite loci in *C. cyclura*, only five were polymorphic in *C. c. inornata*. With two exceptions, the low average allelic diversity and heterozygosity among these loci (2.4 and 0.45, respectively) hindered accurate determination of parentage among the founders. Nevertheless, the data indicated that the potential parental contributions appear equal for the founder males and that, at 10-yr Post introduction, the small amount of genetic diversity at the amplified loci in the founding population was retained. The low level of genetic variation appears to have no negative short-term effects on the translocated or other populations of *C. cyclura* inhabiting the Exuma Island chain, making them excellent candidates for translocation and repatriation programs if physiological and environmental requirements are met.

1092: +.241

Translocation is increasingly used to maintain evolutionary processes, particularly the genetic rescue of fragmented populations, but it is sometimes a costly and unsuccessful conservation tool. Succeeding at genetic rescue depends on the transfer of alleles between populations in the same way that successful parenthood consists in transferring alleles to the next generation. Moreover, there are large differences in the reproductive potential of males and females and growing evidence of sex-biased survivorship after translocation in sexually selected species. Under these circumstances the Trivers-Willard model (TWM), a founding and influential theory in behavioral ecology, makes predictions about how a parent should invest in the offspring of a different sex based on their ability to invest. Like parents, conservation managers also modify their investment in translocations to improve success. Thus, there are remarkable parallels between the predictions of modern evolutionary theory about parental investment in offspring of different sex and the investments of conservation managers in the translocation of alleles between populations via animals of different sex. The TWM for sex-biased parental investment could be a theoretical guide to the problem of maximizing the transfer of alleles for genetic rescue.

1093: +.116

Coyotes (*Canis latrans*) in Yellowstone National Park (YNP) have lived in the absence of wolves (*Canis lupus*) for over 60 years. I examined whether wolf reintroduction in 1995 and 1996 in YNP influenced coyote vigilance and foraging ecology. From December 1997 to July 2000, my co-workers and I collected 1708 h of coyote activity budgets. Once wolves became established in the Park, they once again provided a continuous source of carrion in the Lamar Valley and we found that coyotes began feeding on carcasses throughout the year. Although we documented that wolves killed coyotes, it also became clear that surviving coyotes quickly adjusted their behaviors when wolves were present. When coyotes were near wolves or in areas of high wolf use, they fed on carcasses much more; however, they increased the amount of time spent in vigilance activities and decreased rest. There appears to be a trade-off in which wolf kills provide a quick source of food that is energetically advantageous to coyotes; however, attendant costs included increased vigilance, decreased rest, and a higher risk of being killed. Changes in the behavior of coyotes in response to the reintroduction of this large carnivore may ultimately have wide-ranging cascading effects throughout the ecosystem.

1094: +.216

This paper reviews and updates the distribution and status of two geographically distinct subspecies of New Zealand Saddleback *Philesturnus carunculatus*, a New Zealand forest passerine that is highly susceptible to predation by introduced mammals such as stoats and rats. The recovery of the North Island and South Island saddleback populations has been rapid since translocations to offshore islands free of exotic predators began in 1964, when both subspecies were on the brink of extinction. South Island saddlebacks have gone from a remnant population of 36 birds on one island to over 1,200 birds spread among 15 island populations, with the present capacity to increase to a maximum of 2,500 birds. We recommend that South Island saddleback be listed under the IUCN category of Near Threatened, although vigilance on islands for invading predators and their subsequent rapid eradication is still required. North Island saddlebacks have gone from a remnant population of 500 birds on one island to over 6,000 on 12 islands with the capacity to increase to over 19,000 individuals. We recommend that this subspecies be downgraded to the IUCN category of Least Concern. The factors that limited the early recovery of saddlebacks are now of less significance with recent advances in predator eradication techniques allowing translocations to large islands that were formerly unsuitable. The only two predators that still cohabit some islands with saddleback are Pacific rats or kiore *Rattus exulans* and Weka *Gallirallus australis*, a flightless native rail. Although North Island saddlebacks coexist with kiore, South Island saddlebacks do less well in their presence, possibly because the relict population had no previous history with this species of rat. The impact of Weka as predators of saddlebacks is less clear, but population growth rates appear to be slowed in their presence. It is recommended that while current recovery strategies involving island habitat restoration and translocations be maintained, management effort should also be directed towards returning saddlebacks to selected, "mainland island" sites, where introduced pests are either excluded by predator-proof fences or controlled at very low levels by intensive pest management.

1095: +.075

The introduction of threatened marsupials to islands affords a high degree of translocation success due to the lack of exotic species on islands, or the feasibility of eradicating them. The dibbler *Parantechinus apicalis* is a small marsupial endemic to the southwest of Australia. It is listed under international and national legislation as Endangered, and has been the focus of a successful conservation strategy to introduce captive-bred individuals to an island as a security measure, and as part of a formal Interim Recovery Plan. A total of 88 individuals were released in four groups on Escape Island from 1998 to 2000. The population was monitored using radiotelemetry and trapping techniques from 1998 to 2001. Breeding and dispersal of young occurred within the first year of release. Three years after the initial release, the third generation of wild-born dibblers had entered into the population. The total cost of this translocation exercise approximated \$AUS 0.6 million. The conservation effort to give additional security to dibblers has been successful, at least in the short term, due to the collaboration between four organisations and a commitment to support a monitoring program of the released population over time. 1096: +.209

The wolf population in Scandinavia has increased from functionally extinct to about 100 wolves since the 1970s. In 2001 we surveyed four groups of Swedes to analyze the relationship between experience, knowledge, and people's attitude toward wolves. Although all groups support the right of wolves to exist, Swedes who live in areas where wolves have been restored have more negative

attitudes than the general public. Attitudes toward wolves are not strong among the general public, thus changes are possible. Experience with wolf predation leads to more negative attitudes toward wolves. Hunters in areas with wolves have the most accurate knowledge about wolves but at the same time the most negative attitudes. But within all four groups as knowledge increases attitudes become more positive. Still, the most knowledgeable local hunters have less favorable attitudes than the least knowledgeable members of the general public. High proportions of the population do not care about wolves which makes it difficult to reach them with information, but does make them susceptible to rapid changes if wolves become a media topic. With the restoration of wolves, hunters, the strongest supporters of wolves in the 1970s, are now less supportive than the general public. (C) 2003 Elsevier Science Ltd. All rights reserved.

1097: +.131

The single steps of the species recovery plan "green toad" are presented: It contains the clarification of the historical distribution and the mapping of the recent occurrences as basic research, furthermore investigations of all key populations as well as of the threats and causes of decline. A second step includes the conservation and management of all recent populations by means of legal protection under the nature conservation act and measures based on management plans. Step three plans for the partial recovery of the historical distribution and the connection of currently isolated populations. The measures involved a network of habitats, the consideration of habitat requirements in new mining licenses and other impact projects, as well as options for reintroductions with captive bred animals. The fourth step contains a long-term monitoring of all apparent populations. To spacially define steps two and three, a regional species recovery strategy were worked out for each centre of distribution in Lower Saxony. These species recovery strategies have the aim to stabilize and to connect the recent populations as well as establishing new populations as far as possible. In this paper the example chosen to illustrate the species recovery strategy is the situation in the Helmstedt district. Eleven recent sites with green toads still exist in the Helmstedt district, lying from one to several kilometres apart. Adult specimens and stages of reproduction can be found regularly in only a few sites, while in most sites toads can only be found irregularly, mostly as calling males. All colonised ponds are man-made and it concerns excavation sites, ponds for wastewater treatment, mud deposits and even ponds especially designed for the green toad. In terrestrial habitats only a few specimens have been observed, mostly within a distance from about 1 km maximum in the surrounding of their spawning sites in excavation sites or on field-paths. It can be assumed that migrations between certain sites are possible; an indication is the fast appearance of the species in recently created ponds. The main threats are the frequent drying up of their mostly shallow spawning waters and the continuous natural succession. As a conservation strategy proposals are ordered by priority for existing sites and survey areas suitable for habitat development are planned and presented.

1098: +.078

The green toad is the most threatened species in Sweden. Today about 200 adults remain in three reproducing populations and a more diffuse occurrence of single or a few individuals mainly along the west and east coast of Scania. A conservation program is running since 2000. This includes captive breeding and reintroduction within the former range, restoration of old localities and the creation of many new ones. Our goal is to establish ten self sufficient populations within a six year period.

1099: +.135

The spatial distributions of 20 female and 15 male Arabian oryx *Oryx leucoryx*, reintroduced into the fenced Mahazat as-Sayd protected area (2,244 km²) in western Saudi Arabia between 1990 and 1994, were examined from their release until the end of 1999. Over this period we observed a westward shift in home range location of most male and female founder oryx to include the Rangers' Camp within core areas of activity, despite rain falling in patches throughout most of the reserve. Sporadic and unplanned availability of water had occurred at the Camp during several years. The pre-release enclosure was also located at the Camp, and high quality shading areas could be found underneath portacabins. Oryx that maintained independence of the Camp tended to be older individuals and those released in the first years (1990-1992). Concentration of oryx in the western part of the protected area and around the Camp could potentially reduce the effective carrying capacity of the reserve, change the social structure of the population, facilitate the transmission of disease, modify habitat in the form of a piosphere (a zone of attenuating animal impact away from a watering point) around the Camp, and reduce potential genetic flow within the reintroduced population. Whereas wild-born oryx were observed at the Camp, founders were disproportionately represented, suggesting that potential problems associated with dependence on the Camp may diminish as the total population increases and ages.

1100: +.172

Post-release monitoring, including abundance estimation, is an important part of reintroductions, providing a basis for management intervention designed to achieve long-term persistence. The Arabian oryx *Oryx leucoryx* became extinct in the wild in 1972, surviving as captive populations. Since 1982 reintroductions of Arabian oryx have taken place in Oman and Saudi Arabia.

Modelling of oryx population dynamics has highlighted the importance of precise estimation of population size (N). Between 1990 and 2000 three methods of estimating N have been applied in Mahazat as-Sayd protected area in Saudi Arabia: derived population estimates (DPE) based on known births and deaths, distance sampling, and mark-resighting (MR). This study assesses the feasibility and precision of these methods. Inability to assess precision, interdependence of consecutive estimates, and the assumption that all gains and losses are recorded, make DPE of limited value. At current densities, distance sampling along 455 km of driven transects yields too few detections to derive precise estimates of N. To achieve a coefficient of variation of 20% it would be necessary to drive up to c. 2,900 km of transect; this amount of survey effort could be achieved through pooling of data across repeat surveys of established transects. MR estimates, based on re-sighting of collared oryx, have the potential to yield the most precise estimates of N when the proportion of marked animals reaches 30% of the total population. The most reliable MR estimates available indicate the Mahazat as-Sayd Arabian oryx population had grown to > 400 animals by 2000.

1101: -.061

Museum specimens from the late 19th and early 20th centuries were surveyed for the single nucleotide polymorphism identified previously and used to diagnose populations of the federally threatened Northeastern Beach Tiger Beetle *Cicindela d. dorsalis* (Coleoptera: Carabidae).

Widespread polymorphism was revealed throughout the historical range of this species, suggesting a relatively recent anthropogenic character fixation event associated with the extinction and fragmentation of populations. Implications for the phylogenetic species criterion and for the reintroduction of individuals to formerly occupied sites are discussed.

1102: +.244

Nineteen of the 27 species of Colombian primates are under some type of threat due to habitat loss and illegal traffic of at least 13 species. There is a high number of individuals that are confiscated during official controls and, as a management strategy, their introduction or reintroduction in protected areas is proposed. A *Saimiri sciureus* population was introduced seven years ago in a 60 ha recreational park of dry forest, they were fed on artificial food in semicaptivity, engaging a high economic investment. The effect of progressive reduction of artificial food on the behavior and group composition was evaluated by comparing the values before and after the supply of artificial food reduction. The progressive reduction permitted the group to adapt and make use of the natural resources of the environment by increasing habitat exploration. We propose this strategy as a viable alternative for biological rehabilitation.

1103: +.244

The Persian fallow deer (*Dama mesopotamica*)-among the rarest deer species in the world-has been gradually reintroduced, using individuals from a captive-bred population, in northern Israel since September 1996. As of October 2000, >80 animals were in the wild population. We studied seasonal and circadian attributes of deer home ranges to assess the success of the reintroduction in terms of behavioral adjustments to the wild. We used radiotelemetry to determine locations and analyzed home ranges with the adaptive kernel method. We defined 3 seasons: fawning (Mar-Jun), rut (Jul-Oct), and winter (Nov-Feb). For females (n = 16), rut home ranges were significantly larger than winter home ranges (449 +/- 45 ha [mean +/- SE] vs. 384 +/- 36 ha, P=0.013). During fawning, female home ranges were intermediate (424 +/- 51 ha). Males (n = 5) increased their home ranges in rut season (820 +/- 162 ha [mean +/- SE], P < 0.012) and shifted their locations toward the release point. In winter, males significantly decreased their home ranges (584 +/- 158 ha, P < 0.012), shifted their locations away from the release point, and almost no overlap of core areas was noticeable (1.8% overlap). In fawning (the time of antler casting and regrowth), males continued to shift away from the release point and decreased home ranges (358 +/- 66 ha, P = 0.049) with almost no overlapping of core areas (0.06% overlap). No statistically significant differences were found between day home ranges (males [n = 5]: 621 +/- 220 ha [mean +/- SD], females [n = 16]: 402 +/- 164) and night home ranges (males: 482 +/- 145, females: 389 +/- 183), although day core areas tended to be larger (in all males and 12 of 16 females). All documented aspects of seasonality in female and male home ranges are in accordance with the annual reproduction cycle, and are related to seasonal food availability. These results, combined with previous works, suggest that so far, the reintroduced Persian fallow deer have adjusted well to living in the wild and that the chances of achieving a self-sustaining wild population are good. However, further research for extended period should verify these conclusions.

1105: +.160

We used radiotelemetry and field observations to study survival and reproduction of 718 reintroduced elk (*Cervus elaphus*) in eastern Kentucky, USA, from 1997 to 2001. Capture-related injuries accounted for 49% of the transit and post-release mortality. Annual survival was high across all age and sex classes, and ranged from 0.90 (adult females) to 0.97 (yearling females). Calving rates increased from 66% in 1998 to 92% in 2000. A high nutritional plane may explain the relatively high reproduction among females bred as yearlings, consecutive-year pregnancies, and twinning. Such high survival and reproductive rates are characteristic of colonizing ungulate populations in areas devoid of predators and competitors. Future research should focus on Kentucky-born calves to more accurately determine the effects of meningeal worm (*Parelaphostrongylus tenuis*) and other factors on recruitment, colonization, and population establishment.

1106: -.038

Meningeal worm (*Parelaphostrongylus tenuis*) has been implicated in the failure of several elk (*Cervus elaphus*) restoration attempts in the eastern United States. However, limited post-release monitoring and a paucity of published literature prevents a clear understanding of this parasite's role in past failures. During winters of 1997-2001, the Kentucky Department of Fish and Wildlife Resources translocated 1,044 elk from western states to eastern Kentucky (USA) in an effort to restore a free-ranging population. We monitored 521 radio-collared elk over 4 yr to determine the impact meningeal worm had on population establishment. Thirty (23%) of 129 non-capture related mortalities were attributed to meningeal worm. Twenty-two (73%) of these meningeal worm-caused mortalities were animals <3 yr old. If younger elk born in Kentucky suffer higher mortality rates than older translocated elk, the population growth observed during the initial years of restoration may be temporary. Additional research is necessary to determine the influence meningeal worm will have on elk population growth in Kentucky.

1107: +.051

Hydrastis canadensis L. (goldenseal) is an endangered species of perennial wildflower native to eastern North America and is harvested for its root that contains the alkaloids berberine, hydrastine and canadine. Studies have shown this herb to have anti-inflammatory, antibiotic and anti-pyretic effects. Today, the number of wild goldenseal populations is on the decline, to the point of extirpation in some states, thought to be largely due to over-harvesting and exacerbated by the plant's reproductive strategy. Goldenseal reproduces by both vegetative and sexual means. Juvenile plants reproduce clonally and it takes two to three years for a plant to reach sexual maturity. At this stage the root is considered large enough to harvest. Thus, as wild harvesters collect mature plants, the probability of sexual reproduction is reduced. Consequently, it is thought that there is little genetic diversity within those wild populations that are subject to wild harvesting on a regular basis. Understanding germplasm diversity is critical for crop improvement and breeding programs for endangered species. This information also helps conservation efforts by offering data that can support preservation of habitat, collection monitoring and genetically sound reintroduction strategies. In this study we analyzed several populations of *Hydrastis canadensis* for genetic diversity within and among populations. The samples are from cultivated populations in Kentucky, Massachusetts, New York and Canada and wild populations from Kentucky, Ohio, West Virginia and New York. We used the Random Amplified Polymorphic DNA (RAPD) analysis technique to generate DNA profiles from our samples and to estimate genetic relatedness among and between populations. RAPD analysis is a relatively simple technique and offers the ability to

compare numerous sites within the genome with just a few primers. The results for the cultivated material show 72-86% similarity among the populations tested and the similarity for the wild populations of 20-67%. These numbers are in line with expected results when comparing a clonally propagated group with the wild type.

1108: +.275

The box huckleberry (*Gaylussacia brachycera* (Michx.) Gray) is a slow-growing, dwarf evergreen woody groundcover that is native to both the mountains and coastal plains of Pennsylvania, Virginia, Kentucky, Tennessee, West Virginia, Delaware, and Maryland. It has glossy, dark green, fine-textured foliage, with new growth often red to maroon colored. The box huckleberry's global conservation status is listed as G3 and the state listing for Delaware, Maryland and Pennsylvania is S1 (critically imperiled). In the seven states in which it is native, there are less than 20 known populations of this species. Under permit, plants of box huckleberry have been collected from 14 native habitats in six states. Most of these plants have been established in a protected site at the U.S. National Arboretum in Washington, D.C. We hope to use these plants to achieve the following objectives: 1) In cooperation with the Maryland DNR, enhance the recovery of box huckleberry in the wild by reintroducing the plant back into its native habitat in Maryland, where only one plant remains; 2) determine molecular genetic distances among collected populations to guide decisions regarding conservation, preservation, and breeding; 3) determine optimum propagation and production methods so that this species may be evaluated by commercial nurseries as a slow-growing, native, evergreen landscape plant; and 4) perform controlled pollinations between accessions to create new genotypes.

A role for molecular genetic approaches in conservation of endangered taxa is now commonly recognized. Because conservation genetic analyses provide essential insights on taxonomic status, recent evolutionary history and current health of endangered taxa, they are considered in nearly all conservation programs. Genetic analyses of the critically endangered Far Eastern, or Amur leopard, *Panthera pardus orientalis*, have been done recently to address all of these questions and develop strategies for survival of the leopard in the wild. The genetic status and implication for conservation management of the Far Eastern leopard subspecies are discussed. (C) 2003 Academie des sciences. European water frogs are characterized by anthropic introductions and *Rana ridibunda* may be considered as an invasive species. As such translocations may result in introgression of exotic genes in native populations, i.e. genetic pollution, we studied genetic characteristics (on I I allozymic loci) of natural versus introduced water frogs. Our study contributed to (1) disclose 3 genetic markers allowing the identification of exotic frogs; (2) quantify the proportion of exotic frogs found in natural populations; and (3) suggest how genetic pollution may arise in these frogs. We focus on constraints faced by antelopes reintroductions in and environments, and propose keys to enhance their success, using the oryx project in Saudi Arabia as example:(1) Monitoring and

management of reintroduced populations appear more important than the number of released animals;(2) Because of the low accuracy of population size estimators, we recommend to implement a continuous monitoring and to use several estimators to assess the reintroduced population size;(3) Reintroduction schedule should take into account the unpredictability of food resources in and environments;(4) The re-establishment of desert antelopes depends as a priority on the enforcement of regulations to avoid poaching. 1112: +.020

The black-footed ferret (*Mustela nigripes*) of North America is critically endangered due in part to its extreme specialization on formerly stable and abundant prairie dogs (*Cynomys*). Its close relative, the Siberian polecat (*M. eversmannii*) seems to have been subjected to a varying environment that was not conducive to specialization. One source of environmental variation in Asian steppes was plague (caused by *Yersina pestis*), which was absent from North America. Introduction of plague to North America presents serious challenges to ferret recovery. Partial solutions to other biological and political problems have been found, resulting in improved production in captivity, increased survival post-release, and thriving populations in plague-free South Dakota. We studied survival and demography of black bears, *Ursus americanus*, in Banff National Park (BNP) from 1994 to 2000 to test the efficacy of National Park protection. We monitored 25 radiocollared bears an average of 1.9 years each for a total of 51.8 bear-years. Eighty-two percent of all mortality ($n = 11$) was human-caused, composed of highway mortality (36%), management mortality (27%) and management relocation (18%). Survival was influenced by season and management status. Once bears became a management problem, survival (0.66) was lower than several hunted populations. Adult (0.84) survival was comparable to other unprotected or partly protected populations. Cub (0.64) and yearling (0.67) survival, and reproductive rate ($m(x) = 0.47$ female cubs/inter-birth interval), was slightly lower than other populations in western North America. We combined survival and reproductive rates in a preliminary post-birth pulse age-class Leslie matrix model and estimated population growth rate as 0.95 (95% simulated C.I. 0.79-1.10). Sensitivity analyses showed λ was most sensitive to changes in adult female survival. Responsible management agencies should reduce adult female highway mortality and the likelihood of becoming a management problem, while continuing monitoring to refine demographic analyses to adequately protect this population. 1114: +.132

Translocation of species for conservation purposes is a key element of many recovery programs. While the benefits of translocations seem obvious, potential negative effects have been described. For endangered beach mice (*Peromyscus polionotus* ssp.), repopulation of native, unoccupied habitat using translocated individuals has been extremely successful. Once populations are established, concerns over founder effects and isolation have led to proposals for continued secondary translocations. Unfortunately, little information is available to help formulate protocols for these actions. To test the effectiveness of translocation, the fates of 18 translocated Choctawhatchee beach mice (*Peromyscus polionotus allophrys*) were followed as they attempted to integrate into an established population. We found that translocated groups, repeated for two

seasons, tended to use larger homeranges and significantly more burrows than did resident mice. The monthly (31 day) survival rate of resident mice was 3:4 times greater than for translocated individuals. We hypothesize that differential predation pressure was directly linked to the failure of mice to integrate successfully into the existing population. Given our results, we must advise caution and that additional knowledge be obtained before translocations are used to supplement existing populations. (C) 2003 Elsevier Science Ltd. All rights reserved.

1115: +.147

Monitoring is essential to evaluate the success of translocations, but is frequently neglected. One exception has been the reinforcement of the otter (*Lutra lutra*) population in the Derwent and Esk catchments in North East England, UK, between 1990 and 1993. Here, we use data on otter sprainting activity collected before, during and after translocations to identify relationships with vegetation, food resources and physical river characteristics. Sprainting activity increased significantly with trout density, stream order, and surrounding cover by woodland and semi-natural grassland vegetation, and decreased significantly with stream gradient. The form of these relationships was unimodal, sprainting activity peaking at intermediate levels of environmental variables. A logistic regression model including variables relating to fish density, the physical characteristics of the river and surrounding vegetation cover was able to predict the presence or absence of otter sprainting at different survey sites with an accuracy of 92%. Fish density and the physical characteristics of the river were the most important factors in the model. Models such as this are of practical use for assessing the likely success of future otter translocations, both in North East England and other regions of the UK and Europe. 1116: -.103

The wild water buffalo is highly endangered, with the few remaining populations already affected or likely to be increasingly affected by hybridization with domestic buffalo. The work described here was done to evaluate a genetic method to discriminate wild from mixed ancestry (hybrid) and domestic animals, and to identify with high probability those most likely to be purebred wild. Samples from 45 animals (phenotypically classified into three groups - ten wild, 28 domestic and seven hybrid) were genotyped for ten microsatellite loci. Although genetic distances among the three groups were small, an assignment test identified two of the 'wild' and seven of the 'domestic' as hybrids. However, sample sizes also are small, indicating the need for a conservative approach in the first instance in using these results. As more animals are genotyped, assignments will become more accurate, and a translocation programme to establish a second Nepalese wild population in a protected area could be undertaken.

1117: +.279

Conservation programmes increasingly involve the translocation of animals to reinforce failing populations or establish new ones. To help guide translocation programmes of swift foxes (*Vulpes velox*) or other imperilled species, we aimed to discern factors affecting translocation success among reintroduced swift foxes in Canada. Post-release movements characterized three stages. In the initial acclimation phase, foxes moved erratically and quickly distanced themselves from release sites. During the establishment phase, distances from the release site did not change significantly but daily movements were more wide-ranging than those of Concurrently tracked, resident swift foxes. In the final settlement phase, movements of translocated foxes reflected those of resident individuals. Radio-telemetry showed that survival and reproductive success were

highest for swift foxes with small dispersal distances, suggesting that measures C should be taken to acclimatize animals to release sites. Since females had lower survival rates than males, translocations should also use a greater proportion of females to establish balanced sex ratios in the population. Translocated juveniles dispersed less far but survived and reproduced as well as translocated adults, suggesting that juveniles can be used to establish translocated foxes in small, protected areas, while minimizing demographic effects on source populations. The fact that survival rates and litter sizes of translocated foxes were similar to those of resident animals indicates that translocation can be an effective reintroduction tool for this endangered species, and possibly other foxes.

1118: +.058

The helminth populations found in a group of wild boars collected in central Spain were compared to those in a group of animals imported from a French game farm that produces boars for restocking. Eleven helminth species, including ten nematodes and one acanthocephalan, were found. *Gongylonema pulchrum* and *Macracanthorhynchus hirundinaceus* were only detected in autochthonous wild boars, while *Oesophagostomum dentatum*, *Ascaris suum*, and *Trichuris suis* were detected in imported animals only. Autochthonous wild boars were more frequently and more intensely parasitised by *Ascarops strongylina* than the imported ones. No differences in prevalence nor intensity were found for the species *Capillaria garfiai*, *Globocephalus urosubulatus*, *Metastrongylus* sp., *Physocephalus sexalatus* and *Simondsia paradoxa*. To our knowledge, *G. urosubulatus*, *G. pulchrum* and *S. paradoxa* have not previously been described in wild boars in Spain. Our results highlight the risks of translocating wild animals, with regard to their helminth parasites. Until improved control measures are established, it would be wise to avoid long-distance translocations in order to prevent the potential introduction of foreign parasites. (C) 2003 Elsevier B.V. 1119: -.116

The United States Fish and Wildlife Service has proposed restoring grizzly bears (*Ursus arctos*) to the Bitterroot ecosystem of central Idaho and western Montana, where grizzly bears were extirpated by 1932. We based estimates of future grizzly bear population size and distribution in the Bitterroot ecosystem on resource selection functions developed for the Yellowstone ecosystem and Swan Mountains in northwestern Montana. This method yielded an estimate of 321 grizzly bears in the Bitterroot recovery area. Our analysis suggests that habitat attributes, particularly the paucity of roads and human developments, will help to ensure a viable population of grizzly bears in the Bitterroot ecosystem.

1120: +.057

In recent years wildlife diseases (infectious and non-infectious) have played a relevant role in both wildlife conservation and public health. Global environmental changes have determined a bimodal evolution of wildlife. On one side a huge loss of biodiversity has been observed leading to the increasing of threatened or endangered species. In contrast few opportunistic taxa increased their abundances and ranges. The above scenarios claim the intervention of wildlife veterinarians. In conservation the understanding of the ecological role of the host-parasite relationship and the perturbations on the host population dynamics have to be assessed and eventually modified. In public health the increased overlapping among wildlife, livestock, pets and human beings represents a risk for diseases spread (no matter in which directions). Serious limits are, still now, observed in the acceptance of this 'new world' by veterinary academics. As a consequence

curricula often fail in providing adequate skill at both undergraduate and graduate levels. An addressed approach towards wildlife diseases should be promoted as an essential component of environmental management.

1121: -.060

The population of the scallop *Argopecten purpuratus* in Mejillones Bay, Chile (23degreesS) was estimated using diving-quadrat techniques between July and August 1999. The Population, distributed over an area of 255 ha, was estimated at about 18×10^6 individuals, having a mean length of about 68 mm. Of this number, about 16×10^6 individuals were aggregated into a core area of 51 ha. A subsequent controlled harvest carried out in 33.5 ha of this area in November 2000 produced only 2×10^5 individuals, strongly suggesting that large scale clandestine (illegal) harvesting had occurred since the original population survey. Reseeding of collected scallops was carried out in an interior area of the bay which had low densities of scallops but highly similar physical and chemical seawater characteristics. Post-seeding mortality of the translocated scallops, determined two weeks after the transfer, was 12.5%, with a mean of 2.5 indiv./m² in an 8.2 ha area. The low initial mortality, compared with values in the literature, suggested that the methods of retrieval, transport, and restocking the scallops could serve as a viable repopulation strategy in other areas in the future.

1122: +.025

Allozyme electrophoresis was used to evaluate levels and distribution of genetic diversity in Iberian populations of the threatened coastal sand dune plant *Stachys maritima* (Lamiaceae). During the last century, this species was subjected to severe habitat fragmentation, mainly as a consequence of tourism activities and urban pressures, with a decreasing of area up to 99% in the Iberian Peninsula and a remaining total population size of ca. 250 individuals. Extremely low levels of genetic variation were detected ($P = 14.0$, $A = 1.16$ and $H-e = 0.066$). From the 20 interpretable loci found, only 4 were polymorphic and another one, the *ldh-2* locus, showed a fixed heterozygous banding pattern, which may be attributed to gene duplication. Low values of diversity can be related to small population size and isolation of populations. The degree of threat has been increased from vulnerable (VU) to critically endangered (CR), according to the IUCN criteria. Conservation policies should be focused on maintaining population size and gene flow, in addition to preserving its habitat, although reintroductions and reinforcements appear to be necessary to ensure long-term viability of populations.

1123: +.193

Translocation is a commonly used tool in conservation management. However, because post-release monitoring has been infrequent in the past, reasons for the outcomes of translocations have often been unknown. Here, I review the reintroduction biology (including dispersal patterns, social organisation, survival, habitat use and foraging patterns) of a population of 26 South Island Saddlebacks (*Philesturnus carunculatus carunculatus*), on Motuara Island, New Zealand. After release on Motuara Island, South Island Saddlebacks dispersed widely through forest areas. During their first post-release breeding season, saddlebacks established territories of 1.9 ha-8.8 ha ($X=4.21$ ha, $SD=2.42$) in size, and territorial confrontations were very rare. Saddlebacks bearing both adult and subadult plumage held territories and attempted to breed, and successful breeding produced approximately 10 fledglings. Saddlebacks foraged on a variety of plant species, dead wood and the ground. Except for five-finger (*Pseudopanax arboreus*), a preferred foraging substrate, birds foraged in all plant material in proportion to its availability. Saddlebacks preferred

to forage in the lower levels of the forest. Although vegetation composition differed significantly between territories, all territories contained forest areas, and birds appeared to prefer foraging in larger sized trees. Large territory sizes, breeding attempts by young birds and rarity of territorial confrontations are most likely products of low population density. As density increases, birds are expected to occupy smaller territories, forage more efficiently within these smaller areas, start breeding at older ages, and possibly colonise scrub habitats. The translocated group sustained no more than 50% mortality at 8-10 months after release. In the past, translocations of 15-59 South Island Saddlebacks have been successful, suggesting that the relatively small founder group does not threaten the success of the transfer to Motuara Island. Saddlebacks are flexible in their habitat use, appear to readily adapt to 'new' environments and have high reproductive potential, increasing the likelihood of success of translocations of this species.

1124: +.143

This paper explores the relative effects of host plant dynamics and butterfly-related parameters on butterfly persistence. It considers an empty habitat network where a rare butterfly (*Cupido minimus*) became extinct in 1939 in part of its historical range in north Wales, UK. Surviving populations of the butterfly in southern Britain were visited to assess use of its host plant (*Anthyllis vulneraria*) in order to calibrate habitat suitability and carrying capacity in the empty network in north Wales. These data were used to deduce that only a portion (similar to 19%) of the host plant network from north Wales was likely to be highly suitable for oviposition. Nonetheless, roughly 65,460 eggs (3273 adult equivalents) could be expected to be laid in north Wales, were the empty network to be populated at the same levels as observed on comparable plants in surviving populations elsewhere. Simulated metapopulations of *C. minimus* in the empty network revealed that time to extinction and patch occupancy were significantly influenced by carrying capacity, butterfly mean dispersal distance and environmental stochasticity, although for most reasonable parameter values, the model system persisted. Simulation outputs differed greatly when host plant dynamics was incorporated into the modelled butterfly dynamics. *Cupido minimus* usually went extinct when host plant were at low densities. In these simulations host plant dynamics appeared to be the most important determinant of the butterfly's regional extirpation. Modelling the outcome of a reintroduction programme to *C. minimus* variation at high quality locations, revealed that 65% of systems survived at least 100 years. Given the current amount of resources of the north Wales landscape, the persistence of *C. minimus* under a realistic reintroduction programme has a good chance of being successful, if carried out in conjunction with a host plant management programme.

1125: +.107

We examined a remnant host plant (*Primula veris* L.) habitat network that was last inhabited by the rare butterfly *Hamearis lucina* L. in north Wales in 1943, to assess the relative contribution of several spatial parameters to its regional extinction. We first examined relationships between *P. veris* characteristics and *H. lucina* eggs in surviving *H. lucina* populations, and used these to predict the suitability and potential carrying capacity of the habitat network in north Wales. This resulted in an estimate of roughly 4500 eggs (ca 227 adults). We developed a discrete space, discrete time metapopulation model to evaluate the relative contribution of dispersal distance, habitat and environmental stochasticity as possible causes of extinction. We simulated the potential persistence of the butterfly in the current network as well as in three artificial (historical and present) habitat networks that differed in the quantity (current and X3) and fragmentation of the habitat (current and aggregated). We identified that reduced habitat quantity and increased isolation would have increased the probability of regional extinction, in conjunction with

environmental stochasticity and *H. lucina*'s dispersal distance. This general trend did not change in a qualitative manner when we modified the ability of dispersing females to stay in, and find suitable habitats (by changing the size of the grid cells used in the model). Contrary to most metapopulation model predictions, system persistence declined with increasing migration rate, suggesting that the mortality of migrating individuals in fragmented landscapes may pose significant risks to system-wide persistence. Based on model predictions for the present landscape we argue that a major programme of habitat restoration would be required for a re-established metapopulation to persist for > 100 years.

1126: +.070

Neotropical parrots are among the most threatened groups of birds in the world, and many species are facing extinction in a near future. At the same time, the taxonomic position of many species remains unclear. Karyotype analysis has been used to elucidate the phylogenetic status of many bird groups, also providing important information for both in situ and ex situ conservation plans. The objective of the present study was to describe for the first time the karyotypes of the endangered Hyacinth Macaw, *Anodorhynchus hyacinthinus*, and of the Hawk-headed Parrot, *Deropteryx accipitrinus*. A diploid number of $2n = 70$ and a karyotype similar to the main pattern previously found for the genera *Ara*, *Cyanopsitta*, *Aratinga*, *Propyrrhura*, *Pionites*, *Pionopsitta*, *Nandayus*, and *Guaruba* were found for both species. These karyotype descriptions can be a starting point for the genetic monitoring of these two declining species.

1127: +.165

The fringed darter (*Etheostoma crossopterygum*) was introduced into two streams where neither the fringed darter nor any other species of the same subgenus occur but that otherwise have suitable habitat. Darters were collected from two streams in the Cache River basin, and a combination of darters from each source stream were moved to the receiving streams, which also were in the headwaters of the Cache River basin (20 males and 40 females to each). Darters were moved in late March 2001 at the beginning of their reproductive season, which continues for approximately 2 months. Fringed darter nests were present within 3 days at both introduction sites and nests were found thereafter until late May at which time searching for nests was terminated. Twenty-five nests were found in 2001 compared with 168 nests in 2002. A total of 8714 eggs were counted in 22 nests during 2001 with a mean of 413 eggs per nest ($n = 19$ nests). In September 2001 and 2002, surveys for juveniles and adults indicated successful recruitment in both streams. Mean size of juvenile darters differed significantly between the two introduction sites in 2001. The design of this study allowed for a rapid, initial assessment of the translocations, aspects of which appeared successful. Moving fishes at the beginning of their reproductive season could increase the chance of successful reproduction and eventual establishment. The protocol for translocation of fringed darters might be applicable to other similar and endangered darters such as Barrens (*Etheostoma forbesi*), relict (*E. chienense*), and duskytail darters (*E. perennurum*). Sampling was conducted in other areas of the Cache River basin in search of additional populations of fringed darters. An updated account is given of the distribution of the fringed darter in Illinois. (C) 2003 Elsevier Science Ltd. All rights reserved.

1128: +.005

In response to a policy of fire suppression since early in the 20th century, forest managers have recently initiated emergency programs of prescribed burning to reduce readily combustible fuel loads in many forests of the western United States. The effects of burning on woody plant

composition and structure are relatively well understood; however, little is known about the impact of burning on other taxa. I tested the response of butterflies to fire reintroduction in the Rogue River National Forest and Yosemite National Park. I established replicated transects on three different types of prescribed burn treatment (forest burns, fuel breaks, and riparian burns), as well as control sites, to monitor adult butterfly richness and diversity. Two to three times as many butterfly species occur in forest burns as controls, 13 times as many in fuel breaks as controls, and twice as many in riparian burns as controls. The results of this study suggest that the reintroduction of diverse fire management methods, especially riparian burning, will benefit butterfly diversity in coniferous forests. Further study is required to examine potential proscriptions against riparian burning, including erosion and invasive species encroachment. Both area and density of gaps in the forest canopy were found to explain large amounts of the variation in butterfly richness ($R^2=0.64$ and $R^2=0.80$, respectively). This study demonstrates that using non-traditional taxa (e.g., butterflies instead of trees) to study ecosystem processes may help to provide valuable insights into alternative management strategies. 1129: *-.017*

We report on the social dynamics and behaviour of five lions reintroduced to the Welgevonden Private Game Reserve. Despite initially being together in a boma for three months, the lions did not stay together. Aggression was also noted after the release of a female, which had been placed in the boma earlier after sustaining an injury. The results showed different lions associating and breaking away from the group on various occasions, which illustrated the flexibility of lion social structure when prides are disturbed. The findings are similar to those observed in the Kruger National Park after a lion-cropping programme. The lions that were reintroduced on Welgevonden were variously related, and the way in which they finally associated in prides was based on their relatedness. This raised the question of whether association took place by chance, or whether there was some kind of kin-recognition in lions, resulting in them associating mostly with kin. It was not possible to prove kin-recognition in this study, but the association with kin could lead to genetic problems in the future due to inbreeding.

1130: *+.139*

The critically endangered Seychelles Black Paradise Flycatcher *Terpsiphone corvina* was once found on at least five of the inner (granitic) islands in the Seychelles archipelago, western Indian Ocean. Currently, it is only found on two islands, with c. 98% of the world population (c. 150-200 individuals) occurring on the 10-km² island of La Digue. Creation of additional island populations is therefore considered crucial in improving its conservation status. The presence of native broad-leaved plateau forest in proximity to wetland areas is proposed as an important selection criterion when considering the suitability of other islands for translocation, due to the presumed importance of insect prey (dependent on water) in the diet. We quantified habitat use, territory composition, the effect of water on invertebrate abundance, and foraging and breeding success to determine the importance of native broad-leaved woodland and wetland areas for Flycatchers. Flycatcher territories contained significantly more native broad-leaved woodland (88%) than its availability on the plateau (43%); Flycatchers used native tree species significantly more for both foraging (81%) and nesting (95%) than their availability within territories (71%); and territory size varied inversely with the density of native broad-leaved tree species. Native broad-leaved forest was associated with semipermanent and permanent water bodies and availability of native forest habitat was a good predictor of territory distribution. The number of aerial insects trapped was higher close to water, but there was no effect of the proximity to water

on the number of insects counted on foliage. The majority of identified prey species in adult diet were not dependent on water: Orthoptera and Lepidoptera were the most common prey groups, comprising 66% of identified prey items. There was no effect of proximity to water on foraging or breeding success (c. 35%): depredation was the major factor determining breeding success, and accounted for the majority of nest failures. The importance of wetland areas to Flycatchers therefore appears to have been over-emphasized. The implications for translocation and conservation of the Flycatcher are discussed.

1131: +.244

An approach to an overall management planning for the conservation of endangered species within protected natural areas is presented, based mainly on the development of methods for the diagnosis of the conservation status and the identification of critical life cycle stages (phenophases) of target species. This model includes other aspects inherent in the overall planning of a protected area so as to match its technical, human and economic resources in terms of research and conservation. We provide examples of some island endemics that are included in the "Recovery Plans for the Endangered Plants in the Canary Islands National Parks". The use of demography and genetics is particularly emphasised. We propose reintroductions as one of the most important tools for the management and conservation of endangered plants and the use of "system dynamics" tools as an alternative to traditional population matrix analysis. We provide examples of the application of system dynamics to population dynamics studies and to the design of management actions. (C) 2003 Elsevier Science Ltd. All rights reserved.

1132: +.160

The growth in standard length of endemic soft-muzzled trout *Salmothymus obtusirostris*, translocated to the Zrnovnica river about 25 years ago, was studied. Before the Prancevica dam was built at the other side of the karst mountain where the river springs from, the river Zrnovnica existed only temporarily and therefore did not provide a habitat for fish. The *S. obtusirostris* specimens caught ranged from 15.5 to 33.5 cm in standard length and from 80 to 425 g in weight. The growth in standard length of this population could be expressed by the following von Bertalanffy expression: $L(t) = 48.68(1 - e^{-0.2379(t-0.1261)})$. These results indicate that *S. obtusirostris* adapted to the new environment. They also show translocation to be a useful tool for its conservation. Nevertheless, the protection of this endangered species should be of the utmost importance.

1133: +.010

Beavers were exterminated in Bavaria in 1867. The reintroduction, conducted by the "Bund Naturschutz in Bayern e.V." between 1966 and the late seventies, was very successful: The present beaver population in Bavaria is estimated at more than 6.000 individuals, and it is still growing and expanding into its former range. This success was paralleled by a growing number of conflicts between beavers and human land users in the densely settled and intensively used Bavarian landscape. Beavers fed on crops, beaver dams flooded forests, pastures and basements, beavers dug their burrows under roads, fields and high water dikes, and some of them felled apple trees in gardens. During the 1980s until the early 1990s, the beaver conflicts escalated, less because of the real world problems, but more because politicians and mass media abused this conflict between nature conservation and land owners for personal gain. Taking a closer look at beaver-human-conflicts, we found, that almost all conflicts root in the overuse of landscape by man: beaver conflicts happen mainly in a narrow strip along the river banks. Where man has left some

space to the rivers, there are only very few conflicts with beavers. Such unused areas are not only important for beavers and other plant and animal species, but more and mainly for man himself (e.g. for protection of water and prevention of floods).

1134: +.012

In Austria the last beavers became extinct in the middle of the 19th century. More than 100 years later a successful reintroduction started with a small founder group (50 individuals, most of them from Poland) and was rarely realised by the people. Discovered beaver cuttings seemed to be small sensations and the species had a rather positive image. Unfortunately this changed rapidly when the beaver population started to grow and to disperse from protected areas to places intensively used by agriculture and forestry. Landowners complained about beaver damages and some questions like "Why do we need beavers? Will we be forced to live with that species? How many beavers are enough?" were asked more often.

1135: +.010

Once distributed along the Coastal Plain from South Carolina to Texas, the short-lipped ladies'-tresses, *Spiranthes brevilabris* Lindley (Orchidaceae), appeared in 1999 to be restricted to a single population in Levy County, Florida. That population consisted of 152 plants. Ongoing efforts to locate additional populations of this terrestrial orchid have been unsuccessful. We provide 1) a

technique to germinate seeds of this orchid in vitro using mycorrhizal fungi (symbiotic seed germination); 2) a technique to establish seedlings onto soil ex vitro; and 3) a description of the mycorrhizal fungi that prompted germination and establishment. Two fungal endophytes, both *Epulorhiza* spp. recovered from the roots of the epiphytic orchid *Epidendrum magnoliae* Muhl. (syn. *E. conopseum*) and *S. brevilabris*, were utilized in the inoculation of seed. Germination was rapid (<10 days), and a higher percentage of seedlings developed leaves in vitro when inoculated with the *S. brevilabris*-derived fungus as opposed to the *E. magnoliae*-derived fungus (25% versus 20%). Of 165+ laboratory-grown seedlings transplanted onto soil at six sites in Florida, 100% survived >1 month, and 17 initiated anthesis >6 months.

1138: +.152

For the first time in decades the world population of the critically endangered golden-headed langur has increased. A total of nine langurs births (seven births in 2003), but only three animal losses have been recorded since October 2000, when the ZOOLOGICAL SOCIETY FOR THE CONSERVATION OF SPECIES AND POPULATIONS in partnership with Muenster Zoo initiated the Langur Conservation Project on Cat Ba Island, Vietnam. Increasing conservation awareness among the local indigenous people and improving habitat and wildlife protection constituted the main objectives of the conservation project during the past 2 1/2 years. Poaching could be brought under control through ranger work, a strictly protected langur sanctuary in Cat Ba National Park was established, and active involvement of lo-cal people in protection work takes place. Resulting from a major governmental development plan for Cat Ba Island, habitat destruction and fragmentation have increased and so has the pressure on Cat Ba National Park, that is currently in danger of loosing up to 30 % of its area. The langur project is working to alleviate threats to Cat Ba National Park by contributing to map the future park boundaries and by assisting to apply for UNESCO Biosphere Reserve nomination for the Cat Ba Archipelago. With about 60 individuals, scattered over several isolated subpopulations, the langur population still is extremely small and fragile, and new threats such as proposed military roads, this species still will need all the help it possibly can get. Even translocation of langurs seems to be unavoidable.

1139: +.218

1. We studied a reintroduced population of the formerly critically endangered Mauritius kestrel *Falco punctatus* Temmink from its inception in 1987 until 2002, by which time the population had attained carrying capacity for the study area. Post-1994 the population received minimal management other than the provision of nestboxes.2. We analysed data collected on survival (1987-2002) using program MARK to explore the influence of density-dependent and independent processes on survival over the course of the population's development.3. We found evidence for non-linear, threshold density dependence in juvenile survival rates. Juvenile survival was also strongly influenced by climate, with the temporal distribution of rainfall during the cyclone season being the most influential climatic variable. Adult survival remained constant throughout.4. Our most parsimonious capture-mark-recapture statistical model, which was constrained by density and climate, explained 75.4% of the temporal variation exhibited in juvenile survival rates over the course of the population's development.5. This study is an example of how data collected as part of a threatened species recovery programme can be used to explore the role and functional form of natural population regulatory processes. With the improvements in conservation management techniques and the resulting success stories, formerly threatened species offer unique opportunities to further our understanding of the fundamental principles of population ecology.

1140: +.269

Management plans for threatened or recovering large vertebrate species that are increasing in population size and range focus on the establishment of viable populations within set temporal limits. New Zealand (Hookers) sea lions (*Phocarctos hookeri*) were declared a threatened species in 1997, and New Zealand legislation requires that threatened species of marine mammals must be managed to reduce human-induced mortality and achieve a non-threatened status within 20 years. The present breeding distribution of *P. hookeri* is highly localised, with over 95% of total annual pup production located at Auckland Islands and almost all of the remainder at Campbell Island. Breeding elsewhere has been ephemeral or restricted to < 10 adult females. The only recorded sustainable breeding at a new location has been at Otago, South Island, New Zealand. This breeding population consisted of a total of four breeding females in 2002 and is derived from one immigrant female that gave birth to her first pup in the 1993/1994 breeding season. The New Zealand Department of Conservation management plan specifies that to achieve a non-threatened status *P. hookeri* (1) at Otago must increase in the number of breeding females to greater than or equal to 10, and (2) must establish greater than or equal to two new breeding locations within the 20-year time frame, each with greater than or equal to 10 breeding females. This study (1) projects the population growth trends at a new location (Otago) to see if it will achieve greater than or equal to 10 breeding females within the legislated time frame, and (2) examines the likelihood that other breeding locations will establish elsewhere given the demographic information available for this species. We present 20 deterministic and three stochastic Leslie matrix model scenarios for female population growth for the initial years following the start of breeding at a new location. Our results indicate that (1) a new breeding population derived from one immigrant female is unlikely to reach 10 breeding females in 20 years; this duration is more likely to be 23-41 years (deterministic models) or 23-26 years (stochastic model), (2) the likelihood of two new sites establishing within 20 years is unquantifiable, but the probability is low, and (3) if the legislated outcome and time limit are not revised in the population management plan, the feasibility and effectiveness of re-locating young females could be investigated. (C) 2003 Elsevier Ltd. All rights reserved.

1141: +.226

The Egyptian vulture (*Neophron percnopterus*) breeds in Sicily and, in 22 years of monitoring, has shown a decline followed by a slight recovery. We used Generalised Linear Models to predict: (1) the distribution range, (2) the habitat selection within the range, (3) the quality (i.e., occupation rate, breeding success) of breeding sites. Some 60% of Sicily proved to be unsuitable, being either too densely forested and without cliffs for nesting, or too densely populated, along with intensive agriculture. The models converged, indicating that the pairs select a precise upland habitat where low cliffs, distant from urban areas, are surrounded by arboreal crops and Mediterranean vegetation. The variables predicting the quality of a site are also related to human disturbance, including the distance from a road or the presence of heavy traffic. Natural restocking, in the last 3 years, is occurring in quiet sites and in proximity to extensive grazing land rich in sheep and goat herds. These results focused on short-term programmes for local management of the species aimed at protracting the natural restocking: namely, the activation of (1) a stable system of artificial feeding stations, (2) nest site protection with joint activities for increasing public awareness, (3) a reintroduction project, by hacking, of juveniles born in captivity in Italian and European breeding centres.

1142: +.218

Many species have strong habitat preferences that directly influence population viability. For successful reintroduction of threatened populations that rely on habitat structures, the correct

placement of artificial structures is also important to population persistence. In this paper, we present a hierarchical approach to the problem of translocating animals that rely on permanent habitat structures, in which we first use population dynamics data to identify areas of suitable habitat, and then identify optimal configuration for habitat structures. We use data collected from a non-endangered, conspecific population of the endangered riparian woodrat (*Neotoma fuscipes riparia*) to examine the degree to which the distribution of dens in translocation sites might influence the likelihood that animals persist in their new environment. We characterize the habitats in which dens occur, analyze their spatial clustering, and compare them to temporal changes in population status for sex and age classes. We compare the potential efficacy of translocation efforts using spatial analysis versus solely habitat-based approaches and identify the optimal spatial configuration of dens that should be considered in this translocation effort. We found that patterns of habitat use were positively correlated with overstorey cover, and animal weight was positively correlated with understorey cover. Woodrats appear to select den locations on the basis of understorey cover, but also benefit from dense overstorey cover and distance to nearest tree. Our results suggest that in translocation efforts, artificial dens should be placed in clusters within a radius of 15 m, as values above and below this value showed negative correlations with body mass. Translocations should occur after reproductive events, which occur in April and August for woodrats in southern California. Our analyses provide practical guidelines in determining appropriate timing and spacing for translocation events in the context of animal condition, minimizing disease transmission, and reproduction.

1143: +.211

Optimization and simulation modeling can be used to account for demographic and economic factors simultaneously in a comprehensive analysis of endangered-species population recovery. This is a powerful approach that is broadly applicable but under-utilized in conservation biology. We applied the approach to a population recovery analysis of threatened and endangered piping plovers (*Charadrius melodus*) in the Great Plains of North America. Predator exclusion increases the reproductive success of piping plovers, but the most cost-efficient strategy of applying predator exclusion and the number of protected breeding pairs necessary to prevent further population declines were unknown. We developed a linear programming model to define strategies that would either maximize fledging rates or minimize financial costs by allocating plover pairs to 1 of 6 types of protection. We evaluated the optimal strategies using a stochastic population simulation model. The minimum cost to achieve a 20% chance of stabilizing simulated populations was approximately \$1-11 million over 50 years. Increasing reproductive success to 1.24 fledglings/pair at minimal cost in any given area required fencing 85% of pairs at managed sites but cost 23% less than the current approach. Maximum fledging rates resulted in >20% of simulated populations reaching recovery goals in 30-50 years at cumulative costs of <\$16 million. Protecting plover pairs within 50 km of natural resource agency field offices was sufficient to increase simulated populations to established recovery goals. A range-wide management plan needs to be developed and implemented to foster the involvement and cooperation among managers that will be necessary for recovery efforts to be successful. We also discuss how our approach can be applied to a variety of wildlife management issues.

1144: +.256

Understanding the factors that underlie colonization success is crucial both for ecological theory and conservation practices. The most effective way to assess colonization ability is to introduce experimentally different sets of individuals in empty patches of suitable habitat and to monitor the outcome. We translocated mated female waterstriders, *Aquarius najas*, into 90 streams that were

not currently inhabited by the species. We manipulated sizes of propagules (from 2 to 16 mated females) and numbers of origin populations (one or two). Three origin populations were genetically different from each other, but they were less than 150 km from the streams of translocation. The results demonstrate clearly that both the larger propagule size and the high number of source populations have positive effects on the probability of colonizing a new stream. Thus, in addition to the stochastic factors related to the propagule size it may be essential to consider also the diversity of genetic origin for colonization success.

1145: -.022

Cook's petrel (*Pterodroma cookii*), a New Zealand endemic, now breeds on only three islands at the extremities of its former range. Holocene fossil bones have indicated sites of 11 extinct colonies on North and South Islands, showing that Cook's petrels preferred hills <1000 m high and 20-30 km inland. This is a forest-breeding, burrowing petrel. Atypically for a seasonally breeding gadfly petrel, some birds visit Hauturu (Little Barrier Island) nocturnally through the non-breeding season, but do not land. The breeding season extends from September to April at its northern-most colony on Hauturu but is a month later in the south at Whenua Hou (Codfish Island), where birds are heavier. The pre-laying exodus lasts about 28 days. Egg-laying extends over 38 days in the large northern colony, but barely 15 days in the smaller southern one. Incubation is mainly done in three 14-day spells. Chick-rearing takes about 87 days. Chicks attain almost twice the non-breeding adult weight. There is a desertion period of about 10 days before fledging. Pacific rats (*Rattus exulans*), feral cats (*Felis catus*) and weka (*Gallirallus australis*) have endangered these last colonies. Breeding success, most affected by rat predation of eggs and chicks, deteriorated seriously after extermination of feral cats from Hauturu, but improved significantly after eradication of rats from Whenua Hou. Rats are now a major threat on Hauturu. Cook's petrels should be considered for reintroduction to suitable mainland reserves, to enhance biodiversity and restore nutrient inflows.

1146: +.069

Trounson Kauri Park is a 445-ha fragment of kauri-podocarp forest located in western Northland, New Zealand, and is one of a series of "mainland island" ecosystem restoration projects managed by the Department of Conservation. One of the main objectives at Trounson is to reduce introduced mammalian pest numbers to a level that would allow recovery of those native species still present in the park and allow the reintroduction of local or regionally extinct species. Brushtail possums (*Trichosurus vulpecula*) and rodents (ship rats, *Rattus rattus*, Norway rats, *R. norvegicus*, and mice, *Mus musculus*) were targeted in poison baiting operations using 1080, various anticoagulants, cholecalciferol or cyanide pellets laid in bait stations within the park. These operations suppressed possum and rat numbers to low levels, but mouse numbers were reduced only for short periods. The reduction in possum and rat numbers allowed significant seasonal increases in kukupa (New Zealand wood pigeon, *Hemiphaga novaeseelandiae*) abundance. Feral cats (*Felis catus*) and mustelids (stoats, *Mustela erminea*, weasels, *M. nivalis*, and ferrets, *M. furo*) were trapped around the forest boundaries and at key locations within and around the park. The predator trapping consistently provided predation relief for North Island brown kiwi (*Apteryx australis mantelli*) chicks, which are extremely vulnerable to predation by stoats, such that enough survived in order to sustain and increase the size of the adult population. Attempts were made to re-establish breeding populations of North Island robins (*Petroica australis longipes*), North Island kokako (*Callaeas cinerea wilsoni*), and brown teal (*Anas aucklandica chlorotis*) (three species of locally extinct native birds) to Trounson, but these were only partially successful at best.

1147: +.019

Although analyses of intraspecific variability are an important prerequisite for species identification assays, only a few studies have focused on population genetics and historical biogeography of sturgeon species. Here we present the first study on genetic variability of the last remaining Adriatic sturgeon, *Acipenser naccarii*, derived from mitochondrial and nuclear DNA. Our mitochondrial DNA analyses arranged individuals into three distinguished mitochondrial DNA haplogroups (Po1, Po2 and Buna). Two haplogroups (Po1 and Buna) were correlated to geographical distribution, whereas the third (Po2) was not. It was, however, very closely related to one lineage of its Ponto-Caspian sister species, *A. gueldenstaedtii*. The distribution of nuclear markers (microsatellites and amplified fragment length polymorphism) was strongly correlated to geographical distribution. An assignment test based on nuclear data placed no specimen of *A. naccarii* to *A. gueldenstaedtii* and vice versa. Therefore, the presence of *gueldenstaedtii*-like haplotypes within the Po population is either the result of a postglacial introgression or an ancestral polymorphism and does not indicate a hybrid population. The most valuable tool for forensic species identification purposes is one diagnostic deletion separating all *A. naccarii* from *A. gueldenstaedtii*. As both *A. naccarii* populations are genetically differentiated, stocking of sturgeon from the Po River in Italy into waters of the Buna River would jeopardize the genetic differences between both populations and should thus be avoided.

1148: +.219

White-tailed deer (*Odocoileus virginianus*) were nearly extirpated from the southeastern USA during the late 19th and early 20th centuries. Recovery programmes, including protection of remnant native stocks and transplants from other parts of the species' range, were initiated in the early 1900s. The recovery programmes were highly successful and deer are presently numerous and continuously distributed throughout the southeastern USA. However, the impact of the recovery programmes on the present genetic structure of white-tailed deer remains to be thoroughly investigated. We used 17 microsatellite DNA loci to assess genetic differentiation and diversity for 543 white-tailed deer representing 16 populations in Mississippi and three extra-state reference populations. There was significant genetic differentiation among all populations and the majority of genetic variation (greater than or equal to 93%) was contained within populations. Patterns of genetic structure, genetic similarity and isolation by distance within Mississippi were not concordant with geographical proximity of populations or subspecies delineations. We detected evidence of past genetic bottlenecks in nine of the 19 populations examined. However, despite experiencing genetic bottlenecks or founder events, allelic diversity and heterozygosity were uniformly high in all populations. These exceeded reported values for other cervid species that experienced similar population declines within the past century. The recovery programme was successful in that deer were restored to their former range while maintaining high and uniform genetic variability. Our results seem to confirm the importance of rapid population expansion and habitat continuity in retaining genetic variation in restored populations. However, the use of diverse transplant stocks and the varied demographic histories of populations resulted in fine-scale genetic structuring.

1149: +.061

A trial reintroduction of the European beaver (*Castor fiber*) to Scotland has been proposed and is awaiting Scottish Executive approval. Currently, no data have been published on the actual effects of beavers on the Scottish landscape, although many authors have predicted potential impacts. Such predictions have been based on the impacts of the beaver in other European countries. The

aim of this study is to provide a better predictive capability as to the potential effects on tree felling immediately following beaver reintroduction by using data of beavers in captivity. In 2002, four European beavers were released into two large, semi-natural enclosures - the Willow Carr Site and the Lake Site - in eastern Scotland. This paper represents data from the first year of a three-year monitoring programme to investigate the felling and feeding activities of these beavers. In absolute terms, willow (*Salix* spp.) were the favoured species at both sites, being felled in the greatest numbers, followed by alder (*Alnus* spp.) and birch (*Betula* spp.). In terms of relative abundance, only the selections against birch at both sites, and for willow at the Lake site, were found to be significant. No size-selectivity at the Willow Carr Site was evident, but significantly smaller than average trees of all three genera were felled at the Lake Site. Decreased felling activity was observed with increasing distance from the lodge at the Willow Carr Site, whilst most trees felled at the Lake Site were situated within the shallow margins of the lakes. Approximate felling rates were 0.5 and 0.8 trees per beaver per day, at the Willow Carr Site and Lake Site respectively.

1150: +.045

The European beaver (*Castor fiber*) returned to Denmark in 1999 when 18 beavers were released in Klosterheden State Forest District in the northwestern part of the country. A monitoring programme was initiated to trace the population and distribution of the beavers, beaver-human conflicts, and effects on flora and fauna. The status of flora and fauna in the reintroduction area was systematically investigated prior to the beaver reintroduction. By 2003, beavers inhabited the entire catchment basin in which they were released and had dispersed to a neighbouring river system 25-30 km away. Beaver kits were observed every year and the population was estimated at 51 individuals in 2003. The beavers mainly fed on willow scrubs during the winter season and non-woody plants in the summer. No damage was reported in forests or agricultural production areas but the beavers caused minor problems by flooding an arable field, gardens, meadows, and forest roads and by blocking inlets to a fish farm. Few significant alterations of water flow were recorded but the diversity of the wetland biotopes increased. The only negative effects appeared to be a restriction of spawning migration of sea trout (*Salmo trutta*) by beaver darns in brooks. Other fish species were thought to benefit from the beaver ponds. Ponds enhanced spawning potentials for amphibians and enabled new species of birds to breed in the area. Bats profited by more suitable hunting sites. Occurrence of otters (*Lutra lutra*) increased but no clear relationship with beaver distribution was demonstrated.

1151: +.195

The beaver (*Castor fiber*) was reintroduced to the Netherlands in 1988, in the Biesbosch National Park. In the following years beavers were also introduced in several newly developed nature areas, including the Gelderse Poort, a natural area 100 km upstream from the Biesbosch. Fifteen years later, we see a steadily growing beaver population, living in a still expanding ecological network of traditional nature reserves and newly developed nature areas, especially along the rivers Rhine, Meuse and IJssel. The number of beavers in the Netherlands is estimated at about 200-250 individuals.

1152: +.012

After a long period of absence, beavers (*Castor fiber*) reappeared in Flanders in the spring of 2000, first in the province of Vlaams-Brabant and in 2002 also in Limburg. The beavers originate from the unofficially reintroduced Walloon population. With a view to a future reintroduction project to

restock this not yet reproducing Flemish beaver population, a feasibility study was conducted at the request of AMINAL Nature Division (Ministry of the Flemish Government). This study concluded that the basins of the rivers Schelde and Dijle could carry a viable beaver population of at least 40 families that were all expected to stay in the same area and cause no problems in the wide vicinity. Even before the Flemish government had decided whether or not to proceed with the preparation of an official reintroduction, 20 Bavarian beavers of unknown age and sex were released on 11 April 2003 along the rivers Dijle and Laan. This happened unofficially, without any scientific follow-up and without preparing or informing the local population or other interest groups. Scarcely two months later at least two v beavers had already crossed the city of Leuven. Beavers are now permanently present along the rivers Dijle and Laan south of Leuven. Some traces have also been found on the Use. Complaints are coming in about damage to private as well as to public property and an adaptation of rat control methods is required. Since in the densely populated ulated Flanders many human-beaver conflicts can be expected, the pros and cons of beaver presence in Flanders should be weighed up carefully, taking all interest groups into account.

1153: +.063

The beaver (*Castor fiber*) returned to Wallonia mostly due to clandestine reintroductions of 100 Bavarian beavers between 1998 and 2001. Beaver settlements are now present in most of the river basins, sometimes in seemingly unsuitable areas or in highly urbanised zones. Beavers spread widely during the two years following the reintroductions. The Walloon authorities instituted proceedings against the perpetrators of these releases and, at the same time, instigated a survey and a structure for managing possible conflicts. Forest, fishing and muskrat trapping agents conduct the field survey work and transfer information to the Research Centre for Nature, Forests and Wood (CRNFB) and the Biernausaut Association. With this set-up, a new beaver site can be detected within one month. About 200-250 beavers are now present in Wallonia, at about 60 sites. Only small problems have occurred until now, but they are expected to increase as the beaver population grows and spreads. Thus, beaver management has to continue, to prevent conflicts with human activities but also in accordance with nature conservation objectives such as the implementation of the Natura 2000 programme. A future trans-border co-ordination for surveying beavers should be developed.

1154: +.066

During the 19th century the European beaver (*Castor fiber*) disappeared from most parts of France, except for the Rhone Valley. In the 1970s, beavers caught from the river Rhone were released in the Loire River, near the city of Blois. While this reintroduction was successful and led to the progressive recolonisation of the Loire River and its tributaries, the density of beaver colonies has remained low. Furthermore, habitat quality has decreased in the downstream part of the Loire, and beavers might not find enough suitable sites to settle. This study was designed to estimate the number of suitable places for beaver settlement in a downstream segment of the Loire River, which is still uncolonised, but already explored by pioneer individuals. For this purpose, we searched for relationships between signs of beaver presence (lodges, cut trunks, and remains of browsed plants) and vegetation features, bank characteristics, and human disturbance in a presently colonised region of the Loire River. Beavers selected sites dominated by 10-15 m tall trees to build lodges, irrespective of the tree species. Sites with cut trees were dominated by Salicaceae. Beavers fed on Salicaceae and numerous herbs. Based on these findings, vegetation features in the uncolonised stretch of the river are expected to be favourable to beaver settlement and feeding. However, beavers will have to face river bank protections and more intense levels of

human activity in most of the uncolonised area. These factors may dramatically limit the number of sites suitable for lodge building.

1155: +.110

European beavers (*Castor fiber*) have been reintroduced to many areas within their former range. The resulting populations are still in a phase of population growth and range expansion. From a management point of view it is of interest to understand the pattern of population development that these populations are, or will be, exhibiting. Based on data from two surveys of a province in southwestern Sweden, I have earlier proposed that reintroduced beaver populations may exhibit an irruptive pattern of development, possibly as a result of overutilization of resources and lack of predators. The aim of this study was to see if a repeated study, twelve years after the previous, would support or question the proposed pattern of population development. Data from three surveys of the same province were used. The overall population density for the total area had increased from 0.10 colonies/km² in 1976, to 0.19 in 1987, and to 0.21 in 1999. However, when population density of local areas with time passed since colonisation was related, a peak in density (mean: 0.34 colonies/km²) after 25 years was revealed. Dividing the data into groups, areas colonised more or less than 25 years ago, and beaver population density decreased or increased since the previous survey (1987), showed that a negative change in population density was significantly more common in areas colonised more than 25 years ago. The results support the proposed pattern of population irruption in the studied beaver population.

1156: +.138

After being reduced to about 1,200 animals in eight isolated populations by the beginning of the 20th century, European beavers (*Castor fiber*) have powerfully recovered in both range and population, through relaxation of persecution, natural spread, and widespread reintroductions. Populations are now (2003) established in all countries within their former natural range in Europe except for Britain, Portugal, Italy, and the south Balkans (Greece, Albania, Bulgaria, Macedonia; status in Bosnia-Herzegovina is uncertain). In Asia, there are significant populations in central Siberia, Kamchatka, and on the Amur; and small relict populations elsewhere in Siberia, and in Xinjiang (China)/western Mongolia. The current minimum population estimate is 639,000. Both populations and range are in rapid expansion. We present maps summarizing current knowledge of the world distribution of European beaver and the Eurasian distribution of the introduced American beaver (*Castor canadensis*), and tables of the most recent known population estimates for each country.

1157: +.210

The roles of behavioral studies of individuals in the conservation of wildlife, which should be important for the conservation of birds also, are briefly introduced and discussed in the light of two case studies of the Asiatic Black Bear *Ursus thibetanus* and Sika Deer *Cervus nippon* in Japan. Some local populations of the bear, one of Japan's largest mammal species, are in danger of extinction. At Karuizawa town, Nagano Prefecture, central Japan, some bears have been visiting garbage disposal sites. Sixteen bears were captured, collared, and tracked using radio-telemetry, from July 1998 to September 2001. Three individuals were killed because they were staying within the town and judged as dangerous individuals. The other 16 bears were translocated. This individuals based management with radio-telemetry data can minimize risks of local population extinction of bears. On Kinkazan Island, Miyagi Prefecture, north-east Japan, most members of a 150-strong Sika Deer population were individually recognizable and have been tracked since

1989. Changes in body conditions, such as morphological and nutritional condition of individuals, and lifetime reproductive success were recorded. The data suggested that variances in lifetime reproductive successes among individuals were high, and the population dynamics can be strongly related to survival and reproductive success of the variation among individuals. This long-term study of the deer showed that reproductive strategies of individuals affected population dynamics. While, this study also showed that the population density, food availability, and stochastic variation in environment might seriously affect on survival and reproductive success of each individual.

1159: +.068

In the years 1999-2002, first studies were carried out on the metazoan parasites of Atlantic salmon (*Salmo salar* L.) recently reintroduced into the Elbe River drainage system, after more than 50 years after the complete extinction of the Elbe salmon population. A total of six helminth species were recorded from salmon smolts from three streams of the Elbe River basin (Kamenice River, Jestedsky and Libocansky Brooks) in North Bohemia, Czech Republic, where *S. salar* fingerlings have been released since 1998: *Gyrodactylus truttae* Glaser, 1974, *Crepidostomum metoecus* Braun, 1900, *Diplostomum spathaceum* (Rudolphi, 1819) metacercariae, *Raphidascaris acus* (Bloch, 1799) adults and encapsulated larvae, *Cystidicoloides ephemeridarum* (Linstow, 1872), and *Neoechinorhynchus rutili* (Moller, 1780). Except for *D. spathaceum*, all these freshwater parasites have been received from the helminth fauna of the co-habiting brown trout (*Salmo trutta fario* L.). Due to local ecological conditions, the parasite faunae of both salmon and brown trout exhibited distinct qualitative and quantitative differences in the three localities. The finding of *G. truttae* on *S. salar* represents a new host record. Three helminth parasites of marine origin, the cestodes *Eubothrium crassum* (Bloch, 1779) and *Scolex pleuronectis* Muller, 1788 plerocercoids, and the nematode *Anisakis simplex* (Rudolphi, 1809) larvae were found in the single examined adult *S. salar* from the Kamenice River. New data on the geographical distribution of some nematode parasites of *Salmo trutta fario* L., *Barbatula barbatula* (L.) and *Anguilla anguilla* (L.) are presented.

1160: +.243

American Peregrine Falcons in California (*Falco peregrinus anatum*) have been managed in one of the largest reintroduction programs in the history of endangered species management. However, as for most other widespread natural populations, the spatial and temporal dynamics of California Peregrines have remained poorly understood. Longterm monitoring data on this highly managed species present a unique opportunity for retrospective analysis of the factors contributing to the successful recovery of Peregrine Falcons in California, as well as demographic differences between habitat types. We used a newly developed mark-recapture model (the Barker model), which allows the simultaneous use of recaptures, dead recoveries, and live resightings, to provide estimates of first-year, second-year, and adult survival of Peregrine Falcons in the mid- and south-coast regions of California. Annual survival rates for second-year and adult Peregrines were estimated at 86%. Through model fitting, we show positive effects of urban habitats on first-year survival. In our best-fit models, first-year birds fledged in urban areas had a survival rate of 65%, whereas rural (non-urban) first-year survival was only 28%. The introduction method also influenced first-year survival after dispersal; in rural areas, estimated survival of hatched young (after independence) was lower than estimated survival of wild-reared young. We also show that birds in urban habitats have significantly higher fecundity rates than birds in rural habitats, even though the fecundity of rural breeders has increased significantly over the last two decades. We argue that the strong habitat differences in first-year survival combined with lower fecundity rates

in rural habitats (due to slower improvement in eggshell thinning rates) facilitates spatial structuring of the California Peregrine population. Matrix population models constructed for both rural and urban habitats support this assessment. The temporally averaged population growth rate in urban habitats was estimated as $\lambda = 1.28$, compared to $\lambda = 0.99$ in rural habitats. Yearly analytical λ values in rural habitat predict declining population growth ($\lambda < 1$) throughout the 1980s and increasing population growth ($\lambda > 1$) in the 1990s due to improved reproductive performance. These results indicate that the introduction effort was pivotal in recovering the rural, population in this portion of its former habitat, because intrinsic growth rates alone would have been insufficient to yield the observed population recovery.

1161: +.115

Soil characteristics, disturbance histories, and species richness among distinct groups of plants and animals may be useful predictors of important conservation areas when data are limited. We used multivariate analysis of covariance to test the hypothesis that the species richness of plants, arthropods, herpetofauna, and breeding birds are correlated and increase with soil fertility (silt and clay content in sandy soils), soil variability, and hardwood midstory reduction in subxeric, nutrient-poor longleaf pine sandhills at Eglin Air Force Base in northwest Florida. During 1994-1995 and 1998-1999, we sampled 30 81-ha plots with varying fire-exclusion histories and at two spatial scales of resolution (10 x 40 m and 81 ha). The relationship between the number of plant species and percent silt and clay and its coefficient of variation was significant and positive at the plot level (81 ha) but not at the subplot level (10 x 40 m). Herpetofaunal species richness was the only faunal variable that increased with silt and clay content, but the coefficient of variation did not. Multivariate effects of hardwood reduction were significant in 1998-1999 but not in 1994-1995, which suggests that the reintroduction of fire increased species richness across taxa. Univariate effects of hardwood reduction were marginally significant for plant species richness at the subplot level and not significant for herpetofaunal species richness at either scale. Plant and arthropod species richness were not correlated. Herpetofaunal species richness was not correlated with that of other taxa (plant and animal). The species richness of plants and arthropods were each significantly positively correlated with the richness of breeding bird species at the subplot level during 1994-1995, whereas only arthropod species richness was positively correlated with bird species richness at the plot level in either year. Our results suggest that the restoration of fire regime may be the most effective tool with which to increase diversity in pyrogenic areas considered for conservation protection.

1162: -.015

In Alberta, Canada (1982-2001), and in Idaho, Montana, and Wyoming, United States (1987-2001), wolves (*Canis lupus*) killed various domestic animals, among which the major prey were sheep in the United States (68%, $n = 494$) and cattle in Canada (95%; $n = 1633$). Under recovery programs, the wolf population increased in the United States, and depredation events increased proportionately. In both countries, the number of domestic animals killed each year was correlated with the number of wolves killed by government authorities for depredation management. We tested the ability of antiwolf barriers made of flags hanging from ropes to impede wolf access to food and livestock. In 18 experiments, barriers prevented captive wolves ($n = 9$) from accessing food for up to 28 hours and allowed daily separation of wolves to administer contraceptive pills to a female wolf. Barriers prevented access by wild wolves to 100-m² baited sites during two 60-day tests. We also set barriers around three cattle pastures. In Alberta during two 60-day trials on 25-ha pastures, wolves approached barriers on 23 occasions but did not cross them, and no cattle were killed. Wolves killed cattle on neighboring ranches during the trials and before and after the

trials on the tested ranches. In Idaho four radio collared wolves crossed barriers and killed cattle in a 400-ha ranch after 61 days of barrier exposure. Our results suggest that antiwolf barriers are effective in deterring captive and wild wolves for >1 and 60 days, respectively, and that wild wolves switch to alternative livestock when excluded from one herd of livestock. Our depredation data indicate that protecting livestock from wolves reduces the necessity for killing wolves. Barriers could play a role among the limited set of preventive measures available and offer a cost-effective mitigation tool for the problem of livestock depredation on a local scale.

1163: -.007

As wolf (*Canis lupus*) populations recover in Wisconsin (U. S. A.), their depredations on livestock, pets, and hunting dogs have increased. We used a mail-back survey to assess the tolerance of 535 rural citizens of wolves and their preferences regarding the management of "problem" wolves. Specifically, we tested whether people who had lost domestic animals to wolves or other predators were less tolerant of wolves than neighboring residents who had not and whether compensation payments improved tolerance of wolves. We assessed tolerance via proxy measures related to an individual's preferred wolf population size for Wisconsin and the likelihood she or he would shoot a wolf. We also measured individuals' approval of lethal control and other wolf-management tactics under five conflict scenarios. Multivariate analysis revealed that the strongest predictor of tolerance was social group. Bear (*Ursus americanus*) hunters were concerned about losing valuable hounds to wolves and were more likely to approve of lethal control and reducing the wolf population than were livestock producers, who were more concerned than general residents. To a lesser degree, education level, experience of loss, and gender were also significant. Livestock producers and bear hunters who had been compensated for their losses to wolves were not more tolerant than their counterparts who alleged a loss but received no compensation. Yet all respondents approved of compensation payments as a management strategy. Our results indicate that deep-rooted social identity and occupation are more powerful predictors of tolerance of wolves than individual encounters with these large carnivores.

1164: +.071

The 10 km² island of La Digue, Republic of Seychelles, western Indian Ocean supports the last viable population of the Critically Endangered Seychelles Black Paradise-flycatcher *Terpsiphone corvina*. Small populations recorded on adjacent islands since the 1980s appear to be ephemeral and not self-sustaining. We document the results of the first island-wide survey of the flycatcher on La Digue using the playback of conspecific calls at random points. Previous surveys were based largely on counting the number of singing males. The survey was conducted between April and August 2001 and confirmed (i) the current world population is at least 200 individuals (109-145 territories, 218-290 individuals) in a c. 4.4 km² range, thus accurately quantifying the documented increase in flycatcher numbers since the late 1970s; (ii) territories were more widely distributed than previously recorded and not exclusively associated with coastal plateaux or freshwater bodies, contrary to previous descriptions; and (iii) distribution was determined largely by the presence of high canopy (native) broad-leaved tree species. The importance of canopy height to flycatchers was highlighted by the fact that localized loss of high canopy (native) forest (4%), in a 161 ha study area on the large western plateau, resulted in an equivalent reduction (4%) in the number of territories. In light of our findings we discuss the implications for conservation of the flycatcher on La Digue and its possible translocation.

1165: +.203

Translocations of threatened species play an increasingly important role in conservation management. However, few studies have examined what effects, if any, the translocation process itself (i.e. catching, handling, confining, transferring and releasing an animal into an unfamiliar environment) has on subsequent breeding success. Takahe *Porphyrio hochstetteri* living on offshore "predator-free" islands in New Zealand are a model system for examining such effects because pre-breeding birds have been frequently translocated between established island populations before they pair up and breed at 2-3 years of age. We postulated that "translocated" breeders (i.e. breeders that had been raised on another island) would delay first breeding attempts and/or have lower reproductive success compared with "resident" birds (i.e. bred on the same island that they were raised). The results indicated that translocated birds did not delay breeding and had similar mean hatching and fledging success as resident pairs in their first breeding season and subsequent seasons combined. The results suggest that at least for large or long-lived birds such as Takahe, the effects of any stress from the translocation itself, or the release into an unfamiliar environment, might be either short-lived or not significant enough to hinder subsequent breeding success. We recommend that further research be carried out on other species to determine the baseline effects, if any, of translocations, so that they can be taken into account when considering other determinants of translocation success such as habitat suitability, number of individuals and timing of releases.

1166: +.292

We studied the effect of food supplementation, female age and clutch order on productivity in a translocated species. Food supplementation increased clutch size from 3.9 to 4.4 (average) eggs per nesting attempt, and more than doubled fledging and recruitment success. Supplemented females started a second clutch 9 days sooner after fledging first clutch chicks than unfed females. During second clutches, supplemented females incubated the eggs for a shorter period of time (15.2 days vs. 16.8). Older females laid larger clutches (4.6 vs. 3.7 eggs) than yearlings and incubated second clutch eggs for a shorter period (15.4 vs. 16.6 days). Females laid more eggs in first clutches (4.2 vs. 3.8 eggs), and those eggs took approximately 30% longer to lay than eggs in second clutches. The successful maintenance of hihi populations on the available islands may be dependent on the permanent provision of supplemental food at nest sites. (C) 2003 Elsevier Ltd. All rights reserved.

1167: +.165

The loggerhead shrike, *Lanius ludovicianus*, is a declining songbird that forms breeding aggregations. Despite such reports from several populations, only one statistical analysis of loggerhead shrike territory distribution has been published to date. I use a spatio-temporal simulation technique to test for deviations from randomness in the spatial distribution of point data that takes into account date of nest establishment. I apply this model to data on the distribution of shrike nests in Comanche County, Oklahoma, USA, collected over the 1998 and 1999 breeding seasons. When the data are considered without regard to date of nest-establishment, the results are equivocal; nests are significantly aggregated in 1999, but not 1998. However, when order of nest establishment is taken into account, later nests are significantly more likely to be closer than expected to conspecifics in both years. This is true even when the distribution of simple resources, such as suitable nest-trees, is included in the model. These results are consistent with the hypothesis that loggerhead shrikes 'prospect' for suitable habitat using the distribution of breeding conspecifics. This aspect of loggerhead shrike breeding ecology should be considered for both habitat conservation and captive breeding and reintroduction programs for this species. (C) 2003 Elsevier Ltd. All rights reserved.

1168: +.376

In France, most civil engineering and excavation projects are at present accompanied by compensatory measures with the aim of preserving biodiversity. In order to avoid the destruction of a habitat of high conservation interest in NE France, harbouring two legally protected plant species, an experiment of soil translocation was conducted on an area of 1 ha. The donor site was an extensively managed mesophilic meadow and the receiving site was a neighbouring arable land. The vegetation of the translocated meadow was described 8 and 17 months after soil translocation, and compared (1) with vegetation resulting from more classical restoration techniques tested on the arable land (natural regeneration and seed mixture sowing) and (2) with the soil seed bank and vegetation previously present on the donor site. Results showed that the soil translocation technique permitted the development of many meadow species, including two legally protected species, and few ruderal species despite a large area of bare ground. This technique seems effective in terms of number and abundance of meadow species compared to natural regeneration and commercial seed sowing. In the case of the two classical methods, species richness was lower and only widespread species were present. Topsoil translocation provides a good compensatory method to avoid habitat and species destruction. However, the study should be continued, with the aim of assessing the longer term development and stabilization of the vegetation of the translocated meadow.

1169: +.321

I analyzed the habitat selection of two Alpine marmots *Marmota marmota* (Linnaeus, 1758) populations (A and B) re-introduced in the Friulian Dolomites Natural Park (Eastern Italian Alps) in 1977 and 1983 respectively. Population A showed a higher density of family units than the more recently introduced and still increasing population B. I mapped winter burrows and I conferred proportions of usage of habitat types with their availability by the Jacobs index. Population B positively selected fewer types of habitat than population A, and particularly selected those habitat types more strongly selected by A. Through stepwise discriminant function analysis and oneway ANOVA, I analyzed the characteristics of the winter burrow surroundings, by splitting up the two study areas into sample squares covering 1 ha each. The importance of the alpine meadows and pastures was subordinate to the presence of rocks, especially in the pastures. Comparing the results obtained separately for the two populations, the more recent and less dense population showed a more restrictive habitat and slope selection, in accordance with the ideal free distribution theory. In order to validate the habitat suitability model obtained by discriminant analysis I applied it to two other populations of Alpine marmots present in FDNP and in the Julian Prealps Natural Park.

1170: -.078

The Spiny-tailed or Gidgee Skink, *Egernia stokesii*, has two western subspecies; one of which, *Egernia stokesii badia*, has declined in distribution and abundance because of habitat disturbance and is currently listed as threatened. This study examined all known locations of *E. s. badia* in the Western Australian Wheatbelt to determine its current status. Results show that it is still found over a large part of its previously known range in the eastern part of the northern Wheatbelt, but it has declined or disappeared from most localities in the central Wheatbelt. Reintroduction to previously occupied sites from populations occupying threatened localities (abandoned buildings, farm sheds, etc.) could be undertaken if suitable habitat (e.g. old hollow logs) is established or available at translocation sites and members of family groups are relocated together.

1172: +.071

California condors are one of the most endangered species native to the mainland United States and are subject of intense effort regarding captive breeding and reintroduction. We analyzed 20 years of California condor egg records from the wild and from three captive propagation facilities for fertility, hatchability, and chick survivability, along with changes in egg size due to multiple clutching. Overall annual mean percent of fertile eggs was 80.2%, hatchability was 87.3%, and chick survivability to greater than or equal to 60 days was 95.5%. One egg-laying site had a significantly lower fertility rate (P less than or equal to 0.0001) than the other sites, which was probably due to pair incompatibility rather than any physiological factors. Egg volume of the first egg was significantly greater than both the second ($t = 6.73$, $P = 0.0001$) and third egg ($t = 6.62$, P less than or equal to 0.0001) of the season, while the second egg had a significantly greater volume ($t = 3.20$, $P = 0.0084$) than the third egg. Chicks from the second egg ($t = 3.24$, $P = 0.029$) and third egg ($t = 7.94$, $P = 0.0014$) of the season were significantly smaller than chicks from the first egg of the season. The decrease in egg measures and chick hatch weight due to multiple clutching did not affect hatchability or chick survivability. There were significant positive relationships ($P < 0.0001$) between fresh egg weight and chick hatch weight and between egg volume and chick hatch weight, as well as between fresh egg weight and egg volume. In spite of the decrease in fresh egg weight, egg volume and chick hatch weights, due to egg removal to stimulate double and sometimes triple clutching, the captive propagation program has been successful in producing birds for the restoration of this species. Zoo Biol 23: 489-500, 2004. (C) 2004 Wiley-Liss, Inc.

1173: -.045

A total of 85 brush-tailed bettongs (*Bettongia penicillata*) from Western Australia and two sites in South Australia were translocated to Yathong Nature Reserve (YNR) in western New South Wales in October 2001. Aerial baiting to control the introduced red fox (*Vulpes vulpes*) had been undertaken on YNR since 1996. Thirty-one bettongs were fitted with radio-transmitters at the time of release, and two subsequently. Trapping took place at irregular intervals after the translocation. In all, 73% of telemetered bettongs died within the first six months; all were dead within 13 months. Eight bettongs died within the first eight days immediately following their release, due to causes other than predation. These eight all originated from St Peter Island (SPI), South Australia. A low incidence of breeding on SPI supports the belief that this source population was in poor condition and unsuited for translocation. Overall, 19 of the 33 telemetered bettongs were killed by predators: 14 (74%) by feral house cats (*Felis catus*), two (11%) by birds, and three (16%) by predators, which, although they could not be fully identified, were not foxes. One month after release, surviving bettongs weighed less than they did at the time of their release (mean decrease in mass = 9.7%, range 2.6 - 22.4%, $n = 11$). Within two months of their release most had regained any lost mass (mean change in mass since release = - 0.3%, range - 5.9 to 10.5%). Food resources on YNR appeared sufficient to sustain adult brush-tailed bettongs, despite a period of severe drought. Small pouch young present at the time of release were subsequently lost. Females gave birth and carried small pouch young (up to 50 mm), but no young-at-foot were recorded. Bettongs did not disperse further than 10 km from their release site. Overall, 50% of aerial-tracking locations were no further than 3.2 km from the release site, and 92% no further than 7.0 km. This experimental translocation of brush-tailed bettongs failed due to predation by cats. It demonstrated that foxes were no longer a threat to wildlife on YNR and identified cats as the major impediment to the restoration of locally extinct fauna.

1174: -.020

Deer species (fallow, red, sambar, chital, rusa and hog deer) have formed wild populations in Australian habitats ranging from arid woodland to rainforest and are a growing management issue.

Data were obtained via an Australia-wide land-manager survey that collected information on the liberation, distribution, abundance and management of wild deer in Australia. It is estimated that there are 218 wild deer herds in Australia with 7% of these herds originating from acclimatisation society releases, 35% from deer farm escapes/releases and 58% from translocations (deliberate releases). On average, herds released by acclimatisation societies are estimated to be 107 years old, herds that have escaped from (or been released from) deer farms are 9 years old, and transplanted herds are 6 years old. It is estimated that Australia currently has 200000 wild deer, with 85% of these deer originally released by acclimatisation societies, 6% through escapes/releases from deer farms and 9% by translocation. Poor knowledge of the impacts of wild deer by land managers and the absence of consistent legislation governing the management of farmed and wild deer are factors that have exacerbated deliberate releases of deer and the escape of deer from farms. Management strategies for wild deer in Australia need to be developed by land managers to address the escape and release of deer from farms, the illegal translocation of deer into the wild and the management of existing wild deer herds.

1175: +.042

Although the theoretical effects of a severe reduction in effective population size (i.e. a bottleneck) are well known, relatively few empirical studies of bottlenecks have been based on extensive temporally spaced samples of a population both before and after a bottleneck. Here we describe the results of one such study, utilising the Jenolan Caves (JC) population of the brush-tailed rock-wallaby (*Petrogale penicillata*). When first sampled in 1985 (n = 20) the JC population comprised similar to 90 individuals. Subsequently the population crashed, and by 1992 only seven individuals remained. In 1996 the entire population (n = 10) was again sampled. Genetic diversity in the pre- and post-crash JC population was compared using 11 polymorphic microsatellite loci and PCR-SSCP analysis of the mitochondrial DNA control region. Only a single unique control region haplotype was detected in the pre- and post-crash JC population, although variant haplotypes were present in other *P. penicillata* populations. Of the 35 microsatellite alleles present in the pre- crash population, nine (26%) were lost during the bottleneck. The average number of rare alleles declined by 72%, allelic diversity was reduced by 30% and average heterozygosity declined by 10%. These observations are consistent with theoretical predictions. Additional analyses revealed that a *P. penicillata* female at Wombeyan Caves was the only survivor of a 1990/91 reintroduction attempt using animals from JC. Of the microsatellite alleles detected in this female, 21% (4/19) were no longer present in the post-crash JC population. Furthermore, the genetic profiles of animals from the recently discovered Taralga population indicate that they are not derived from JC stock, but represent a threatened remnant of a hitherto undetected natural *P. penicillata* population.

1176: +.226

Large blue (*Maculinea anion*) is probably the most famous butterfly species in Europe. It has been focusing attention of scientists, collectors, conservators since 18th century, especially in Great Britain. The mystery of the extraordinary life history was solved a hundred years ago by F. W. Frohawk and T. A. Chapman. Caterpillars are initially endophytic and live in *Thymus* flowerheads but at the beginning of the fourth (final) larval instar they leave the plants. If lucky larvae are adopted by *Myrmica* ants (Fig. 1) and they continue their development in nests preying upon host brood. Formerly large blue occurred locally on nearly 100 sites in Southern England. Fast decline was observed and until 1970 only 3 colonies survived (Fig. 2). Detailed ecological demands were not understood enough to undertake effective conservation measures. Key factors were discovered by J. A. Thomas in 1970s. Although *M. anion* larvae are transported to nests by workers of all

Myrmica species, the rate of survival differs significantly among species. A butterfly population is dependent on high number of *M. sabuleti* nests present near *Thymus* plants. The host ant is very sensitive to habitat quality and in English climate it is abundant only on heavily grazed southern slopes (Fig. 3). Changes in land management, abandonment as well as myxomatosis in 1950s, which almost completely eliminated rabbits - natural mowers, led to disappearance of *M. anion* habitat. After extinction, the reintroduction programme has started very soon, following proper habitat management. Large blue populations were restored successfully on some sites using Swedish stock; further reintroductions are planned. In continental Europe, *M. anion* is endangered in many countries, but habitat requirements vary in different climatic zones. In Poland, where declining is very fast, it is suspected that larvae at least at the NE part of the country develop in nests of different than *M. sabuleti* Myrmica species (Fig. 4). Conservation measures should respect this possible local specificity, but first of all further extensive ecological studies are urgently needed.

1177: +.062

Current Species Status: Threatened (WA Wildlife Conservation Act 1950), Critically Endangered (ranking by WA Threatened Species Scientific Committee), Endangered (Commonwealth Environment Protection and Biodiversity Conservation Act 1999), Critical (Action Plan for Australian Reptiles, 1993), Critically Endangered under IUCN (2000) Red List Criteria A2c and D, listed as Critically Endangered in the IUCN 2000 Red List of threatened animals. Habitat requirements and Limiting Factors: *Pseudemydura umbrina* inhabits shallow, ephemeral, winter-wet swamps on clay or sand-over-clay soils with nearby suitable aestivating refuges. Clearing and drainage have destroyed most original habitat within its very small former range. Existing protected habitat marginal. Recovery Plan Objective: To decrease the chance of extinction of the Western Swamp Tortoise by creating at least three wild populations and increasing the total number of mature individuals in the wild to >50. Recovery Criteria: Criteria for successful achievement of the Objective are: 1. Complete extension of the Ellen Brook Nature Reserve to the west to include Western Swamp Tortoise habitat currently within private properties. 2. An increase in the number of adult, sub-adult and juvenile (> 2 years old) tortoises at Ellen Brook Nature Reserve to more than 50 by 2007. 3. Persistence of a population of more than 40 adult, sub-adult and juvenile (> 2 years old) tortoises at Twin Swamps Nature Reserve and reproduction (egg laying) of re-introduced tortoises demonstrated by 2007. 4. The creation of a population from captive-bred animals at Mogumber Nature Reserve of more than 35 adult, sub-adult and juvenile (> 2 years old) tortoises by 2007. 5. The maintenance of a captive population of at least 12 breeding adults producing at least 20 two-year-old animals each year. 6. The creation of a second captive colony at another accredited Zoo in Australia. 7. The creation of a semi-captive 'insurance' colony of at least 20 tortoises at the Harry Waring Reserve of UWA or some other site. 8. The selection by the Recovery Team and endorsement by relevant authorities of a third suitable translocation site. The criteria for failure to achieve the objective are: 1. A decline in numbers of the Western Swamp Tortoise in the wild. 2. Cessation or significant reduction (to less than 10 hatchlings per year) in captive breeding. 3. The maintenance of more than 50% of the non-hatchling world population of *P. umbrina* in a single captive colony. Recovery Actions: The Western Swamp Tortoise Recovery Team will coordinate implementation of the following actions. 1. Employment of Chief Investigator 2. Management of Ellen Brook, Twin Swamps and Mogumber Nature Reserves 3. Tortoise population monitoring 4. Captive breeding 5. Translocations 6. Education, publicity and sponsorship. Biodiversity benefits: The Western Swamp Tortoise represents the subfamily Pseudemydurinae monotypically and is little changed from fossils from the early Miocene at Riversleigh in Queensland. Ellen Brook and Twin Swamps Nature Reserves protect wetland ecological communities that are now threatened because of

clearing and drainage. Twin Swamps and Ellen Brook Nature Reserves protect threatened ecological communities and Mogumber Nature Reserve protects species of threatened plants.

1178: -.066

The Hazel Grouse is mainly threatened by habitat loss as result of inadequate forest management (large clear-cuts, coniferous monocultures, ceasing of coppice forest use) and habitat fragmentation. The current distribution (map Fig. 1, c. 2000-4000 ind.) is confined to four isolated populations in the Rheinisches Schiefergebirge (continues in Belgium/Luxembourg), Black Forest, Bavarian and Bohemian Forests (continues to the Austrian Waldviertel) and Bavarian Alps (continues in Austria and Switzerland). In the Bavarian Alps and the Bavarian Forest, suitable habitats occur on large and less fragmented areas, so that the Hazel Grouse is not actually threatened there. The isolated and fragmented remaining populations in the Rheinisches Schiefergebirge and Black Forest are virtually endangered. However, conservation measures (e.g. forestry use in small mosaic patches acceptance of gaps, support of amentiferous pioneer tree species) could be performed relatively quickly and at rather low costs. The population of Capercaillie has declined drastically due to habitat destruction and fragmentation through e.g. large clear-cuts, short rotation periods, dense coniferous plantations, increase of forest roads, disturbances by tourism and high ungulate densities. The current occurrence (map Fig. 2, c. 1600 ind.) is restricted to a few isolated populations. The largest (meta-) population (800 ind.) occurs in the Bavarian Alps and is connected with Austrian and Swiss populations. The population in the other Bavarian mountains has dramatically declined (mainly c. 30 remaining birds in the Bavarian Forest, neighbored to c. 100 in the adjacent Bohemian Forest in Czech Republic). In the Fichtelgebirge there is a small, isolated population of about 40 ind. In the Black Forest (600 ind.), the decline was less pronounced due to intense conservation measures. In Thuringia, the population decline was severe (from 300 ind. in 1970 to 20-30 ind. in 1990, after translocation of wild-captured Russian birds now 30-40 ind.). The populations in Saxony and Hesse and the only lowland population in Lusatia (S-Brandenburg/N-Saxony) have become extinct. Reintroduction schemes in five mountain ranges have been stopped because of poor success. Viable meta-populations of Capercaillie will probably survive only, in the Alps and in the Black Forest, provided that forestry management fulfils the habitat needs of this grouse. The example of Fichtelgebirge demonstrates, however, that even small and isolated populations are able to survive for longer periods and are worthwhile to start conservation measures.

1180: +.101

In the North Bilaspur Forest Division in Madhya Pradesh, India, the sloth bear (*Melursus ursinus*) population is ecologically isolated, and some bears have developed aggressive behavior. Available bear habitat is highly fragmented and degraded and is interspersed with human habitation. In this study we assessed habitat use patterns of sloth bears with the goal of establishing management guidelines to reduce human-bear conflicts. Goodness-of-fit comparisons showed that expected use of each habitat category differed from habitat availability. Bear sign was most frequent in sal forest followed by land near water, sal mixed forest, and mixed forest. However, bear use of terrain categories was not different from expected use. A large number of bear dens were near water and human settlements. Bears regularly used more than 50% of observed den sites. Because of nearness to human settlement and degraded habitat, bears largely depended on villages for food, resulting in frequent human-bear encounters, some of which led to maulings and fatalities. One management priority is to protect highly preferred habitats of sloth bears. Bear population control and translocation of bears from isolated habitat patches to more suitable areas may be carried out simultaneously with education and awareness programs to conserve this species and to mitigate

human-bear conflicts on a long-term basis.

1181: -.137

For many years, the primary strategy for managing grizzly bears (*Ursus arctos*) that came into conflict with humans in the Greater Yellowstone Ecosystem (GYE) was to capture and translocate the offending bears away from conflict sites. Translocation usually only temporarily alleviated the problems and most often did not result in long-term solutions. Wildlife managers needed to be able to predict the causes, types, locations, and trends of conflicts to more efficiently allocate resources for pro-active rather than reactive management actions. To address this need, we recorded all grizzly bear-human conflicts reported in the GYE during 1992-2000. We analyzed trends in conflicts over time (increasing or decreasing), geographic location on macro- (inside or outside of the designated Yellowstone Grizzly Bear Recovery Zone [YGBRZ]) and micro- (geographic location) scales, land ownership (public or private), and relationship to the seasonal availability of bear foods. We recorded 995 grizzly bear-human conflicts in the GYE. Fifty-three percent of the conflicts occurred outside and 47% inside the YGBRZ boundary. Fifty-nine percent of the conflicts occurred on public and 41% on private land. Incidents of bears damaging property and obtaining anthropogenic foods were inversely correlated to the abundance of naturally occurring bear foods. Livestock depredations occurred independent of the availability of bear foods. To further aid in prioritizing management strategies to reduce conflicts, we also analyzed conflicts in relation to subsequent human-caused grizzly bear mortality. There were 74 human-caused grizzly bear mortalities during the study, primarily from killing bears in defense of life and property (43%) and management removal of bears involved in bear-human conflicts (28%). Other sources of human-caused mortality included illegal kills, electrocution by downed power-lines, mistaken identification by American black bear (*Ursus americanus*) hunters, and vehicle strikes. This analysis will help provide wildlife managers the information necessary to develop strategies designed to prevent conflicts from occurring rather than reacting to conflicts after they occur.

1183: +.108

The NSW Threatened Species Conservation Act 1995 (TSC Act) is unique and effective in Australian jurisdictions in recognising threatened populations. Section II of the TSC Act provides for the listing of endangered populations. There were 28 endangered populations listed under the TSC Act (January 2003) for which there were two approved recovery plans, one publicly exhibited draft plan and four plans in preparation. Monitoring was being undertaken for only six populations. The TSC Act would be strengthened by: (i) adding an objective which states that recognising threatened entities is fundamental to the legislation; (ii) changing the definition of population to make it consistent with IUCN terminology; (iii) simplifying Section 11; (iv) better resourcing for faster preparation of plans and their implementation; and (v) including population monitoring in all recovery plans. The process of saving threatened species is occurring at the level of population; for example, through priority sites for threat abatement, translocation, replicates for research treatments and habitat protection. The objective of recognising and the process of listing threatened populations are fundamental to sound threatened species legislation.

1184: +.167

The history of extinction in the wild and present status of the European bison, *Bison bonasus*, is briefly summarised. Reasons for the extinction of this species include the overabundance of other large herbivores, cattle grazing in forests, war, and other political instabilities. Restitution (the recovery) of the species began with 54 animals and started with the reproduction of bison in zoos

and reserves, increasing population numbers and distribution as wide as possible, and resulting in release into the wild (1952). The European Bison Pedigree Book (EBPB) played a very important role in maintaining the purity of European bison herds. Present (year 2000) numbers and distribution of the species in enclosed (191) and free-roaming herds (31) is larger than shortly before its extinction in the wild; a situation that would seem to assure the bison's better survival. At least 2,864 European bison have been registered by the EBPB (2001) globally, of which c. 60% were free- or semi-free ranging. The actual world population is a few hundred larger, because not all breeding centres reported data to EBPB. Many threats remain which could seriously influence the future development of European bison populations. Reintroductions were somewhat chaotic, not always respecting the separation of genetical lines and numbers increased slowly. Established free-ranging herds are often small and isolated, and tend to be subject to human influence, including use of traditional management methods, as well as supplemental feeding during winter. As yet, a viable population within a continuous range has not been established. Recent simulations have indicated that population of at least 100 individuals could be counted as demographically safe. There are only four such herds. Recent European bison gene pool consists of only 12 diploid sets of genes; those of the Lowland line originate from only seven founders. The world herd is highly inbred ($F=20.2\%$), especially the Lowland line ($F=32.4\%$), as found in the 1980s and those indices are still increasing. Inbreeding affects viability, the interval between calving and skeletal growth, to a higher degree in the Lowland-Caucasian line than in the Lowland line. Many indices suggest that the European bison has lost its genetic variability and this continues to occur. The genetic contribution of founders is uneven; remaining significantly unaltered over the last decades. Ecology of the species has been reviewed, based mostly on studies concerning the largest population in Bialowieza Forest. Natural mortality has considerably decreased due to a reduction in the natural forces of selection. However, diseases have recently appeared in several herds which may pose a serious threat to European bison populations. Balanoposthitis of unknown aetiology has appeared in a few herds, as well as tuberculosis in one herd. Both diseases may exert a deleterious effect on European bison herds. Future goals in conservation and management of European bison are recommended. Captive breeding is very important for preservation of the species and serves to maintain its genetic purity and reintroduction to natural ecosystems should continue. The establishment of the European bison Gene Resource Bank could be very important for the future of the species. In the wild, numbers must increase to attain the management goal of creating self-sustaining populations of both genetic lines. Regulated culling in local populations will be necessary for managing optimal bison habitat. Attention should however be given to the chosen scheme of elimination according to the sex and age of the groups. Further introductions to the wild are necessary to establish a 'continuous' range and ensure the long-term survival of viable populations. There are proposals to create such populations in the Eastern Carpathians, as well as in Russia. Lowland European bison are well distributed in Belarus, and together with Lithuanian and northern Polish populations they may create another region within the bison's contemporary range. These populations must be monitored and allowed to increase in size. Ecological corridors need to be established between them or a programme for assisted migration (translocations) developed. Pure Lowland and Lowland-Caucasian lines should be separated in the wild, as well as in enclosed breeding centres, up to the time of their likely natural contact. This isolation is of particular importance for preserving the genetic variability within Lowland-Caucasian line. Pure animals should be separated from European x North American bison hybrids within the Caucasus Mountains and elsewhere. Current genetic management requires a more balanced genetic contribution of animals representing founder genes, which are currently under-represented or not present in free-ranging herds, and must be identified and included in European bison populations. The aetiology and epidemiology of European bison diseases, especially of the male genital organs, should be determined and their effects on the risk of extinction assessed. The place of the European bison in ungulate communities and the species effect on the carrying capacity of

contemporary forest ecosystems in Europe need to be determined. A review of the European bison's status clearly indicates that its recent numbers and distribution are much better than before its extinction in the wild at the beginning of the 20th century. The European bison is classified as an Endangered (EN) species on the IUCN Red List of Threatened Species, mainly due to the many continued threats. While these threats exist, the European bison's full recovery and re-naturalisation in the wild cannot be guaranteed. It should therefore also be included in the Habitat Directive and in Appendix II of the Bern Convention.

1185: -.072

The new Canid Action Plan synthesises the current knowledge on the biology, ecology and status of all wild canid species, and outlines the conservation actions and projects needed to secure their long-term survival. Aiming at conservation biologists, ecologists, local conservation officials, administrators, educators, and all others dealing with canids in their jobs, the authors aspire to stimulate the conservation of all canids by highlighting problems, debating priorities and suggesting action. The 36 taxa of wild canids that comprise the family Canidae, ranging in size from the tiny fennec fox to the mighty grey wolf, and found in every continent except Antarctica, are special. They are special because they have, as perceived friend or foe, preoccupied the imaginations of mankind for millennia; because the breadth of their adaptations makes them enthralling to science; and because the contradictory facets of their relations with people perplex the conservationist. The increase in numbers of people, the spread of settlement, and the exploitation of natural resources of previously little-disturbed wild lands, together with persecution, are threatening some of these canids with extinction. The possibility that we are heedlessly, perhaps needlessly, mismanaging many of them is saddening; the probability that our negligence will force several more to extinction should fill us with bottomless dismay. It demands action, and that is why we have compiled this new Canid Action Plan. Following a short introduction and a chapter on phylogeny, classification, and evolutionary ecology of the Canidae (Part 1), Part 2 provides the latest information on the distribution, biology and conservation status of each species, organised by geographical region. The accounts also list current field projects, and their contact details are provided in an appendix. The Canid Specialist Group's members are active worldwide. Nine of the 36 taxa covered are threatened (3 Critically Endangered, 3 Endangered and 3 Vulnerable), and one is considered Near Threatened. Six species (7%) were listed as Data Deficient, and 20 (56%) species as Least Concern (Appendix 1). The threatened canids are: Darwin's fox (CR). Until recently, known only from the Island of Chiloe (Chile) until rediscovered 600km away in the coastal mountains, where domestic dogs threaten them with disease or direct attack. Red wolf (CR). Currently the subject of taxonomic debate, red wolves were declared Extinct in the Wild by 1980, but have been reintroduced into eastern North Carolina, where they are now locally common. Hybridisation with coyotes is the primary threat. Island fox (CR). Restricted to the six largest of the eight California Channel Islands, each island population is considered a separate subspecies, and four have declined precipitously. Threats include hyperpredation by golden eagles and the introduction of canine diseases. Ethiopian wolf (EN). Less than 500 individuals remain, confined to eight locations in the Ethiopian Highlands. Previously listed as Critically Endangered, continuous loss of habitat due to high-altitude subsistence agriculture remains the major threat, along with disease (particularly rabies). African wild dog (EN). Formerly distributed throughout sub-Saharan Africa, excluding rainforests, wild dogs have disappeared from 25 of the former 39 range states. More than half of the mortality recorded among adults is caused directly by human activity. Dhole (EN). Formerly distributed across Asia, dholes have undergone widespread decline and are threatened by depletion of their prey base, habitat loss, persecution, competition and disease. Dingo (VU). Austronesian people transported the dingo from Asia to Australia and other islands in between 1,000 and 5,000 years

ago. Pure dingoes occur only as remnant populations in central and northern Australia and in Thailand, and they are threatened by cross-breeding with domestic dogs. Bush dog (VU). Despite a supposedly widespread distribution in South American forests, this species is perceived as rare, and threatened by habitat conversion and human encroachment. Blanford's fox (VU). Present in arid mountainous regions of the Middle East and north-eastern Egypt eastwards to Afghanistan, where human development could pose a threat. In contrast to the threats faced by threatened canids, several species are thriving in human-dominated landscapes and incur the loathing of farmers and hunters alike. Red foxes are notoriously successful in urban settings, and coyotes, golden jackals, crab-eating and kit foxes seem able to thrive amidst human settlements. Management prompted by rabies control, fur harvest, and livestock predation leads to the slaughter of hundreds of thousands of canids annually. Part 3 of the Plan considers nine major issues in canid conservation, namely canid society, conservation genetics, assessing and managing diseases, management of canids near people, impact of exploitation and trade, survey and census techniques, captive conservation, reintroduction and meta-population management, and conservation education. Part 4 is arguably the most important section. It includes a chapter on the need for setting priorities and measuring success in canid conservation, and the detailed Action Plan for canid conservation into the 21st century. Although we have sought to refine and consolidate these entries, they represent the views of the many experts around the world who suggested them, who debated them in our workshops and in the forum of our international congress, hosted by the WildCRU in Oxford in September 2001. The list of proposed projects makes no claim to be comprehensive, but it is the result of extremely wide consultation. The plan itself, together with the databases concerning existing members and research projects, are all available on the web at <http://www.canids.org>. The Action Plan was prepared in parallel with our edited monograph entitled *The Biology and Conservation of Wild Canids* (Oxford University Press, 2004) which contains comprehensive reviews of the science underpinning this Action Plan, together with 14 case studies of wild canid biology.

1186: +.197

Background. As part of SNH's species management decision-making framework there is a need to address the role of translocation or reintroduction of native species. This report uses international experience from six countries: USA, Sweden, Netherlands, Spain, Australia and New Zealand to assess how translocations have been used to further biodiversity policy, and its suitability as a species management tool. The report identifies the differing, but complementary, ways in which translocations have been used in longaltered environments, similar to Scotland, and those which are still undergoing rapid landscape and habitat changes. The results will contribute to the ongoing debate within Scotland. **Main findings.** In some countries, such as the USA and New Zealand, native species translocation is an established part of the biodiversity armoury, in others they are only recently beginning to be addressed. The CBD, EC conservation Directives and the Bern Convention have all emphasised the need for environmental and species sustainability. Translocation is identified as an important mechanism to achieve these objectives. There are few formal policy frameworks in place for the use of translocation as a tool for achieving biodiversity policy outcomes. The best developed identified translocation policy framework has been produced by the Department of Conservation in New Zealand. In most countries translocation is part of the toolkit of species recovery or action plans and accompanied by other policy elements. Translocation is a long-term staged process. The ESA uses translocation according to need. It is applied equally to populations, races, sub species and species. The determinant is threat and need. In the USA the scientific case comes first. Biological criteria are paramount under the ESA. In Europe translocations are used as part of the suite of tools to help deliver individual biodiversity Plans, and protected areas were core to translocation programmes. In all countries national

landscape action plans are seen as essential prerequisites. There is no simple formula for deciding on the use or no use of translocation as a tool for biodiversity policy or outcomes. Review of international policy and practice for native species conservation translocations Commissioned Report No. 034 (ROAME No. F03NC04B) Contractor: EcoText COMMISSIONED REPORT Summary. Cost efficiency is rarely given overt consideration in choosing options within plans. Extinction is viewed as more expensive. Stakeholder engagement is key to delivery at every stage of recovery plans and in the success of translocation programmes. In all countries, cultural practices are important in determining the acceptability of translocation programmes. New Zealand has adopted a systematic, standardized procedure for evaluating the needs where translocation may be appropriate. There is a clear need for an unequivocal set of policies that identify the role and function of translocations in the Scottish context. Translocation cannot exist as a tool in isolation - it is part of a wider set of options used for delivering biodiversity policy and practice. A rigorously transparent approach to translocation will pay dividends, both in establishing the scientific case and in developing stakeholder support for individual projects.

1187: +.143

Scientists have been implementing a programme to reintroduce Bearded Vultures into the Alps during the last 25 years. This paper summarizes the results at the alpine scale. This effort has been facilitated through the implementation of the International Bearded Vulture Monitoring (IBM) Project of the National Park Hohe Tauern/EGS since 2001. A single database facilitates homogenous collection and collation of information over the entire study area. All alpine observations are analysed as soon as they reach the co-ordination office. After an evaluation process they are distributed to participants to give everybody access to the whole database. Data are transferred to Geographical Information Systems (GIS) for spatial analyses. Dispersal, pair formation and other relevant factors for population development are examined. The monitoring intensity throughout the Alps is regularly checked. With the help of external GIS tools, dispersal routes can be determined, resulting in a better understanding of the spatial distribution of the species by age and sex.

1188: +.129

Since 1984, when the population of Black Vultures in Europe was estimated at less than 300 pairs, a spectacular recovery has taken place in Spain where 1,334 breeding pairs were recorded in 2001. The main reasons for the recovery has been the reduction of various threats, including prohibition of the use of poison for predator control and protection of most breeding areas. The Black Vulture is now extinct in most of the other countries within its historical distribution range. Only one colony is left in the Balkans, in the Dardia Forest Reserve in Greece, and there are some generally declining colonies in the Caucasus. The total European population is now estimated at 1,456-1,489 pairs, of which 92% are in Spain. Conservation results achieved for the species in Spain show its capacity to respond to integral species and habitat protection. The conservation experience of Spain and western Europe in general is now being applied to the eastern part of the European population. The Black Vulture Conservation Foundation (BVCF) has been working since 1986 to re-establish a continuous population in the species' former European distribution area, by connecting the separate populations of Spain in the west and the Balkans in the east. Conservation of existing colonies is supported and re-stocking or reintroductions are carried out where the causal factors responsible for the population decline have been removed.

1189: +.247

In 2002, an "Action Plan for the Recovery and Conservation of Vultures on the Balkan Peninsula and Adjacent Countries" was drafted as a joint effort of national and international NGOs. Based on the Action Plan, Memoranda of Understanding have been negotiated and concluded between Albania, Macedonia and Bulgaria. The Action Plan is promoted by the Frankfurt Zoological Society (FZS), the Black Vulture Conservation Foundation (BVCF) and the Foundation for the Conservation of the Bearded Vulture (FCBV), with the support of LPO/FIR, BirdLife International, the Royal Society for the Protection of Birds (RSPB), IUCN-Europe, the Eastern Griffon Vulture Working Group (EGVWG), the Bulgarian Environmental Partnership Foundation (BEPF) and NGOs from the range countries. The Action Plan provides the most recent update on the status of the four European vulture species, describes the threats to the individual populations, and makes conclusions about the necessity for immediate conservation actions. Additionally it identifies the need for further research (status, threats, conservation situation), conservation actions (increasing natural food availability, establishment of feeding places, habitat conservation, activities against the use of poison, education, restocking and reintroduction) and coordination/cooperation events (workshops, seminars, public participation, Balkan Vulture web site) for the four vulture species in Albania, Macedonia, Bulgaria, Greece, Serbia, Montenegro and the Ukraine. It is to be extended to include additional countries. Projects are mainly financed by the FZS and the first activities were implemented in 2002 and 2003, with the involvement of 28 different local NGOs and governmental institutions. First results have been encouraging, and this joint effort could lead to the recovery of vultures and their habitats in south-eastern Europe in the medium- and long-term.

1190: +.167

The note presents 9 observations of adult female of Peregrine Falcon *Falco peregrinus* in the fields of Western Wielkopolska. It was a wintering individual which hunted city pigeons. Since 1990 a reintroduction program for Peregrine Falcon has been carried out. Following the release of over 200 individuals, breeding pairs were recorded only in towns. Due to the slow reconstruction of population, every observation of falcons, including the wintering ones, is important in determining new pairs.

1191: +.132

Snake River sockeye salmon *Oncorhynchus nerka* were listed as endangered in 1991. Prior to listing, a captive broodstock program was initiated to prevent species extinction and to begin rebuilding the population. Reintroduction plans for captive broodstock progeny have followed a "spread-the-risk" philosophy incorporating multiple release strategies and lakes. Since 1993, more than 860,000 presmolts, 158,000 smolts, 325,000 eyed eggs and 880 adults have been reintroduced to the habitat. From this production, 312 anadromous sockeye salmon have returned to adult trapping facilities in the Sawtooth Valley of Idaho. Monitoring and evaluation efforts have focused on maximizing the use of limited hatchery-rearing space and on identifying and prioritizing the most successful reintroduction strategies. Comparisons of presmolt overwinter survival and out-migration success from nursery lakes have shown that (1) presmolts released directly to Redfish Lake in October have emigrated more successfully than presmolts reared in Redfish Lake net pens prior to release, (2) presmolts released directly to Alturas and Pettit lakes in October have emigrated more successfully than presmolts released directly to lakes in July, and (3) presmolts reared at the Idaho Department of Fish and Game (IDFG) Sawtooth Fish Hatchery emigrated more successfully than presmolts reared at the IDFG Eagle Fish Hatchery following July releases to Alturas and Pettit lakes. Presmolts that spent one winter in Redfish Lake prior to out-migration were interrogated more successfully at lower Snake and Columbia River dams than

smolts released in the outlet of Redfish Lake. Smolt-to-adult return rates for anadromous adults produced by the captive broodstock program from 2000 to 2002 varied from 0.6% for unmarked fish returning in 2002 to 0.4% for a combined smolt and presmolt release group in 2000. Using captive broodstock techniques, the program has successfully prevented the extinction of Snake River sockeye salmon and increased Population abundance in the habitat. However, without Substantive improvements in smolt-to-adult survival, program efforts will likely be insufficient to rebuild the population to self-sustaining levels.

1192: +.034

The gene pool of Lowland European bison consists of only seven founders' genes and in consequence the high inbreeding within this line is observed. The four free roaming herds of Lowland European bison were analyzed. On the beginning the founding group for every herd was determined and the pedigree analysis was done. The founding group in Bialowieza Forest consists of 28 (9, 19) released animals and two calves, which fathers were not included in the group. The Borecka Forest herd started from 15 (7, 8) bison and 5 (2, 3) from Borki reserve, Knyszyn Forest with 6 (3, 3) and Pila forest district with 8 (4, 4) individuals. The contribution of the pair of founders (PLANTA and PLEBEJER) was highest in all groups but differed in size between herds. The comparison of founder equivalent (fe) showed that all analyzed Polish herds had more genetic variability in the moment of their creation than the captive part of the population. The highest distance (from 1.01 to 2.40%) was observed between free herds and the captive part of current population. The inbreeding coefficient for Bialowieska founding group was equal to 25.05% and lower than mean kinship for the group (32.15%). The difference between those two parameters was smaller for Borecka Forest (30.68% vs. 30.82%). In conclusion should be stated that free roaming Polish herds lost genetic variability during the process of creation and the process of heterozygosity decrease exists mainly because of herds' isolation.

1193: +.100

Problems of an active protection of *dryas satyr*, a species becoming extinct in Poland, are discussed. In total 30 localities of this species were known prior to 1939. But during the period 1940 - 1978 only 5 localities were known. Thus 25 localities ceased to exist, including 18 situated in cool meadows and low peatbogs. During 1986 - 1995 only 2 localities remained, including one created by introduction in 1973. Up to 2004 the species was permanently established in four new localities in vicinity of Krakow after new introductions in 1997 and 1999. Its populations there amounts 30 to 400 specimens during a flight period. A success in introduction of *dryas satyr* is achieved by transfer of fertilized females to new sites. In this way an accidental transfer of diseases and parasitoids, possible during the transfer of caterpillars and pupae, was avoided. Females lay eggs in the most suitable ecological niches. In order to assure the survival of this species in the Polish lepidopterofauna, the number of new localities should be increased. This would prevent its extinction by accidental local disasters (fires, floods etc.).

1194: +.058

The activity pattern of the Sand Goanna *Varanus gouldii* in northern South Australia was estimated by radio telemetry during the summer months. Individuals were located within the Arid Recovery Reserve where introduced European Rabbits *Oryctolagus cuniculus*, Feral Cats *Felis catus* and European Foxes *Vulpes vulpes* were removed. Interaction between the re-introduced Greater Stick-nest Rat *Leporillus conditor* and the Sand Goanna, a potential significant predator in the absence of cats and foxes, was examined. Mean activity area for Sand Goannas was 5.9 ha (+/-

1.0, $n = 9$), and their summer activity was concentrated on sand dunes rather than the adjacent inter-dunal swales. Tracks of Sand Goannas were found more often around Greater Stick-nest Rat nests than control sites. However, Sand Goanna predation on re-introduced Greater Stick-nest Rats could not be confirmed and most deaths of radio-collared Greater Stick-nest Rats coincided with a period of exceptionally high maximum temperatures and were probably due to heat and dehydration. Sand Goannas scavenged Greater Stick-nest Rat carcasses, and analysis of scats and stomach material revealed that although invertebrates were the most common prey item, mammal material (hair and bones) was present in 20% of scats.

1197: +.140

Populations live in habitats whose quality varies spatially and temporally. Understanding how populations deal with these variable habitats can aid our understanding of theoretical issues, and practical issues of biological invasions and biodiversity conservation. I investigate these issues by superimposing simple models of population growth and dispersal on spatiotemporally fractal landscapes, and examining the properties of the landscapes, and of the populations inhabiting them. The properties of the simulated landscape sequences are comparable to those of real habitats. The simulated populations exhibit a range of dynamic behaviors; these behaviors are strongly influenced by the fractal parameters of the landscapes. The results may help explain several important phenomena seen in reintroductions of threatened and endangered species, introductions of biological control agents, and biological invasions. These phenomena include frequently observed lags between population introduction and initial population growth and spread, and the observed high frequency of failure of introductions.

1198: -.060

In November 1993, unusual mortality occurred among endangered Laysan ducks on Laysan island, one of the remote refugia of the Northwestern Hawaiian Islands National Wildlife Refuge (USA). Ten live ducks were emaciated, and blood samples documented anemia, heterophilia, and eosinophilia. Pathology in 13 duck carcasses revealed emaciation, marked thickening of the proventricular wall, abundant mucus, and nodules in the gastrointestinal tract. Histology revealed granulomata associated with nematodes in the proventriculus, small intestines, and body walls of nine of 10 ducks examined on histology. We suspect that low rainfall and low food abundance that year contributed to enhanced pathogenicity of parasite infection, either through increased exposure or decreased host resistance. Because the Laysan duck is found only on Laysan island and is critically endangered, translocation of this species to other islands is being considered. Given that we have not seen pathology associated with *Echinuria* spp. in native waterfowl on other Hawaiian Islands and given the parasite's potential to cause significant lesions in Laysan ducks, it will be important to prevent the translocation of *Echinuria* spp.

1199: +.001

The Vietnamese sika deer (*Cervus nippon pseudaxis*) is an endangered subspecies of economic and traditional value in Vietnam. Most living individuals are held in traditional farms in central Vietnam, others being found in zoos around the world. Here we study the neutral genetic diversity and population structure of this subspecies using nine microsatellite loci in order to evaluate the consequences of the limited number of individuals from which this population was initiated and of the breeding practices (i.e., possible inbreeding). Two hundred individuals were sampled from several villages. Our data show both evidence for limited local inbreeding and isolation by distance with a mean F_{ST} value of 0.02 between villages. This suggests that exchange of

animals occurs at a local scale, at a rate such that highly inbred mating is avoided. However, the genetic diversity, with an expected heterozygosity ($H(e)$) of 0.60 and mean number of alleles (k) of 5.7, was not significantly larger than that estimated from zoo populations of much smaller census size (17 animals sampled; $H(e)=0.65$, $k=4.11$). Our results also suggest that the Vietnamese population might have experienced a slight bottleneck. However, this population is sufficiently variable to constitute a source of individuals for reintroduction in the wild in Vietnam.

1200: +.119

The current distribution of the Hermann's tortoise, *Testudo hermanni* (Gmelin, 1789), in Italy is very scattered. Most of populations occur along the Tyrrhenian coast, particularly southern Tuscany, and Latium, where the most high density was observed. Other populations, probably autochthonous, can be found in Campania and in Calabria. Along the Adriatic coast, the biggest populations can be found in Apulia, Abruzzo and Molise. The species also occurs in some sites of Sicily and Sardinia. In the northern Italy, the Hermann's tortoise has almost disappeared and can be found only in the Po River Delta, such as the Bosco della Mesola. Sites are mainly located in the coasts but, in some cases, also in the inland up to mountains slopes. Further sightings in other areas concerned isolated individuals probably released from captivity. In the present paper the results of a population study carried out in the Bosco della Mesola Reserve, are discussed. The population structure is dominated by adults over 20 years old. The home range size was larger for the females than for the males. Longer daily distances were covered in spring and summer, while movements were greatly reduced during post and pre-hibernation periods. Conservation strategies should be based on: (1) verifying the taxonomic status and the origin of the Italian population through the analysis of genetic distances; (2) monitoring all the major populations in order to assess their status and dynamics; (3) establishing new protected areas in Mediterranean coastal habitats, to protect autochthonous populations and increase population density in case of low numbers. In order to increase the reproductive success of the Hermann's tortoise within protected areas, enclosures should be set out where to raise pairs of breeders. Young turtles should be released in core areas of the reserves, without anthropic disturbance. Moreover, the sites where females laid eggs should be fenced by wire net, in order to prevent predation up to the hatching. The goal is to create a pool of specimens useful for reintroduction and restocking.

1201: +.125

Under the biological species concept, the intraspecific variability and true species richness of Palearctic mammals has often been overlooked, and therefore the need to conserve it. Recovery projects of endangered European mammals in Western Europe rely mainly upon translocation of conspecifics from viable populations in Central or Eastern Europe. From a wildlife management and restoration ecology point of view, many such recovery projects have been successful. However, from a biodiversity perspective it could be argued that they could have failed to protect the original European biodiversity. The increasing evidence of a complex phylogeographic pattern in many European mammals - especially in the Mediterranean region - has led to a reconsideration of the conservation unit and highlights the need for species-specific programmes for assuring the survival of threatened, distinctive populations. Such programs should also include captive breeding. It is therefore suggested that a two-level classification of captive breeding programmes is needed according to the degree of threat of concerned taxa, to maximise available resources without jeopardising in situ conservation. It is proposed to distinguish between a) level I captive breeding programmes, which are part of the conservation strategy for seriously threatened taxa and need to be financed by state or federal agencies, and b) "prophylactic" level II for vulnerable taxa or populations, and for which funds may be available mainly from the private sector. Available

evidence suggests that given adequate husbandry techniques and prerelease training, even captive-bred carnivores can be successfully reintroduced to the wild. However, a closer collaboration among zoological gardens, zoologists and agencies involved in wildlife conservation is needed to avoid ill-conceived, potentially dangerous captive-breeding and re-introduction projects.

1202: +.147

Ungulates in Italy have experienced in the last decade a further increase of their distribution and, possibly, consistence. This trend has been very obvious in the central and northern part of Italy, on the contrary, in south Italy the increase of ungulates populations is quite slow if any. A partial exception is Sardinia where Sardinian red deer (*Cervus elaphus corsicanus*) has been reintroduced into the four provinces of the island. In this frame the relevance of the increase of ungulates for the increase of wolves (*Canis lupus*) in Italy must be emphasized. Ungulates management has also experienced a general development in the last decade, even if deep differences between south and central-north Italy still persist. Well conducted reintroductions have allowed to fill many gaps in the species distribution. Ungulates hunting bags size, suggest an increased importance of ungulates in the hunting activities in Italy. Selective hunting with rifles on cervids and bovids was established in wide areas of north and central Italy, mainly as consequence of roe deer (*Capreolus capreolus*) widespread presence. Wild boar (*Sus scrofa*) hunting still represents a problem for ungulate management in Italy. Almost 50% of the provinces where wild boar is hunted does not collect hunting bag statistics, and only 35% of them try to roughly estimate the consistence of the populations. The traditional dogs hunting of wild boar has expanded to areas where wild boar was recently and illegally reintroduced, as south Italy and the Alps region, and this is a serious problem for the development of a more rational and correct hunting practices. New possibilities of hunting management of red deer in central Italy, and in the future of alpine ibex (*Capra ibex*), are to be considered. An increase of the presence of trained wildlife managers in public administrations is suggested, as a further step in the development of a proper management of ungulates and other wildlife. Scientific research on ungulates in Italy was, in the last decade, quite uneven both in the species and in the disciplines chosen. There is a clear opportunistic approach to subjects, that often has no link with the real necessities of wildlife management. The development of long term studies is suggested, together with a more efficient coordination among scientist in the choice of the research subjects. Last but not least a more efficient founding mechanisms is needed in order to avoid money waste and to promote serious research programmes.

1203: +.099

In 1968, an international team of experts, led by academician J. Kratochvil, made two reports on the historic and current occurrence of the European lynx *Lynx lynx* (Linnaeus, 1758) in Europe (KRATOCHVIL et al. 1968 a, b). Reports made for IUCN and WWF analysed the reasons for the extinction of the European lynx in many European countries and examined ways of its conservation in the countries where it was still found. At the beginning of 1960's, the Slovak population of the European lynx was estimated at 500 animals (HELL 1968). A number of the animals were captured in the six-ties for use in Slovak zoological gardens and some offspring were successfully reared (GRESSNER 1963, 1964). The first three lynx came to the Zoological Garden in Ostrava in December 1965; they were captured in the Slovak Beskydy (Beskids) Mountains. The first progenies were reared in 1967. KUNC (1967, 1969), STEHLIK (1971 b) and KUNC et STEHLIK (1982) encouraged regulation of the numbers of the European lynx by catching them into live traps. Thus, a total of 95 European lynx from the Slovak (Slovensky) Beskydy mountains, Slovensky Rudohorie, Slovensky Kras, Nizke and Zapadni Tatry (Low and Western Tatras), Velka Fatra and Vsetinske Vrchy came to Ostrava Zoo in the period from 1965 to

1992. Most of them came from permitted captures made in the above localities in Slovakia. In several instances there were young animals who came to the zoo after losing their mother (this was the case of lynx from the Nizke and Zapadni Tatry and Vsetinske Vrchy). Catching lynx in Slovakia was regulated - quotas for capture and the prices were determined by the Central Committee of the Slovak Hunters Union (Slovensky polovnický zväz) in Bratislava, who also inspected the activities. This co-operation was terminated in the Autumn 1984, when the Slovak Ministry of Culture and the Slovak Ministry of Agriculture and Food decided, and we were informed, that lynx in Slovakia would only be captured by the zoological gardens in Bratislava and Bojnice and, at a later stage, the Zoo in Kosice. For this reason, the Ostrava Zoo did not get its contract for the catching season of 1984/1985. This was the end of the participation of the Zoological Garden in Ostrava in the ongoing reintroduction of the European lynx in Vosges and in the Sumava Mountains (Bohemian Forest), and this proved to be a difficult matter to explain to our French partners. The relatively rich material in Ostrava Zoo was utilised for breeding, scientific work, education as well as promotion and for reintroduction programs (STEHLIK 1985). The research of the European lynx in Ostrava Zoo was based on suggestions made by SLADEK (1970) and was in harmony with the current requirements laid on zoological gardens. The acquired knowledge contributed to finding solutions to issues concerning the ecological function of beasts of prey in the wild and helped to determine an optimum closed season and an effective way of conserving the species. Based on this knowledge gained from studying reproduction and post-natal development, STEHLIK (1979 a) called for total conservation of the European lynx in Slovakia, at least for a test period. From 1970 to 1992, Ostrava Zoo supplied 50 captured European lynx into several European reintroduction projects (Tab. 1). Its participation in the reintroduction of the European lynx was a pioneer step at the time, taking all the political measures into consideration that complicated the exports and imports of animals and made it practically impossible for people to travel abroad. We would receive a number of invitations to symposia (e.g. Murau, Spiegelau, Strasbourg in 1978) and frequent invitations to provide expert views in localities of reintroduction (e.g. Gran Paradiso), however, we had never received the permission to leave the country. We have to bear in mind that, in those days, there was only limited experience with the reintroduction of felines. NOVELL et JACKSON (1996) stated that there were attempts to reintroduce the wild cat (*Felis silvestris*) in Bavaria between the years 1984 and 1989, to reintroduce the Canadian lynx (*Lynx canadensis*) in the state of New York from 1988 to 1990 and that of the Bobcat (*Lynx rufus*) in the Cumberland Island, Georgia, in 1988 and 1989. It was not until 1988 that the Re-introduction Specialist Group (RSG) was formed within IUCN/SSC. Today, it has over 300 members all over the world, who are involved in overall reintroduction projects for animals and plants. In 1998, this group of experts prepared Guidelines for Re - introductions for IUCN. The guidelines declare that re-introduction is always a long, comprehensive and costly process, the main target of which is to found a viable population. It is an attempt to bring a species or sub-species back to the location of their historical occurrence where they had been made or had become extinct. Preparatory work for such projects includes evaluation of historical information, local ecological conditions, social behaviour of the species, the size of the home ranges, food availability, predators and diseases. The potential migration range is taken into consideration, socio-economic conditions are evaluated and an enlightenment campaign waged. Post-reintroduction activities include monitoring of individual animals, studying their adaptation, mortality evaluation and observation of the behaviour of reintroduced animals, demographic and ecological studies. An important role is played by publishing in mass-media and professional publications (IUCN 1998). Reintroduction of beasts of prey into their former localities is often difficult not only for biological but also for social and political reasons. Reintroduction of large beasts, especially, is a potential conservationist hazard, often inducing concern in the general public (CARBYN et FRITTS 1998). Typically, the problem is the minimum size of vial population and inbreeding (BALLOU 1998).

1205: +.240

Burrow-nesting petrels have been extirpated from many traditional breeding sites by human-induced factors, especially the introduction of predatory mammals. Petrels have proven to be extraordinarily difficult to attract or restore to secure sites due to their strong philopatry, and low intrinsic rates of population growth. Translocation and/or attraction techniques are needed to establish additional populations of endangered petrels to restore species to part or all of their historic range and to restore the keystone role of petrels in terrestrial ecosystems. We attempted to restore a colony of Common Diving Petrels (*Pelecanoides urinatrix*) on Mana Island, New Zealand, by a combination of broadcasting vocalisations, and by transferring and hand-feeding nestlings until they fledged. Calls were broadcast at night almost continuously during 1993-2003, and 239 chicks were transferred during 1997-99. About half the chicks fledged, and 20 of these have returned to Mana Island, along with 51 unbanded birds. Fifteen of the returned chicks have bred on Mana Island, and at least 14 parent-reared chicks fledged in 2002.

1206: -.011

Floristic and structural characteristics of vegetation inhabited by Southern Emu-wrens, *Stipiturus malachurus*, were examined for three geographically isolated subspecies in South Australia. Of the 47 plant species recorded in quadrats, 29 of these (61%) occurred in the habitat of a single subspecies. Structurally, there were no significant differences between habitats used by the three subspecies; however, some trends were apparent. All three subspecies used dense habitat; however, *S. m. intermedius* (Southern Mount Lofty Ranges) used habitat that, on average, was denser than habitats used by *S. m. polionotum* (Coorong) or *S. m. halmaturinus* (Kangaroo Island). Habitat used by all subspecies was most dense at ground level and decreased with height. *S. m. intermedius* used two distinct vegetation types (swamp and dry-heath) that were floristically, but not structurally, different. The habitat at Cox Scrub Conservation Park (CP), where *S. m. intermedius* existed prior to a wildfire in 1983, was neither floristically nor structurally different from that currently inhabited by *S. m. intermedius*. The continued absence of *S. m. intermedius* from Cox Scrub CP reflects its limited dispersal ability. Since the habitat is extensive, Cox Scrub CP would be a suitable translocation site for *S. m. intermedius*. Successful translocation would greatly reduce the risk of a single fire event eliminating a substantial proportion of the remaining population of *S. m. intermedius*.

1209: +.120

The White-winged Guan (*Penelope albipennis*) is a cracid endemic to the Northwestern Peruvian dry forests that is critically endangered due to poaching pressure and habitat loss. In the year 2000, a species reintroduction program was established which consisted in the release of captive born and raised animals from the Barbara D'Achille captive breeding center. The guans were released in areas where the species had disappeared and that were safe for reintroduction and conservation. Between September 2001 and July 2003, 20 White-winged Guans were released at the Chaparrí Private Conservation Area, Lambayeque, Perú. The bird's adaptation to the area was measured through its dispersion, survival and reproduction. Based on the measured dispersion distance, it has been found that it is actually feasible to link the reintroduced population with the surrounding wild populations. Survival has been established at 55 %, measured two years after the animals were released. With respect to reproduction, 3 wild-born chicks were born from reintroduced parents.

1211: +.075

To evaluate inter- and intra-population divergence of the endangered Siberian crane a comparative analysis of mtDNA D-loop region (490 bp) sequences was performed for 17 captive cranes including 14 originating from the eastern and 3 from the central nesting area. Thirteen variable sites form 9 haplotypes, 6 belonging to the eastern nesting site individuals, 2 belonging to the central nesting site and one being common for both nesting areas. The haplotype network analysis did not show significant separation of these two groups. The data obtained could provide genetic grounds for the programs of restoration of the central nesting area population by captive breeding and reintroduction to the wild using the eastern nesting site population gene pool. These results could also be a basis for further evaluation of Siberian crane populations genetic divergence needed for its adequate protection.

1212: +.275

Most studies using demographic PVA models in a context of species restoration have concluded that rather than the rate of introduction, the total number of individuals released had the most important significant influence on the chance of success. In this article we use a genetic simulation model including deleterious and adaptive alleles to assess the impact of the method of release on the change in population mean fitness. We systematically compare a strategy that consists in releasing all individuals at the same time with a strategy that consists in staggering releases over a long period of time. Our results show that the former strategy is more beneficial for long-term fitness when considering advantageous genes only, while the latter is better when considering deleterious genes only. If deleterious and adaptive alleles are considered together, the best strategy depends then essentially on which of these types of alleles has the stronger influence on the change in total fitness. Although the relative contributions of the variance in total fitness due to adaptive and deleterious alleles may vary with the initial frequencies and the selective and dominance effects of these alleles, our results show that the optimal rate of release is mostly dependant on the expected long-term population size. Thus from a genetic view-point, the temporal release strategy of reintroduced populations should be considered with respect to their environment's carrying capacity.

1213: -.000

Although the Louisiana black bear (*Ursus americanus luteolus*) is currently listed as threatened under the Endangered Species Act, there have been no attempts to estimate range-wide abundance. This subspecies was thought to occupy a near contiguous range across southern Mississippi, Louisiana and east Texas but is now restricted to three isolated areas in Louisiana. In 1964, Louisiana initiated a restocking program in which black bears from Minnesota were introduced into two of these areas. It is not clear how the additions affected population structure or if substantial breeding occurred between native and introduced bears. Using baited sites to snare hair samples, and microsatellite DNA analysis to distinguish individuals, we estimated abundance of two geographically isolated bear populations in south central Louisiana: Inland and Coastal. Additionally, we examined genetic variation both within and between the two populations. Mark recapture analysis of the distribution of individual captures during two primary sampling periods resulted in population estimates of 77 +/- 9 for Coastal and 41 +/- 6 for Inland. Genetic analysis revealed significant population differentiation ($F_{ST} = 0.206$) between the two populations. The apparently smaller Inland population exhibited more diversity than the Coastal, which suggests that the genetic structure of the Inland population has been influenced by the reintroduction. Both of these populations are isolated and face considerable demographic and genetic threats, thus conservation measures to protect both are warranted. However, the Coastal population is more representative of Louisiana black bears prior to reintroduction and special consideration should be

given to insure its integrity.

1214: +.144

British *S. vulgaris* are classified as a separate subspecies, *S. v leucourus*, to mainland Europe. While *S. vulgaris* is not under threat across most of its Eurasian range, in Britain, Ireland and Italy populations are declining, mainly due to the introduction of the American grey squirrel (*S. carolinensis*). In this study, we conducted an extensive survey of mitochondrial DNA variation in British *S. vulgaris* populations and a preliminary survey of continental European populations. Our main aims were to determine the extent to which any populations of *S. vulgaris* in Britain are partially or wholly the product of artificial translocation of red squirrels from continental Europe, and whether continental population variation will provide information on post-glacial reforestation patterns in Europe. We found that the majority of extant populations of British *S. vulgaris* are of continental ancestry, many with a very recent (last 40 years) Scandinavian ancestry. The Scandinavian haplotype has rapidly become the most dominant in northeastern Britain, despite not appearing in northern English populations until 1966. This suggests that these squirrels may have an adaptive advantage in the non-native spruce dominated conifer plantations of northern England. Our preliminary examination of continental populations demonstrated that they are sufficiently differentiated to allow a phylogeographic study of this species.

1215: +.022

The translocation of individuals from one population to another is a common technique in wildlife conservation. However, the outcome of translocation programs is not always properly evaluated and the relative contribution of released individuals to the resident population often remains unknown. We used mitochondrial DNA and autosomal genetic markers to evaluate the success of a translocation program of Eurasian otters (*Lutra lutra*) in Sweden. The program is regarded as successful because of subsequent population growths. Norwegian otters used for the restocking program could be genetically differentiated from Swedish otters. The releases took place at two sites. In an area south of the first site, where 47 otters were released, no genetic contribution of the introduced animals to the population could be observed and the genetic diversity was lower than before the releases. At the second site, the release of seven otters led to a change in genetic composition of the resident population. The results of this study suggest that the growth of the otter population after the restocking may not be as dependent on the releases as initially suspected. The genetic effects of the translocations appear to be restricted to areas in the immediate vicinity of the release sites.

1216: +.213

Genetic factors influence the population viability of rare species, yet the fitness consequences of inbred and outbred progeny are seldom tested empirically in reintroduction strategies designed for species recovery or habitat restoration. Rare and endangered plants of *Silene* (Caryophyllaceae) occur on four continents, including North America. In Oregon, inbred and outbred progeny were monitored for three years after experimental reintroduction of a narrow endemic, *S. douglasii* var. *oraria*, into formerly grazed habitat within its presumed historical range. Survival and reproduction were compared for progeny that were derived from the seeds of self-versus cross-pollinated flowers produced in situ at Cascade Head, a UNESCO Biosphere Reserve where the largest of three extant populations occurs. Progeny of cross-pollinated flowers had significantly greater field survival in all years than did offspring of selfed or open-pollinated flowers ($P < 0.01$). Outbred progeny also significantly exceeded other treatment cohorts in canopy area, and produced more

reproductive stems and flowers than other progeny types of the same maternity. For plots varying in plant density, mortality was greatest in the high-density competitive regime but the survivors reached significantly larger sizes and reproductive capacities than in low density plots ($P < 0.05$). In all, successful conservation plans involving reintroduction may require genetically diverse progeny to offset inbreeding depression as well as suitable planting densities and source populations.

1217: +.079

The Chihuahuan Desert Ecoregion (CDE), located in the central and northern regions of Mexico, and in southern Arizona and New Mexico and west Texas in the United States, comprises desert and semi-desert regions among the most biologically diverse in the world. CDE reptile and amphibian biodiversity alone consists of approximately 217 species. Many factors (e.g., habitat destruction) affect amphibian and reptile populations in the CDE. Though collection for the commercial trade may impact these populations, the magnitude of this impact has not been thoroughly investigated and is poorly understood. The objectives of this report are to: present information gathered on collection, trade, and regulation of the amphibians and reptiles of the CDE; assess the current and potential impacts of collection and trade; evaluate the effectiveness of existing regulations; and make recommendations regarding the steps needed to ensure that collection and trade are sustainable and do not pose a significant threat to CDE reptile and amphibian populations. Mexico Reptiles have long played an important role in the lives of native Mexican people, as a source of food, clothing, arts and crafts manufacture, traditional medicine, and other uses. The diversity of the Mexican CDE herpetofauna is among the highest in all desert ecoregions, with more than 130 reptile species known to exist in the Chihuahuan Desert. Mexico's legal framework includes laws, regulations, norms, international agreements, national plans, and governmental dispositions, all of which are used to promote the protection and sustainable use of Mexico's natural resources, including its native reptiles. With limited exceptions - primarily involving noncommercial, scientific use - Mexico prohibits the export of native reptiles and amphibians, and all legal shipments must be accompanied by a permit. In addition to this legal regime, there are five protected areas in the CDE in Mexico, including the Cuatro Ciénegas Area for the Protection of Flora and Fauna, the Canon de Santa Elena Area for the Protection of Flora and Fauna, the Mapim Biosphere Reserve, the Maderas del Carmen Area for the Protection of Flora and Fauna, and the Sierra Gorda Biosphere Reserve. These protected areas cover in excess of 1 million hectares. Though there is some targeted hunting of reptiles, especially for more commercially valuable species such as rattlesnakes and Bolson tortoises, collecting is frequently opportunistic. Domestic demand for pet reptiles has increased in the recent past, and there is an established trade in markets and some pet stores within Mexico. Some of this trade is common in established markets, where other pet animals such as aquarium fishes or songbirds are offered; however, the numerous street markets in major urban centers as well as at some busy crossroads and stretches of road also act as selling points. Most of this trade is targeted at nationals seeking personal pets or for resale in established businesses. At least 82 species, or approximately 63% of the approximately 130 reptile species found in the Mexico portion of the CDE, are subject to some kind of trade. Most of this trade is targeted at demand for pets, followed by demands for meat, skins, and traditional medicine. Of the 82 species identified in domestic or international trade, 6 are listed in Appendix I or II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), 4 are classified as Threatened by IUCN-the World Conservation Union (2002), and 51 in the NOM 059 ECOL 2001. Seventeen of the 82 species are endemic to Mexico. Rattlesnakes, used for skins, rattles, meat, fat, venom, and as live animals, are the most commonly traded Chihuahuan Desert reptiles. Several reptile species, including Bolson tortoises *Gopherus flavomarginatus*, Coahuilan box turtle *Terrapene coahuila* and black spiny softshells

Apalone ater, may be particularly threatened due to their population status. Five main distribution and trade centers for CDE reptile species were identified in three major areas, including: Plateros Magical/Religious Center, Zacatecas; Charco Cercado, San Luis Potos; three Mexico City Marketplaces (the Mercado de Sonora, the Mercado Nuevo San Lazaro, and the Mercado Emilio Carranza). Virtually all of the trade in reptiles and amphibians in these distribution and trade centers is illegal. There is also an international, illegal trade in Mexican reptiles and reptile products, primarily to the United States. Because Mexican law generally prohibits the export of native reptiles, virtually all export of live reptiles, reptile parts, and products from Mexico is illegal. However, the offer for sale of numerous CDE reptile species endemic to Mexico by reptile dealers outside of Mexico, especially in the United States, indicates that illegal exports are taking place. Although many of these species are now bred in captivity within the United States, the original founder stock was likely exported illegally from Mexico. Also, there are frequent seizures of live reptiles, as well as parts and products, at the U.S./Mexico border. However, neither of these information sources gives a clear picture of the extent of exports from Mexico. Demand for live rattlesnakes, skins, and parts for use in traditional medicine appears to have led to significant population reductions in some areas, such as Plateros, Zacatecas. However, basic biological information on most CDE reptile species is scarce, making it difficult to evaluate the impact of collection and trade on wild populations. This is compounded by the fact that these species face other threats in many areas, such as habitat loss by deforestation, agriculture, overgrazing, exotic species introduction, pollution, and watershed depletion. To ensure that collection and trade are not a threat to CDE reptile species in Mexico, TRAFFIC recommends the following:

Enforcement:

1. Enforcement programs, which involve frequent inspections of important trade centers, should be enhanced to provide a more effective deterrent to illegal trade activities.
2. Wildlife inspector numbers should be increased and specific training provided (e.g., species identification, reptile handling, etc.) to ensure more effective regulation of the large-scale trade in reptiles and other wildlife.
3. Long-term investigations of reptile traffic networks, from their natural collecting areas to their final sale, are needed to fully understand the extent and impacts of this trade.
4. Protocols for disposing of confiscated wildlife, products, and byproducts, emphasizing the proper maintenance and handling of live specimens, including the creation of centers devoted to dealing with live confiscated wildlife, should be developed as a priority.

Management:

5. The UMA (Unidad para la Conservacion, Manejo y Aprovechamiento Sustentable) system should be assessed to determine whether sufficient controls and monitoring mechanisms are in place. If so, the system should be promoted, especially with regard to captive production of reptiles. These efforts should focus on threatened species that are in significant demand for pets or other uses. Other UMA efforts might include exhibits, ecotourism, and reintroduction programs.
6. Expanded knowledge of the biology and size of the populations of these species is imperative, especially for threatened and heavily collected species.
7. Standardized gathering and reporting of wildlife collection and trade information (investigations, seizures, repatriations, prosecutions, etc.) and greater facilitation of information exchange and consultation among government offices and other parties are greatly needed.
8. Rehabilitation and release programs for seized animals, based on scientific data on the biology and distribution of each species, taking into account the potential for disease, genetic pollution, and other risks to wild populations, should be developed.

Education:

9. Environmental education programs focusing on local communities should be developed, to increase awareness of Mexican laws and promote the value of these communities' natural resources.

United States of America Though dozens of reptile and amphibian species are exploited throughout the United States, little is known about the extent of these activities or their impacts on wild populations. This is particularly true for the large number of small lizards and snakes such as those found in the CDE. The collection and sale of reptiles and amphibians in the United States is generally regulated at the state level. For CDE species, the wildlife legislation and regulations of New Mexico, Arizona, and Texas are applicable

to activities involving reptiles and amphibians in each of those jurisdictions. Federal legislation and regulations generally apply to federally protected species, activities on federal lands, and interstate and international commerce. The domestic trade in amphibians and reptiles from the CDE is almost impossible to quantify, because take of most species is not regulated in New Mexico, trade from Arizona is illegal, and Texas has only recently begun gathering data from collectors. There is no reason to believe that large numbers of animals from Arizona are commercialized. Commercialization does occur in New Mexico, but there was no current information available at the time of this study. Information on collection and sale of nongame species was available from Texas for 1999. In Texas during 1999, 14 351 specimens of reptiles and amphibians were reported to be collected by 53 Resident or Nonresident nongame permit holders. Of these, 4861 were amphibians and 9493 were reptiles. These numbers do not include rattlesnakes collected for rattlesnake roundups, and thus the overall figure is likely to be much higher. Ninety percent of all specimens collected in the CDE in Texas in 1999 originated in only five counties, with the top eight collectors accounting for 90.3% of the total harvest. Available data indicate that the number of snakes removed from the wild is not extraordinary. In 1999, the Texas Parks and Wildlife Department (TPWD) nongame database showed that 985 snakes were collected in the CDE. Of these, 325 were garter snakes *Thamnophis* spp. and 307 were rattlesnakes *Crotalus* spp. Seventy-three kingsnakes were collected (all species of *Lampropeltis*); 42 were gray-banded kingsnakes. Thirty-two ratsnakes *Elaphe* spp. and 48 Trans-Pecos ratsnakes *Bogertophis subocularis* were reported collected by nongame permit holders. Several other species were collected in smaller numbers. International trade in reptiles from the CDE in the United States is difficult to assess, due to a number of factors. Though some data are available from the U.S. Fish and Wildlife Service (USFWS), these data raise as many questions as they provide answers, largely because the data collected by the USFWS are often not species-specific, do not include any locality information, and frequently don't indicate the origin (wild-caught or captive-bred) of the animals. Despite these limitations, USFWS data are of some value in an analysis of CDE species trade. A thorough review of U.S. export data showed that there are approximately 50 reptile species found at least in part in the CDE that appear to be involved in international trade. The export of turtle species found in the CDE likely involves few, if any, turtles actually collected from the CDE. For example, the export of red-eared sliders almost exclusively involves turtles produced on farms in Louisiana and elsewhere in the southeastern United States. The same is true for the export of most other turtle species found in trade. The export of live CDE snake and lizard species does not appear to be a significant concern. Most species are apparently being exported in small numbers, and at least some of these species are being produced in captivity, with little indication of increasing trade throughout the time period examined. A review of USFWS data showed that at least seven species found in the CDE are traded as parts or products. Though the export of native CDE species as parts or products involves far fewer species than are involved in the live trade, this practice may be having a far greater impact on individual species because the trade in parts and products is more likely to involve wild-caught adult animals. Of some concern is the exploitation of several venomous reptile species for meat, skins, and leather products. This is especially true of the Western diamond-backed rattlesnake, which is exported in a large array of forms. The most significant trade in this species appears to be meat, with well over 2000 kilograms of meat exported over the six-year period examined. A significant volume of skins and skin products was also exported during this period, including 1616 skins, 712 shoes/boots, 1407 small leather products/skin pieces/leather trim, 34 handbags, 79 garments, 939 pieces of jewelry, and 753 unspecified items. Based on the lack of field studies and monitoring data on the trade in reptiles and amphibians, it is not possible to draw definite conclusions about the threats posed by collection and trade. However, based on life history pattern, geographic extent of range, and detectability, it is likely that the vast majority of reptile and amphibian species found in the CDE are widely enough distributed that collecting will not lead to regional or global species extinction. Almost all

amphibian and reptile collecting is done from roads or inaccessible canyons. Enormous areas are on private land or so remote that collecting for trade is inefficient, and there are extensive areas of suitable and occupied habitat that are never collected. Collecting and trade in the CDE probably should not be considered a threat to species that are relatively widely and continuously distributed, are small in size, and that possess a life history characterized by relatively short life span and high reproductive rate. The seven most collected species from the CDE in Texas in 1998-99 accounted for 79% of all species collected. It is impossible to evaluate quantitatively the impact of collecting on the populations that were exploited without detailed information on collecting effort, geographic extent of collecting, and demographic information on the exploited populations. However, the three amphibians-tiger salamander *Ambystoma tigrinum*, Couch's spadefoot *Scaphiopus couchii*, and green toad *Bufo debilis*-are common and widely distributed. The two lizards-common sideblotched lizard *Uta stansburiana* and marbled whiptail *Cnemidophorus tigris*-are also widespread and continuous in their distributions throughout much of the CDE. *Gila* monsters *Heloderma suspectum*, turtles in general, and the prairie rattlesnake *Crotalus viridis* are species that, based on natural history, may be locally vulnerable to overcollecting. Species with fragmented ranges, such as the massasauga *Sistrurus catenatus* or Western hog-nosed snake *Heterodon nasicus*, even if the geographical extent of the range is large, may also be susceptible to local population extirpation. Because of their vulnerability and the life history characteristics of long-lived organisms, turtle populations may be eliminated from specific sites from overcollecting. The yellow mud turtle *Kinosternon flavescens* and desert box turtle *Terrapene ornata luteola* were collected in large numbers in Texas. Though both species are common and widespread, yellow mud turtles are generally found when locally concentrated in ponds, stock tanks, and playas, and desert box turtles have a low reproductive rate. It is reasonable that these and similar species could be significantly impacted by intensive collecting. The pattern of collecting in Texas indicates some generalities that are relevant to reptile and amphibian collecting throughout the region. First, few collectors account for the great majority of specimens collected. Second, few species were collected in large numbers. The species that were collected in large numbers are widespread, small bodied, and, except for amphibians and turtles, are relatively short lived. A third generalization was that collecting was very patchy, with a small number of areas being intensively collected. In Texas, the same stretches of roads that have been popular with collectors for decades continue to produce specimens, and remain the principal areas used by collectors. There are enormous expanses of habitat throughout the entire ecoregion that are not visited by collectors. Thus, given available information, collection and trade do not appear to be a significant threat for the vast majority of CDE reptile and amphibian species in the United States. However, for a select number of species with particular vulnerabilities and/or life history characteristics, over-collecting may at least be impacting local populations and bear further attention. Based on this information, TRAFFIC recommends the following: Collection and Trade Monitoring: 1. To ensure that collection and trade of CDE amphibians and reptiles is sustainable, implementation of a legally binding monitoring system of take and trade in these groups is needed. Such a monitoring system must be based on the legal status of amphibians and reptiles and rules regulating their take. Such systems have been implemented in Texas and New Mexico and have provided valuable information on the trade of amphibians and reptiles in the state. Field Research: 2. It is not often feasible to census amphibian and reptile species directly because of the large geographic areas involved, the time and expense required to measure these populations, and the inherent difficulties in measuring amphibian and reptile populations with confidence. Instead, targeted research should be aimed at producing sufficient information about collecting amphibians and reptiles to guide management decisions. 3. Information is needed on the amount of suitable habitat available for species with relatively small distributions and that require very specific habitat types in relation to the amount of area where they are collected. 4. Research on source-sink phenomena in exploited amphibians and reptiles would be useful, and has yet to be

conducted for any exploited amphibian or reptile. Information on source-sink dynamics of selected species may clarify whether populations are self-sustaining, or to what extent habitat corridors and large uncollected areas are needed to sustain populations of exploited populations on a regional basis

1218: -.057

In the article there are written the results of works with population of bitterling that are in danger of extinction. That populations used to live in reservoir that emerged as a result of the clay exploitation, than were moved to another reservoir that was the result of the clay and the sand exploitation. After four years there was affirmed a full success of introduction to the reservoir in Szejkwice (that emerged as a result of the clay exploitation) and to the reservoir in Rogoznik (emerged as a result of the sand exploitation). Owing to the acid water that was input to the reservoir near Rudy, there was determined the extinction of the populations of bitterling and bivalves. All works were led by consent of Department of Environment, financed and inspected by Provincial Nature Conservator.

1220: +.389

The aim of this roundtable session was to discuss reintroduction of native crayfish and habitat restoration providing practical recommendations of value to environmental authorities, decision makers and local managers. A (re)introduction may be appropriate: a) to reintroduce a population recently lost, b) to extend the distribution of an ICS into historic range and c) to create new or isolated populations to conserve genetic diversity or the species. Before (re)introduction it is imperative to demonstrate the probability that the receptor locality is empty of crayfish, to know the reason for crayfish extinction, and that the reason is removed before restocking. Before restocking, the receptor locality should also be assessed for crayfish suitability, including: water type and chemistry, physical conditions (shelter), presence of crayfish plague, risk of NICS, predatory fish. In general, major constraints in a restocking project is money and availability of stocking material. General recommendations: a) if have abundant/readily available and acceptable donor population use adults and young/juveniles as available, b) if short of stock boost with hatchery rearing, and c) if want population quickly, stock as many as can afford and several times. Trade offs: time vs. cost. Genetic distinctiveness/possible spread of diseases must be considered. In general, the preferential ranking is donor from: 1) same watercourse, 2) same catchment, 3) adjacent catchment or one nearby in the same biogeographic region for crayfish, and 4) any other catchment. Habitat restoration can be a valuable action, and should be prioritised to: 1) give greatest overall benefit to the ecosystem, 2) benefit ICS and 3) be achievable and cost effective. Natural characteristics of waterbodies in local area should be considered. A key factor in the protection of ICS populations is the knowledge and attitude of local people. Objectives and actions should be agreed with local stakeholders to improve chances of success.

1221: +.044

Conservation of the endangered noble crayfish (*Astacus astacus*) requires preservation of existing populations and reintroduction into suitable habitats, as currently underway in several regional projects in Germany and Poland. Therefore, knowledge about the genetic variation between populations is vital but, unfortunately, still restricted. By means of ISSR-PCR (Inter-Simple Sequence Repeats - Polymerase Chain Reaction) eight stocks in Germany and Poland were analysed. These semi-arbitrary multiloci markers had not previously been used in population studies of the noble crayfish. A total of 22 unambiguous and polymorphic markers were detected

to use in the subsequent statistical analysis. The number of polymorphic loci in one population ranged from 4 to 19. Therefore the ISSR markers proved suitable for assessing within- and between-population DNA variations and establishing significant separation of most of the stocks. Shannon's Index, a relative estimate of genetic diversity within populations, ranged from 0.06 to 0.51. UPGMA cluster analysis based on pairwise ROGERS' (1972) genetic distance revealed two main clusters corresponding to populations sampled in the western and eastern part of the study area. Results are relevant on the local, regional and supra-regional (landscape) level. The implications for conservational management and restocking programs are presented.

1222: +.216

The Glomma and Halden watercourses in Norway were hit by crayfish plague in 1987 and 1989. Reintroduction of the noble crayfish started in 1989 in the Glomma and in 1995 in the Halden watercourse. Norway has especially good conditions for reintroduction of the native crayfish after crayfish plague, as there is no alien plague-carrying crayfish species in the country. In the Glomma watercourse, approx. 15 000 adult crayfish and 10 000 juveniles have been stocked while in the Halden watercourse the figures are 19 000 adults and 26 500 juveniles. All stocking sites were previously regarded as very good crayfish localities. Four years after stocking, natural recruitment was recorded at all adult crayfish stocking sites in the Glomma watercourse and at most sites in the Halden watercourse. Current crayfish density is, however, much lower than pre-plague densities even at the sites where population development has been in progress for more than 10 years. Extensive post-stocking movements were recorded among adult crayfish. Some sites seemed more suitable for settling, resulting in a great variation in CPUE between the different test-fishing sites. Juveniles seem more appropriate as stocking material if the goal is to re-establish a population in a particular area, due to their stationary behaviour, which seems to remain as they grow larger.

1223: +.163

In Tyrolean like in other European freshwaters, crayfish populations decreased in numbers and qualities. They are today regarded as endangered animals. The *Astacus astacus* (Linnaeus, 1758) population of historical evidence in Tristacher See and its out flowing stream Tristacher Seebach (mentioned already by Emperor Maximilian I in 1504) became extinct in the late 1990s. After the restoration of the stream we started a species conservation programme with various specific protection measures, including breeding and restocking of young-of-the-year and adult *A. astacus*. Females, after having released their young in the hatchery, were stocked together with males in a 200-m-section of Tristacher Seebach, previously populated by *A. astacus*. In October, the young-of-the-year crayfish were released in another area of the same stream. To show the importance of habitat diversity and shelter, four sites for introduction were selected describing a gradient of habitat diversity. We monitored general characteristics of the population (sex, size, densities) and compared them to habitat conditions. Individual crayfish were tagged with gloss-paint pens to allow an observation of their movements between the different sections over the summer months. We found significant results when migration behaviour, population assemblage and habitat conditions were compared. Males frequently moved longer distances than females. Migration length corresponded to the gradient of available structures and shelter. Heterogeneous riprap was somewhat preferred to artificial shelter like bricks or plastic tubes. Sections without additional shelter showed almost no presence of crayfish. Sex and size distribution within assemblages appeared also to be affected by habitat conditions. Our results indicate the importance of monitoring in species reintroduction projects, as this research demonstrated the immediate effect and importance of habitat structure and affirmed the success of the protection measures. This may in fact help to avoid future failure.

1225: +.090

In December 1998, Alsace knows the first French reintroduction of Otter *Lutra Lutra*. Six individuals from the Breeding Centre of Hunawihr were released over one three years period. The territorial evolution of four otters is followed-up daily during an average of 269 days thanks to the radio-tracking. From September 2000, only signs of presence make it possible to monitor the population. Signs of breeding were probably discovered in 2000 and 2001. A study of the diet was engaged between April 2002 and March 2003. It shows the perfect opportunism of otters coming from captivity and consuming preys available which vary in quantity and quality among seasons. Fishes constitute 98% of the diet. The Cyprinidae are preferred in autumn and winter and then are replaced in spring and summer by the Cottidae, the Cobitidae and the Salmonidae. Today, not less than 130 km of rivers are occupied by offers. Nevertheless, since the end of the year 2001, the experiment is stopped because of genetic "incompatibility" between captive and wild populations of otters which penalizes the total success of the project and the stability of the species in Alsace.

1226: +.053

Wolf management can be controversial, reflecting a wide range of public attitudes. We analyzed wolf management case histories representing a spectrum of approaches in Canada and the United States. During the early 20th century, wolves were considered undesirable. They were subject to persecution and were extirpated from large areas of their original range. With increased environmental awareness in the 1970s, attitudes toward wolves began to change. Wolf conservation became a focus of public interest, providing conditions that favored regional wolf recovery. However, in regions where livestock production or big-game hunting is valued, wolves have continued to be controlled by management authorities or through the actions of individual

citizens. With US wolf populations recovering in the conterminous states, a rule was approved to delist the species from endangered to threatened status under the Endangered Species Act. Notwithstanding the intent of legal instruments, history has demonstrated that societal values ultimately determine the survival of species such as the wolf.

1227: +.001

Long-term maintenance of captive populations followed by release of captive animals into the wild is one of many approaches to endangered species conservation. To assess captivity's effects on behavior, a simulated predator was presented and response behaviors measured in oldfield mice, *Peromyscus polionotus subgriseus*. The animals tested were from four populations collected from Ocala National Forest, Florida, and held in captivity for varying numbers of generations: 35, 14, 2, and 0 (wild caught). Results show (1) that the more generations a population has been in captivity, the less likely an individual is to take cover after seeing a predator and (2) variance in predator-response behaviors increases with generations in captivity. These results point to two ways in which captivity can compromise animal behavior and, in turn, the success of reintroduction programs. First, because individuals from populations that have been in captivity for multiple generations seek refuge less often than their wild counterparts, they might experience increased mortality in the wild due to predation. Second, increased behavioral variance could translate into decreased survivorship upon reintroduction. Therefore, more individuals will need to be released to reach the targeted wild population size. 1228: +.007

We present a spatially explicit population model for analysing the expansion of brown bears (*Ursus arctos*) after the reintroduction program in central Austria. The model is based on field investigations into brown bears in Austria and Slovenia and on current knowledge of brown bears. The landscape of the eastern Alps is represented by a GIS-derived raster map defining local habitat suitability and five major spatial barriers to dispersal. The population model follows the fate of individual bears and simulates reproduction, dispersal, home range establishment, and mortality in annual time steps. We indirectly adjust unknown or uncertain model parameters with 10-year data on the number of females with cubs in central Austria and determine key variables of population dynamics, such as population sizes and growth rates within different population nuclei, dispersal distances, or mortality rates, for model parameterisations that reproduce the data on females with cubs. We estimated a current (1996 - 2000) growth rate of the population in Austria and adjacent parts of Italy of some 14%; a high proportion of this growth was due to immigration from Slovenia. Consequently, the growth rate of the subpopulation in central Austria, which probably is isolated functionally (i.e., no exchange of females) from the nuclei along the Austrian - Slovenian border, yielded some 7%. This subpopulation may comprise seven residents, and we estimated for females a 33% risk of extinction during the 1992 - 2000 period. Validation and confirmation of our model results with data on bear densities that were not used for model construction and parameterisation supported our findings. The high female mortality rates, together with the vulnerability of the small population to chance events (i.e., demographic stochasticity), are the most pressing threat for the population in the eastern Alps. Our approach could be widely applied for analysing dynamics of rare and endangered species in which the paucity of data precludes an appraisal of the state of the population using standard methods.

1229: +.055

It has been argued that spatially explicit population models (SEPMs) cannot provide reliable

guidance for conservation biology because of the difficulty of obtaining direct estimates for their demographic and dispersal parameters and because of error propagation. We argue that appropriate model calibration procedures can access additional sources of information, compensating the lack of direct parameter estimates. Our objective is to show how model calibration using population-level data can facilitate the construction of SEPMs that produce reliable predictions for conservation even when direct parameter estimates are inadequate. We constructed a spatially explicit and individual-based population model for the dynamics of brown bears (*Ursus arctos*) after a reintroduction program in Austria. To calibrate the model we developed a procedure that compared the simulated population dynamics with distinct features of the known population dynamics (= patterns). This procedure detected model parameterizations that did not reproduce the known dynamics. Global sensitivity analysis of the uncalibrated model revealed high uncertainty in most model predictions due to large parameter uncertainties (coefficients of variation CV approximate to 0.8). However, the calibrated model yielded predictions with considerably reduced uncertainty (CV approximate to 0.2). A pattern or a combination of various patterns that embed information on the entire model dynamics can reduce the uncertainty in model predictions, and the application of different patterns with high information content yields the same model predictions. In contrast, a pattern that does not embed information on the entire population dynamics (e.g., bear observations taken from sub-areas of the study area) does not reduce uncertainty in model predictions. Because population-level data for defining (multiple) patterns are often available, our approach could be applied widely.

1230: +.059

Myrica rivas-martinezii A. Santos and *Sideritis discolor* Bolle, two endangered endemic species of the laurel forest from the Canary Islands, were studied by using RAPD markers with the goal of assessing their within- and among-population apportionment of genetic variability. Ten and 11 oligonucleotide primers assayed in three populations of each of *M. rivas-martinezii* and *S. discolor* resulted in 32 molecular markers in the former species and 49 in the latter (90.6% and 100% polymorphic, respectively). The value of the coefficient of genetic differentiation among populations was very high for *M. rivas-martinezii* ($F_{ST}=0.487$) but only moderate for *S. discolor* ($F_{ST}=0.149$). These results suggest that gene flow among populations is extremely low in *M. rivas-martinezii* and quite substantial in *S. discolor*. The UPGMA cluster obtained from Dice's coefficient mixed individuals from different populations in *S. discolor* but not in *M. rivas-martinezii*, where they were grouped by their island of occurrence. On the basis of these results and given the vulnerability of these two species, we suggest protection of all natural populations. However, if habitat conservation is not possible, our results suggest that for *S. discolor*, the La Virgen population would make a good donor population because of geographical and genetic factors. The high genetic differentiation detected among populations of *M. rivas-martinezii* suggests that each island should be considered as a distinct management unit. However, considering the situation of this species on La Palma Island with only two isolated individuals, reintroductions of germoplasm from El Hierro may be a viable way to guarantee the existence of *M. rivas-martinezii* on that island.

1231: +.117

Viola pumila Chaix is known in Italy, only in small populations growing in the Po Valley, Emilia-Romagna Region (Italy). Due to its scarce distribution and to the scarcity of populations the species is considered rare and in danger of extinction in this territory. A project of integrated in situ/ex situ conservation has, therefore, been promoted. A few hundred plants were obtained in vitro from collected wild seeds and were subsequently transplanted in natural sites in the

Novellara e Reggiolo lowlands (Province of Reggio Emilia), and in the Botanical Garden of Modena with the aim to set up a conservation collection. This project was carried out thanks to cooperation between the Botanical Garden, local Administrations and the Association of Voluntary Ecological Wardens of Reggio Emilia.

1232: +.067

The feasibility of translocation to establish a population of the eastern box turtle (*Terrapene c. carolina*) was studied at Floyd Bennett Field, Brooklyn, New York, USA. The 579 ha site, originally salt marsh, was filled during the 1920's to construct a now-abandoned airport. It consists primarily grasslands, native shrub thickets and woodlands, and mixed stands dominated by giant reed (*Phragmites australis*). These human-created uplands are managed by the U.S. National Park Service for recreation and ecological restoration. Prior to this work, the site did not support a population of this species, but it is historically native to adjacent uplands. *T. c. carolina* were collected from sites on Long Island, New York, that were undergoing development, and released after data on size, mass, age, and sex were recorded. From 1987 through 1990, 335 individuals were released into developing woodlands. To provide data on dispersal, home range establishment, and initial survival, fifty-three of these were radio-tracked for up to seven years. Though individually variable, the *T. carolina* dispersed homeward. Of the 53 radio-tagged individuals, 13 (24.6%) left the site, 25 (47.2%) established home ranges, and 15 (28.3%) died before determination of home range establishment could be made. Most individuals established home ranges within a kilometer of the release point. However, some dispersed greater distances. Of the 25 individuals that established home ranges, 17 (68%) did so in the release year, two (8%) in outyear 1, three (12%) in outyear 2 and three (12%) in outyear 3. Annual known survival over five years post-release was 71%. Though not statistically significant, annual survival was 64% over the first two years and 84% over the final three. Principal causes of "mortality" were dispersal from the site and pneumonia, both of which were greatest initially, plus winter kill, a random event. Patterns of growth, home age size, activity season, habitat use, annual reproductive output, and production of young were generally comparable to natural populations of *T. carolina*. These results suggest that translocation have potential for establishing new populations of *T. carolina*, though long term viability is still uncertain. However, any contemplated translocation would need to address the initially high loss dispersal and disease. Moreover, since there are few sites of adequate size and quality, at least 500 ha of predominantly woody habitat, lacking populations of this species, its appropriateness is limited.

1233: +.078

Using large-scale data analysis to assess life history and behavioural traits: the case of the reintroduced White stork *Ciconia ciconia* population in the Netherlands.- The White stork *Ciconia ciconia* has been the object of several successful reintroduction programmes in the last decades. As a consequence, populations have been monitored over large spatial scales. Despite these intense efforts, very few reliable estimates of life history traits are available for this species. Such general knowledge however constitutes a prerequisite for investigating the consequences of conservation measures. Using the large-scale and long-term ringing and resighting data set of White storks in the Netherlands, we investigated the variation of survival and resighting rates with age, time and previous individual resighting history, and in a second step supplementary feeding, using capture-recapture models. Providing food did not seem to affect survival directly, but may have an indirect effect via the alteration of migratory behaviour. Large-scale population monitoring is important in obtaining precise and reliable estimates of life history traits and assessing the consequences of conservation measures on these traits, which will prove useful for

managers to take adequate measures in future conservation strategies.

1234: +.269

The behavior of reintroduced, captive-born animals is understudied, limiting the scientific understanding and utility of reintroduction as a conservation tool. This work describes changes in locomotor and foraging behaviors in captive-born golden lion tamarins over the first 18 months after their release into the wild. The subjects included 73 individuals living in and around the Poco das Antas Biological Reserve in Brazil between 1984 and 1996. The differences between animals that survived 6 months after release and those that did not indicate that initial deficiencies in locomotor and foraging abilities are related to survival. Behavioral changes in both juvenile and adult individuals during the first 6 and 18 months after release appear to be primarily related to locomotor abilities; however, the effect of provisioning on foraging abilities is unknown. Juvenile animals showed a larger number of changes relative to adults during the first 6 and 18 months, suggesting that placing tamarins into complex environments early in development may promote the expression of natural behaviors and increase survival opportunities after their release. However, when this is not possible, the best mechanism for reintroducing adult members of this species involves intensive post-release support rather than pre-release training, which confers few behavioral advantages. Recommendations for future reintroductions with this and other species include introducing animals to complex environments early in development, and collecting data systematically. (C) 2004 Wiley-Liss, Inc.

1235: +.209

This thesis deals with the nature conservation of reptiles and amphibians in the Netherlands, the present practices and what should be done to improve them. Most of the species of the herpetofauna, as these groups together are known, are in a state of continuing decline. Obviously something is wrong; apart from the role played in this decline by loss of habitat, measures in the field are not effective for the sustainable survival of these species. This thesis has been written to rectify this; based on current knowledge of the ecology of these protected animals and on own experiences with nature management, it is meant to provide a guide and practical tool when carrying out the appropriate measures in the field. The introduction describes work that has been done internationally, especially at European level, to protect the herpetofauna. Further, how this has influenced policy plans and legislation in the Netherlands. It also points out the shortcomings, both in the approach of the policymakers, as well as in the current training of nature managers, and how these are reflected by the measures taken in the field. This information provides a background for chapter 7, the last chapter of this thesis, where the practice of management is discussed. The remaining chapters include five articles on ecological research; they also show how much time is needed to improve our knowledge on the ecology of these animals. Also, not understanding it can unwittingly create marginal conditions for a species, as was the case for the Slow-worm and Sand Lizard with the forest management on the Utrechtse Heuvelrug in the 1980s; this is described in the first two articles. That long-term surveys of population dynamics are more than necessary, is shown by the great fluctuations in the presence and activity of the European tree frog over the six years it was studied in the southwest of the Netherlands. Methodology is also discussed in this third article, and a practical formula given for estimating population size. Pond characteristics form the subject of the next article, wherein statistical analysis illustrates how they can indicate the possible presence and therefore the suitability of a pond for amphibians. Practical indications are given, useful when constructing new ponds as part of the Pond Action Plans. The last article has implications for the reintroduction of species into new or former habitats. That there is phenotypic variation within species of amphibians occurring within 200 kilometres of each other, shows that,

to avoid failure, this should be taken into account in the selection both of the source population and the location of the habitat into which the animals are to be introduced. All these aspects are brought together in the final chapter where the practice of the conservation of both groups is discussed in turn. The habitats are the point of departure, and it is shown how conservation measures with plants or landscapes in mind can bring about deterioration or loss of habitat for a particular species of reptile or amphibian. The integration of management goals should be the approach for as far as is possible, but legal obligations may force us to take species specific measures into account for herpetofauna. Heathlands are of utmost importance for reptiles and the most relevant features of the management for this type of habitat are highlighted. For their part, amphibians find their major aquatic habitat in ponds. Details are given of the management for various amphibian species, both in ponds, and as far as we know it, in their habitat on land. The extensive literature on these subjects, found at the end of Chapters 1 and 7, as well as that of the articles, provides opportunity for going further into depth. The recommendations from Chapter 7, dealing with the structure of the vegetation to a considerable extent, should improve the situation of the herpetofauna in the Netherlands.

1236: +.260

Limited data indicate that Shiras moose (*Alces alces shirasi*) occurred in low numbers in Idaho throughout the 19th century. Harvest was allowed in Idaho during 1893-1898, after which seasons were closed. Shiras moose were fully protected in Idaho from 1899-1945. Moose populations increased during the 20th century and harvest seasons resumed in 1946. Harvest has focused on mature males, allowing continued population growth through the end of the 20th century. Rapid population growth during 1980-2000 resulted in moose dispersing westward from the Rocky Mountains and southward from the Panhandle region of Idaho. The management goal for moose in Idaho is to provide opportunities for recreational hunting and harvest of mature male moose. Although some managers assess moose populations directly by aerial survey, most managers rely on indirect measurements (e.g., hunter success rate and antler spread of bulls harvested) to assess the impact of harvest on moose populations. Other population indicators (e.g., dispersal into previously unoccupied areas, damage to private property) have been used as indicators of social tolerance for expanding moose populations. Where moose have approached the limit of social tolerance, attempts to stabilize or reduce populations by harvest of females and translocation of 'problem' moose have been utilized. Both a historic perspective of moose abundance and a revised statewide population estimate are provided.

1237: +.267

This 344-page book is part of a series on Iguanas: Biology and Conservation. The book is divided into 3 parts, which are further divided into 20 individually authored chapters. The first part deals with diversity, which further includes the evolution of iguanas: an overview of relationships and a checklist of species, genetic contribution to Caribbean iguana conservation, genetic structure of the turks and caicos rock iguana and its implications for species conservation, and sodium and potassium secretion by iguana salt glands: acclimation or adaptation. The second part deals with behavior and ecology, which further includes behavior and ecology of rock iguanas, evidence for an appeasement display and population differences. The third part deals with conservation, which further includes translocation strategies as a conservation tool for west Indian iguanas: evaluations and recommendations, and ecotourism and its potential impact on iguana conservation in a Caribbean. Remaining chapters include determinants of lek mating success in male galapagos marine iguanas: behavior, body size, condition, ornamentation, ectoparasite load, and female choice. The book highlights a list of contributors and their respective institutions. Each chapter

contains a list of references. The text is written in English. Users of this book will include zoologists, conservationists, and ecologists.

1239: +.128

Severe bottlenecks can reduce genetic diversity and increase inbreeding as individuals are forced to mate with close relatives, but it is unknown at what minimum population size the negative fitness consequences of bottlenecks are expressed. The New Zealand avifauna contains a large number of species that have gone through bottlenecks of varying severity, providing an exceptional opportunity to test this question by using the comparative method. Using decreased hatchability as a measure of fitness costs, we found that hatching failure was significantly greater among both native and introduced species that had passed through bottlenecks of <150 individuals. Comparisons between pre- and postbottleneck populations of introduced species suggest that hatching problems arise even in populations founded by <600 individuals. Our study confirms that hatching failure is widespread and persistent among birds passing through severe bottlenecks and that the population sizes at which this fitness cost is expressed are several times greater than the number of individuals currently used to found most new populations of endangered species. We recommend that conservation managers revise the protocols they use for reintroductions or they may unwittingly reduce the long-term viability of the species they are trying to save.

1240: +.121

Fishes listed under the U.S. Endangered Species Act receive intensive management, but evaluations of population characteristics are rare. We report population and habitat characteristics of federally threatened greenback cutthroat trout *Oncorhynchus clarki stomias* in 12 streams in north-central Colorado surveyed in 1998 and 1999. Our objectives were to assess population size, structure, and distribution, to evaluate a model developed by Harig and Fausch (2002) to assess translocation success, and to compare population characteristics to those reported in the recovery plan. Allopatric population sizes in 10 streams varied from 170 to 7,347 greenback cutthroat trout at least 75 mm long, whereas the 2 streams with brook trout throughout supported 0-142 greenback cutthroat trout. Populations displayed few upstream-downstream trends in fish abundance or mean length, and the coefficient of variation among sampled reaches within streams averaged 61%. As the density of fish at least 75 mm long increased, the percentage of juvenile (<75 mm) fish in a population increased, the percentage of adult (>125 mm) fish longer than 200 mm decreased, and the average weight of a 200-mm fish declined. The abundance of juvenile fish was positively correlated with summer water temperature. Population estimates were highly correlated with the translocation model index values, suggesting that the translocation model may apply to other cutthroat trout taxa in similar environments. Of the 12 streams for which our extensive field data are available, 4 satisfied the recovery criteria we studied and other criteria in the recovery plan; 8 did not. We conclude that many populations of greenback cutthroat trout, including some that meet recovery criteria, are still at risk of extinction and that a reliable monitoring protocol needs to be established.

1241: +.109

A single stocking of 611 wild flannelmouth suckers *Catostomus latipinnis* in 1976 represented the first successful reintroduction of a native fish in the lower Colorado River. Flannelmouth suckers ranging in age from young of the year to 24 years were captured during 1999-2001; their population was estimated as at least 2,286 (95% confidence interval, 1,847-2,998). Recruitment

appeared sporadic, consisting of consecutive years of low recruitment (<10%) supplemented by a stronger (31%) year-class. Historically, this native fish was rare and was believed extirpated from the lower river by 1975, but it now reproduces naturally in a reach dramatically altered by water development. This successful reintroduction indicates that one native fish can successfully tolerate environmental alterations whereas another, the razorback sucker *Xyrauchen texanus*, apparently cannot. Other opportunities may exist in altered rivers to benefit native fishes where they were absent or historically rare.

1242: +.034

Bearded vulture populations in the Western Palearctic have experienced a severe decline during the last two centuries that has led to the near extinction of the species in Europe. In this study we analyse the sequence variation at the mitochondrial control region throughout the species range to infer its recent evolutionary history and to evaluate the current genetic status of the species. This study became possible through the extensive use of museum specimens to study populations now extinct. Phylogenetic analysis revealed the existence of two divergent mitochondrial lineages, lineage A occurring mainly in Western European populations and lineage B in African, Eastern European and Central Asian populations. The relative frequencies of haplotypes belonging to each lineage in the different populations show a steep East-West clinal distribution with maximal mixture of the two lineages in the Alps and Greece populations. A genealogical signature for population growth was found for lineage B, but not for lineage A; furthermore the Clade B haplotypes in western populations and clade A haplotypes in eastern populations are recently derived, as revealed by their peripheral location in median-joining haplotype networks. This phylogeographical pattern suggests allopatric differentiation of the two lineages in separate Mediterranean and African or Asian glacial refugia, followed by range expansion from the latter leading to two secondary contact suture zones in Central Europe and North Africa. High levels of among-population differentiation were observed, although these were not correlated with geographical distance. Due to the marked genetic structure, extinction of Central European populations in the last century resulted in the loss of a major portion of the genetic diversity of the species. We also found direct evidence for the effect of drift altering the genetic composition of the remnant Pyrenean population after the demographic bottleneck of the last century. Our results argue for the management of the species as a single population, given the apparent ecological exchangeability of extant stocks, and support the ongoing reintroduction of mixed ancestry birds in the Alps and planned reintroductions in Southern Spain.

1243: +.013

Two new species of ricefishes or buntingi, *Adrianichthys roseni* and *Oryzias nebulosus*, are described from Lake Poso, Sulawesi Tengah, Indonesia, bringing to 12 the number of endemic ricefishes known from Sulawesi. *Adrianichthys roseni* and its sole congener, *A. kruyti*, are distinguished from other relatively large-bodied ricefishes, *Xenopoecilus*, in having orbits that project beyond the dorsal profile of the head; paired preethmoid cartilages (versus single or absent in *Xenopoecilus*); and 13-16 (versus 8-13) dorsal fin rays. Also, as in *A. kruyti*, the lower jaw of *A. roseni* is enclosed in the upper jaw when the mouth is closed; however, the upper jaw is not as large and broadly expanded as in *A. kruyti*. *Adrianichthys roseni* differs further from *A. kruyti* in having fewer scales in a lateral series (approximately 63-65 versus 70-75), attaining a smaller maximum recorded standard length (90 mm versus 109 mm), and having the lateral process of the pelvic bone in line with the fifth, rather than the eighth, pleural rib. *Oryzias nebulosus* shares with *O. nigrimas*, also from Lake Poso, a unique sexual dichromatism in preserved specimens: adult males are dark gray to black, whereas females are a lighter grayish-yellow to brown. Relative to

O. nigrimas, *O. nebulosus* is a small species (maximum recorded SL 33 mm versus 51 mm), with pelvic fins relatively anterior (lateral process of pelvic bone is in line with the third, fourth, or fifth, modally fourth, rather than the fourth or fifth, modally fifth, pleural rib), dorsal fin relatively anterior (origin above the 12-14th anal fin ray as opposed to the 15-17th anal fin ray), precaudal vertebrae 11-13, modally 12 (versus 13-14, modally 13), and relatively straight, narrow and slender (as opposed to curved, broad, and robust) ossified and cartilaginous portions of the gill arches. Endemic buntingi are threatened by introduction of exotic species, overfishing, and pollution. A conservation plan includes rearing native fishes for local use as ornamental fishes and possible reintroduction.

1244: +.072

Comparative mapping of more than 100 region-specific clones from human chromosome 3 in Bornean and Sumatran orangutans, siamang gibbon, and Old and New World monkeys allowed us to reconstruct ancestral simian and hominoid chromosomes. A single paracentric inversion derives chromosome I of the Old World monkey *Presbytis cristata* from the simian ancestor. In the New World monkey *Callithrix geoffroyi* and siamang, the ancestor diverged on multiple chromosomes, through utilizing different breakpoints. One shared and two independent inversions derive Bornean orangutan 2 and human 3, implying that neither Bornean orangutans nor humans have conserved the ancestral chromosome form. The inversions, fissions, and translocations in the five species analyzed involve at least 14 different evolutionary breakpoints along the entire length of human 3; however, particular regions appear to be more susceptible to chromosome reshuffling. The ancestral pericentromeric region has promoted both large-scale and micro-rearrangements. Small segments homologous to human 3q11.2 and 3q21.2 were repositioned intrachromosomally independent of the surrounding markers in the orangutan lineage. Breakage and rearrangement of the human 3p12.3 region were associated with extensive intragenomic duplications at multiple orangutan and gibbon subtelomeric sites. We propose that new chromosomes and genomes arise through large-scale rearrangements of evolutionarily conserved genomic building blocks and additional duplication, amplification, and/or repositioning of inherently unstable smaller DNA segments contained within them. Between January and April 2000, the cyprinid fishes *Zacco platypus* and *Squalidus chankaensis* in Uji River, Kyoto Prefecture showed inactive swimming and hemorrhages on the fins, skin and eyes. No bacterial or viral agents seemed involved in the disease outbreak; however, numerous metacercariae of unidentified trematodes of the family Bucephalidae were found encysted in the fins, skin, musculature and eyes of diseased fish, suggesting these parasitic infections were the etiological agents. The metacercariae comprised two species, designated here as *Metacercaria A* and *Metacercaria B*. It is assumed that the infection started with an accidental introduction of infected first intermediate hosts, the freshwater mussel, *Limnoperna fortunei*, into Uji River, and that *Z. platypus* and *S. chankaensis* served as the second intermediate hosts, and the sheatfish *Silurus biwaensis* as the final host to complete their life cycles. This is the first case of bucephalid infections of freshwater fishes in Japan. The Yodo River system, including Uji River, is the only area in Japan where the bucephalid infections have so far been confirmed. Comments are made on the possible danger of translocation of even a single infected first, second or final host from Uji River to Lake Biwa or other water systems.

A stochastic population model has been developed for exploring the conservation management of the endangered fish trout cod (*Maccullochella macquariensis*) in the circumstances of incomplete understanding of the ecology of the species as well as the absence of appropriate data for the estimation of some vital rates. The model includes a stage-structured approach with environmental and demographic variation, and examines three types of density dependence: Beverton-Holt, Ricker and a biomass approach that we have developed to incorporate intraspecific competition beyond recruitment to 1-year olds. The stochastic model was used to explore the current and future status of the protected and last self-sustaining natural population of trout cod, restricted to a 200 km section of the Murray River in south-eastern Australia, under the different density-dependent mechanisms. Current practices for reintroducing trout cod were also evaluated. The analysis indicates that the protected natural population may be stable provided that it remains free from any significant disturbance. However, the analysis also indicates that trout cod may be very sensitive to any reduction in adult survival and remain potentially vulnerable to continued anthropogenic disturbance, in particular fishing. The analysis also indicates that the current practice of releasing fingerlings to establish a reintroduced population was more likely to fail than releasing on-grown 1-year-old fish at reintroduction sites. Furthermore, the traditional density-dependent mechanisms have less support than the applied biomass approach. The stochastic population model developed becomes a resource for guiding the conservation management and further research into the ecology of trout cod. This report covers the results of the western pond turtle head-starting and reintroduction project for the period of June 2002-September 2003. Wild hatchling western pond turtles from the Columbia River Gorge were reared at the Woodland Park and Oregon Zoos in 2002 and 2003 as part of the recovery effort for this Washington State endangered species. The objective of the program is to reduce losses to introduced predators like bullfrogs and largemouth bass by raising the hatchlings to a size where they are too large to be eaten by most of these predators. In 2002, 27 females from the two Columbia Gorge populations were equipped with transmitters and monitored until they nested. Four more females carrying old transmitters were also monitored; only one of these transmitters lasted through the nesting season. In 2003, 30 females were monitored. Twenty-three of the females monitored in 2002 nested and produced 84 hatchlings. The hatchlings were collected in fall 2002 and reared in captivity at the Woodland Park and Oregon zoos in the head-start program. Twenty-seven of the turtles monitored in 2003 nested. Six of the turtles nested twice, producing a total of 33 nests. The nests will be checked in September and October 2003 for hatchlings. Of 121 head-started juvenile western pond turtles collected in the Columbia Gorge during the 2001 nesting season, 119 were released at three sites in the Columbia Gorge in 2002, and 2 held over for additional growth. Of 86 turtles reared in the head-start program at the Woodland Park and Oregon Zoos fall 2002 through summer 2003, 67 were released at sites in the Columbia Gorge in summer of 2003, and 15 held over for more growth. Fifty-nine juveniles were released at Pierce National Wildlife Refuge in July 2002, and 51 released there in July 2003. Sixteen of those released in 2002 and 16 released in 2003 were instrumented with radio transmitters and monitored for varying amounts of time for survival and habitat use between the time of release and August 2003, together with juveniles from the 2001 release which were monitored from June 2001 through August 2003, and juveniles from the 2000 release which were monitored from August 2000 through August 2003. The number of functioning transmitters varied due to transmitter failures and detachments, and availability of replacement transmitters, as well as opportunities to recapture turtles. By August 15, 2003, a total of 39 turtles were being monitored: 6 from the 2000 release, 8 from the 2001 release, 10 from the 2002 release, and 15 from the 2003 release. During the 2002 field season trapping effort, 280 turtles were captured in the Columbia

Gorge, including 236 previously head-started turtles. During the 2003 trapping season, 349 turtles were captured in the Columbia Gorge; 304 of these had been head-started. These recaptures, together with confirmed nesting by head-start females and visual re-sightings, indicate the program is succeeding in boosting juvenile recruitment to increase the populations. Records were also collected on 160 individual painted turtles captured in 2002 and 189 painted turtles captured in 2003 during trapping efforts at Pierce NWR, to gather baseline information on this native population. Eight female painted turtles were monitored by telemetry during the 2002 nesting season; 4 nests were recorded for these animals, plus 35 nests located incidentally. Preferred habitat for nesting was identified based on the telemetry results, to be considered in anticipating future turtle habitat needs and in management planning at Pierce NWR. Bonneville Power Administration (BPA) funding supported activities in the Columbia River Gorge from June 2002 through September 2003.

1248: +.108

We compared the historic and current geographical ranges of 43 North American carnivores and ungulates to identify large-scale patterns in range contractions and expansions. Seventeen of the species had experienced range contractions over more than 20% of their historic range. In areas of higher human influence, species were more likely to contract and less likely to persist. Species richness had also declined considerably since historic times. The temperate grasslands and temperate broadleaf-mixed forest biomes lost the highest average number of species, while the boreal forest and tundra showed fewer numbers of species lost. Species contractions were a result of Euro-American settlement and postsettlement development in North America. These effects have been widespread and indicate a rapid collapse of species distributions over the course of only 1 to 2 centuries. The results of this study can be used to improve scientists' knowledge of historical reference conditions and to provide input for wildlife reintroductions and for the creation of wildlife reserves.

1249: -.164

During summer and autumn of 1994-1997, we determined the movements and mortality of 38 adult male Eastern grey squirrels (*Sciurus carolinensis*) that had been captured in urban-suburban backyards and translocated to a large forest. The squirrels did not fare well. Squirrels not found dead or classified as 'probable mortality' disappeared from the forest with a median time to disappearance of 11 days. Ninety-seven per cent (37 of 38) of the squirrels either died or disappeared from the release area within 88 days.

1250: -.061

As natural populations of endangered species dwindle to precarious levels, remaining members are sometimes brought into captivity, allowed to breed and their offspring returned to the natural habitat. One goal of such repatriation programmes is to retain as much of the genetic variation of the species as possible. A taxon of giant GalApagos tortoises on the island of Espanola has been the subject of a captive breeding-repatriation programme for 33 years. Core breeders, consisting of 12 females and three males, have produced more than 1200 offspring that have been released on Espanola where in situ reproduction has recently been observed. Using microsatellite DNA markers, we have determined the maternity and paternity of 132 repatriated offspring. Contributions of the breeders are highly skewed. This has led to a further loss of genetic variation that is detrimental to the long-term survival of the population. Modifications to the breeding programme could alleviate this problem.

1251: +.210

In order to evaluate the success of a population of red-legged partridges *Alectoris rufa* reintroduced into a 33.7 km² study area, we estimated 15 demographic parameters from 1996 to 1999 by regularly monitoring the population through winter, spring and summer mapping censuses. During the study period, late winter population and spring dispersal decreased, pair number, brood number, brood production rate, chick survival and over winter losses were stable, whereas average brood size, juvenile number, age ratio, adult spring to summer survival, late summer population, and population growth rate from spring to late summer all increased. The population showed a moderate improvement in the overall productivity, mainly related to increased production of young and to a decrease in adult mortality. The improvement in breeding performance took place, in particular, after the second year of study with the conclusion of the releasing session of reared birds.

1252: +.211

This paper explores my shifting understandings of interactions primarily between salmonid fish culture and fish conservation during the latter half of the 20th century. The idea that conspecific natural and cultured fish were largely interchangeable among phenotypically similar populations began to change with the advent of molecular genetic markers. With the gradual clarification of major geographic lineages beginning in the 1970s came awareness that translocations among anadromous lineages were generally destined for failure; in contrast, gene flow more readily occurred among non-anadromous lineages and sometimes, species. Within lineages, data concurrently were accumulating that showed adaptations to their respective environments distinguished cultured and wild populations. Reduced obstacles to gene flow at this level often resulted in homogenizations among wild and cultured fish in areas where widespread hatchery releases occurred; conversely, adaptive radiations in vacant habitats sometimes occurred over a few decades from single source hatchery releases. Current ideas relating to salmonid interbreeding, population substructure and culture evolved from these observations. Among lineages, resistance to gene flow is much greater between anadromous than purely freshwater populations or species. Within lineages, ease of gene flow in both anadromous and freshwater populations is problematical with regard to cultured and wild populations because large-scale supplementation programs erode local adaptations and fine-scale population substructures. At this level, a potential ability to regenerate natural substructure upon relaxation of supplementation is offset by uncertainties of time scales and intrinsic capabilities of homogenized populations. However, management that separates harvest and reproduction of wild and cultured subpopulations can minimize these losses. Some generality of this strategy to other fishes is supported by losses of local adaptations and outbreeding depression in black basses following population admixtures that parallel those observed in salmonids.

1253: +.125

Many *Pterodroma* species are threatened, and translocations to predator-free islands are desirable for several species. As these birds are highly philopatric, only chicks that have not yet imprinted on their natal colony should be transferred but techniques to identify suitably aged *Pterodroma* nestlings are needed. We investigated feeding frequency, meal size and chick growth in Pycroft's petrel (*P. pycrofti*) on Red Mercury Island, New Zealand to provide this information. Mean daily probability of being fed decreased from 0.47 60-23 days before fledging to 0.004 in the last seven days before fledging. Mean meal size was 34 g and morphometric measurements at fledging were similar to mean adult measurements. The best indicator of chick age was wing length.

Transferable Pycroft's petrel chicks should have wings measuring 149 - 184 mm and weigh 218 - 250 g.

1254: *-.015*

The Chequered Skipper butterfly (*Carterocephalus palaemon*) is extinct in England but extant in Scotland and Continental Europe. The possibility of re-introducing the species is under active consideration by conservation bodies, but ecological differences between Scottish and English populations raise the question of which populations should donate individuals, Continental European, or Scottish? We used mitochondrial DNA sequences (CO I, CO II and Cyt b) from potential donor populations to test the hypothesis that ecological differences could have arisen as a result of differing routes of post-glacial colonisation from separate refugia and subsequent isolation of UK populations. Shared haplotypes between populations in Belgium, Norway, Scotland and England provides no evidence to support the hypothesis that populations in Scotland result from an alternative post-glacial colonisation route. As the genetic evidence remains equivocal we suggest that choice of donor stock for a re-introduction to England should be made primarily on ecological grounds.

1255: *+.151*

Barbary deer, *Cervus elaphus barbarus*, were reintroduced in the Mhebes reserve, Bizerte governorate (Tunisia). They came from the El Feidja reserve, situated in the Jendouba governorate (Tunisia). A comparison of the antler development of stags of both reserves was made to get an indirect appreciation of the success of this reintroduction, and of habitat effect on the biology of the species. The following criteria, measured on the right-hand antlers collected between 1980 and 2000, were compared: beam, brow tine and tray tine lengths, coronet circumference and beauty. Four classes of probable age were distinguished after the number of tines on the right-hand antler: class 1 (1 tine, 1 year), class 2 (2 to 4 tines, 2 to 4 years), class 3 (5 tines, 5 to 7 years) and class 4 (6 tines, 8 to 10 years). As of class 2, the antler development in Barbary deer was lesser in Mhebes than in El Feidja. These results tended to show that the tropical conditions in the Mhebes reserve were not as good as in the El Feidja one, where salt licks have been distributed. The conclusion is that the management of the Mhebes reserve has become a priority.

1256: *+.038*

We used artificial social stimulation (decoys, vocalization playbacks, and artificial nests) to initiate group displays in six (two females, four males) Caribbean Flamingos *Phoenicopterus ruber ruber* that had not successfully bred since their introduction to Guana Island, British Virgin Islands, in 1992. During a control period prior to the introduction of stimuli, flamingos exhibited no social displays or nest building activities. All flamingos were observed approaching the decoy area as a flock within four hrs of the decoys being introduced, and Head-Flagging displays were exhibited by two birds within the first 24 hrs. In a 12-hr watch conducted two-weeks post decoy introduction, there were significantly more group display behaviours, as well as nest-building, as compared with the control period and immediately after the introduction (3.6% as compared with 0% and 0.35%). Two individuals performed the majority of group displays (although at least one social display posture was observed for each bird) and three birds exhibited nest-building behaviour. Overall, individuals spent most of their time feeding and resting/sleeping (> 95%) during all observation periods. We show for the first time that decoys and vocalization playbacks could have a positive impact on breeding success in the wild by inducing group displays and nesting behaviours in this group of introduced flamingos. We suggest that social attraction

techniques may be a useful tool to stimulate breeding in small captive and wild small populations of flamingos.

1257: +.265

Since November 1997 the Madagascar Fauna Group has released 13 captive-bred black and white ruffed lemurs (*Varecia variegata variegata*) into the Betampona Reserve in eastern Madagascar. The release programme has three major aims: (1) to assess the ability of captive-bred *V. v. variegata* to adapt to life in their natural habitat; (2) to investigate the contribution that such a release programme can make to reinforcing the existing small wild population of *V. v. variegata* in Betampona; and (3) to contribute to the long-term protection and conservation of the reserve. Criteria for the selection of release candidates, veterinary screening and pre-release experience in naturalistic environments are described and discussed. Methods for post-release monitoring of health and behaviour are covered in detail. The importance of considering the social dynamics of the species involved is emphasised. The survival of five of the releasees, plus successful reproduction and integration with the wild population have led to the conclusion that the release was a success.

1258: +.006

In South Africa efforts are currently being made to manage several sub-populations of African wild dogs (*Lycaon pictus*) occurring in isolated, fenced reserves, as a meta-population. This study represents an attempt to estimate the minimum reserve size for the reintroduction of a pack of wild dogs, as a sub-population. Minimum area requirements were based on the area required to support an adequate population of the most important prey species in the diet of a pack of wild dogs. A pack size of five is the threshold below which reproductive failure is likely, and the area requirements of five wild dogs are estimated to be 65 km² in northern, 72 km² in eastern and 147 km² in northeastern South Africa. The presence of perimeter fencing at release sites is a potentially complicating factor, however, as in some cases wild dogs learn to use fences as a hunting tool, permitting the capture of larger prey than is normal. In the event of this happening, larger areas may be required to prevent local population declines in preferred prey species. In general, the use of larger areas is advisable to allow for variation in prey population sizes and the prey profile of wild dogs post-release, and would also be necessary if wild dogs are to be reintroduced into an area with existing populations of lions and spotted hyaenas.

1259: +.123

Understanding human attitudes often is vital to the success of restoration projects, especially those invoking controversial species such as carnivores. Support for restoration activities may differ depending on residence location of the respondent; thus, understanding the spatial distribution of attitudes is important when selecting suitable restoration sites. We used black bear (*Ursus americanus*) restoration as an example of how to calculate and use a spatially explicit model of human attitudes based on demographic variables to select restoration sites in Mississippi, USA. We sampled 2 populations (5,975 landowners adjacent to 10 Public land areas and a random sample of 490 Mississippians) to determine human attitudes toward black bear reintroduction in Mississippi. We chose a series of reintroduction and demographic questions to develop 2 logistic regression models to predict support for reintroduction, and we validated the models. One model was developed using all demographic variables (how many acres respondents owned in Mississippi and for how long, as well as their age, sex, education, income, community size, and race) to determine the relationship between support for reintroduction and demographic variables. The

second model used only, age, race, and sex demographic variables. Age, community size, race, sex, and number of years of landownership were significant predictors of support for bear restoration for the first model and age, race, and sex were significant predictors for the second model. Using the second model and the U.S. Census Bureau (1990) block group data, we predicted the proportion of each block group supporting restoration. Most of Mississippi had block groups with >50% support for bear restoration. We were able to determine a statewide distribution of attitudes. Additionally, we documented that attitudes of landowners immediately adjacent to public land may differ from those of residents of the area surrounding the public land (both adjacent and not). We suggest using our approach for other restoration projects to better integrate human attitudes into the restoration program.

1260: -.107

1. Hen harriers *Circus cyaneus* prey on red grouse *Lagopus l. scoticus* and high breeding densities of harriers can limit the number of grouse available for shooting in the autumn. Ultimately, grouse hunting contributes to the maintenance of heather moorland, an ecologically important habitat for biodiversity in general and hen harriers in particular. Predation rates vary widely among harrier individuals. Understanding which factors influence this variation would be useful to target management to mitigate the effect of harriers on grouse, such as diversionary feeding. 2. We used a simple habitat-based approach to test whether we could identify harrier nests to which most grouse were delivered. Using remote sensing habitat data, we tested whether delivery rates of dead grouse to the nest by hen harriers were higher for those pairs nesting in sites with more heather *Calluna vulgaris*. A relationship between heather cover and grouse delivery rates might have been expected as grouse densities were correlated with heather cover. 3. After adjusting for annual variation in grouse abundance, the rate at which grouse were delivered to harrier nests was positively associated with the proportion of heather cover within 2 km of harrier nests. This was primarily due to the positive effect of heather cover on female delivery rates. 4. This result allowed us to use habitat data to predict the harrier nests to which most grouse chicks would be delivered. Comparison of predictions of the model with observations of food delivery to nests indicated that, in terms of grouse chick delivery, the model correctly predicted the top 50% of harrier nests in five of six years. 5. We undertook an experiment where carrion was provided to certain harriers at nest sites, in order to decrease their predation on grouse. Data from this experiment showed that when harriers were given diversionary food, the relationship between grouse predation rate and habitat was removed, with grouse predation reduced to negligible levels in most cases. This demonstrated the increased benefit of feeding birds with the highest proportion of heather cover within 2 km of their nest sites, rather than feeding birds at random within the conflict population. 6. Synthesis and applications. The amount of heather cover around hen harrier nests can be used to predict which pairs will predate most grouse within a population. This information should facilitate targeted management practices, which may accrue greater benefit for grouse stocks and potentially reduce the conflict between grouse shooting and conservation of biodiversity.

1261: +.242

1. Few examples of habitat-modelling studies of rare and endangered species exist in the literature, although from a conservation perspective predicting their distribution would prove particularly useful. Paucity of data and lack of valid absences are the probable reasons for this shortcoming. Analytic solutions to accommodate the lack of absence include the ecological niche factor analysis (ENFA) and the use of generalized linear models (GLM) with simulated pseudo-absences. 2. In this study we tested a new approach to generating pseudo-absences, based on a preliminary ENFA habitat suitability (HS) map, for the endangered species *Eryngium alpinum*. This method of

generating pseudo-absences was compared with two others: (i) use of a GLM with pseudo-absences generated totally at random, and (ii) use of an ENFA only.³ The influence of two different spatial resolutions (i.e. grain) was also assessed for tackling the dilemma of quality (grain) vs. quantity (number of occurrences). Each combination of the three above-mentioned methods with the two grains generated a distinct HS map.⁴ Four evaluation measures were used for comparing these HS maps: total deviance explained, best kappa, Gini coefficient and minimal predicted area (MPA). The last is a new evaluation criterion proposed in this study.⁵ Results showed that (i) GLM models using ENFA-weighted pseudo-absence provide better results, except for the MPA value, and that (ii) quality (spatial resolution and locational accuracy) of the data appears to be more important than quantity (number of occurrences). Furthermore, the proposed MPA value is suggested as a useful measure of model evaluation when used to complement classical statistical measures.⁶ **Synthesis and applications.** We suggest that the use of ENFA-weighted pseudo-absence is a possible way to enhance the quality of GLM-based potential distribution maps and that data quality (i.e. spatial resolution) prevails over quantity (i.e. number of data). Increased accuracy of potential distribution maps could help to define better suitable areas for species protection and reintroduction.

1262: +.096

Information on population size and distribution of the Komodo monitor (*Varanus komodoensis*) has so far been restricted to early reports or to surveys conducted on only part of the species' range. We carried out a study based on transects through sampling plots and single-catch trapping events to assess the extent to which the distribution of *V. komodoensis* has changed since the last comprehensive survey was conducted, in 1971. We also report on the status of the habitat and identify conservation priorities. Resident Komodo monitor populations are now found on only four islands in Komodo National Park and on the island of Flores in south-east Indonesia. Average population density estimates recorded on Flores were more than 60% lower than those reported for Komodo National Park. Habitat fragmentation and poaching of prey species currently represent the main threats to the Komodo monitor, and protection of monsoon forest in west and north Flores is crucial for the long-term conservation of the species.

1263: +.252

Queen conch (*Strombus gigas*) stocks in the Florida Keys once supported commercial and recreational fisheries, but overharvesting has decimated this once abundant snail. Despite a ban on harvesting this species since 1985, the local conch population has not recovered. In addition, previous work has reported that conch located in nearshore Keys waters are incapable of spawning because of poor gonadal condition, although reproduction does occur offshore. Queen conch in other areas undergo ontogenetic migrations from shallow, nearshore sites to offshore habitats, but conch in the Florida Keys are prevented from doing so by Hawk Channel. The present study was initiated to determine the potential of translocating nonspawning nearshore conch to offshore sites in order to augment the spawning stock. We translocated adult conch from two nearshore sites to two offshore sites. Histological examinations at the initiation of this study confirmed that nearshore conch were incapable of reproduction, whereas offshore conch had normal gonads and thus were able to reproduce. The gonads of nearshore females were in worse condition than those of nearshore males. However, the gonadal condition of the translocated nearshore conch improved, and these animals began spawning after three months offshore. This finding suggests that some component of the nearshore environment (e.g., pollutants, temperature extremes, poor food or habitat quality) disrupts reproduction in conch, but that removal of nearshore animals to suitable offshore habitat can restore reproductive viability. These results indicate that translocations are

preferable to releasing hatchery-reared juveniles because they are more cost-effective, result in a more rapid increase in reproductive output, and maintain the genetic integrity of the wild stock. Therefore, translocating nearshore conch to offshore spawning aggregations may be the key to expediting the recovery of queen conch stocks in the Florida Keys.

1264: +.009

During the twentieth century, the North Island kokako population in Taranaki, New Zealand, was reduced almost to extinction. Following initial habitat loss, predation by introduced brush-tailed possums and ship rats was identified as the main cause of decline. These predators can now be controlled to levels that will allow kokako populations to survive. This makes the translocation of kokako to Taranaki a possibility. This study examines the ecological requirements of kokako, predator control, translocation techniques, and evaluates the suitability of four Taranaki sites for translocations. The costs of predator control and benefits to other species are also considered. All four sites investigated proved ecologically suitable, but varied in terms of costs, practicality, and the benefits to other species. The two sites still holding remnant kokako-Waitaanga and Moki-Makino-are the most difficult sites to access and would be the most expensive to establish and operate. would be the cheapest site in which to establish predator control. Egmont is the second cheapest option and there are synergies with blue duck and North Island brown kiwi programmes. Waitaanga, Moki-Makino and Egmont are all large forest blocks (>10 000 ha) and predator control would be carried out in core areas (c. 4000 ha) with the risk that birds might disperse through the remainder of the forest. Whitecliffs is a more discreet block, and predator control could be carried out across its entire area.

1265: +.198

Brachycome muelleri Sonder (*Corunna daisy*) is an endangered annual herb, endemic to the upper Eyre Peninsula of South Australia. It is restricted to a single population occupying an area of approximately 3 ha on steep, south-facing cliff-foot slopes of the Baxter Hills. Its unique habitat, within an otherwise generally and region, optimises soil moisture retention through the provision of concentrated water catchment, shade, and low evaporation rates during the growing season. Weeds had the potential to significantly disrupt recruitment, growth and reproductive output, but grazing did not constitute a direct threat to the population. Fresh seeds were innately dormant, requiring a period of after-ripening before they would germinate. Dormancy was artificially broken by gibberellic acid (GA(3)) treatment. Germination was optimal at 20degreesC, and it was proposed that temperature plays an important role in regulating germination in situ. *B. muelleri* seeds did not respond to smoked water treatment, and GA(3) (1000 mg l(-1)) was recommended as a routine seed treatment to stimulate germination. Trial translocations using seed as founder propagules resulted in low establishment, growth and flowering rates. Established seedlings provided several advantages over seed as founder propagules, including higher success rates, more vigorous growth, and improved seed yields in the first season. Successful regeneration, proliferation and expansion of a new translocated population was observed and recorded over four consecutive years. We suggest that conservation management of this species should include the establishment of several new populations by translocation to suitable, isolated, weed-free sites. (C) 2003 Elsevier Ltd. All rights reserved.

1266: +.092

Thirty-two kokako (*Callaeas cinerea wilsoni*) were translocated to Kapiti I. between 1991 and 1997 to establish a viable 'insurance' population since the species is threatened on the New

Zealand mainland. Kokako were translocated from remnant mainland populations at Little Barrier I., Mapara Wildlife Reserve, and Mount Bruce National Wildlife Centre (a captive rearing facility). Population growth may at various times have been limited by an unrecognised male sex bias, by accidental poisoning, and by annual variation in food availability and mate choice behaviour of translocated kokako. The number of pairs (14) and presence of at least seven young birds in April 2003, balanced sex ratio, and the adequate amount of suitable habitat (at least 200 ha) indicate that the established kokako population on Kapiti I. appears likely to be self-sustaining. Monitoring provided valuable information about the lack of breeding females, to which managers responded by translocating young female kokako to Kapiti I. Lessons learnt from monitoring kokako on Kapiti I. are relevant to other translocations of kokako and perhaps other species.

1267: +.071

The last wild California Condor (*Gymnogyps californianus*) was brought into captivity in 1987. Captive breeding was successful and reintroduction efforts began in 1992. The current population is descended from 14 individuals belonging to three genetic "clans." This population bottleneck led to the loss of genetic variation and changes in allele frequencies, including a probable increase in the frequency of the putative allele for chondrodystrophy, a lethal form of dwarfism. We use studbook data to analyze the current genetic and demographic status of the population and explain how it is managed to meet specific goals. In August 2002 the population consisted of 206 individuals distributed among three captive-breeding facilities and three reintroduction sites. The population is managed to preserve genetic diversity using the concept of mean kinship. Growth of the total population has been between 10% and 15% per year since 1987, but the growth of the captive population has been only about 5% per year since 1992 due to the removal of chicks for reintroduction. Assuming that founding birds within clans were half-siblings, the birds used to found the captive population theoretically contained 92% of the heterozygosity present in the hypothetical wild base population. About 99.5% of this heterozygosity has been retained in the current population. Alleles from most founders are well represented across captive-breeding facilities and reintroduction sites. The genetic status of this population compares favorably with other species that have been rescued from extinction by captive breeding.

1268: -.013

Angiopteris chauliodonta, endemic to remote Pitcairn Island, was until recently thought to occur in only two small populations. Survey work carried out on the island in 1997 increased the number of populations to six, but as the total number of plants found was 774 (of which only 147 were mature adults) the species should be regarded as critically endangered. The species occurred in native fern-rich *Homalium taypau* and *Metrosideros collina* forest that was in many areas heavily invaded by *Syzygium jambos* and *Lantana camara*. RAPD analysis identified related populations but there was no correlation between genetic and geographical distance. The highest levels of genetic diversity was partitioned within populations ($H-S = 0.154$; $DST 0.116$), although the larger populations were not necessarily the most diverse. Threats are primarily due to forest clearance, invasive species and erosion. Conservation management for this species will be through reinforcement of existing populations to maximise their genetic diversity and translocation of new populations to suitable habitats. 1269: +.148

We modeled populations of lynx (*Lynx canadensis*) and snowshoe hares (*Lepus americanus*) to determine prey densities required for persistence of lynx translocated to the southern portion of the

species' range. The models suggested that a density of 1.1-1.8 hares/h is required for lynx persistence; these densities are higher than those reported for most hare populations across the USA. We found that lynx dispersal and density-independent mortality substantially increased the hare density required for lynx persistence. Reintroduction success was associated with number of release events, total number of animals released, and timing of release relative to the phase of the hare population cycle. However, no release protocol could override the negative effects of low prey density or high population losses. We conclude that successful lynx reintroduction requires high hare densities and minimal anthropogenic disturbance; few areas in the contiguous USA currently possess such qualities. 1270: +.004

The largest and most fecund population of the endangered *Purshia subintegra* is restricted to limestone mesas in Verde Valley, Arizona, USA, where habitat destruction is imminent. To examine factors limiting its distribution and potential for expansion, we compared recruitment and survival of seedlings growing in soils from occupied and unoccupied habitat in caged field experiments and compared survival of caged and wild seedling cohorts from 1998 to 2003. In field tests, seeds germinated in soils from occupied and unoccupied habitats. Seedling survival, however, was greatest in currently occupied habitat and dropped to zero in some unoccupied habitats with the onset of severe drought. Among 16 factors measured, soil moisture significantly explained between 62% and 71% of the variation in recruitment in both wild and caged plots. Shrubs conferred protection to wild seedlings, but decreased caged seedling survival. For 5 yr following germination, caged seedlings had greater survival than natural seedling cohorts indicating that reintroduction was comparatively more successful than natural recruitment. Expansion of *P. subintegra* into novel habitats is limited by soil moisture capacity, and this condition varied during the experimental time frame. Reintroductions to limestone mesas are possible and most promising if cages and supplemental watering are used.

1271: +.091

European otters declined dramatically from the 1950s, disappearing from many rivers. We report here on long-term monitoring (from 1977) in 3 catchments in western Britain that were recolonized naturally and in 2 catchments in eastern England that were reinforced by captive-bred otters. A minimum of 16-years data was collected on each river until 2002. At a series of sites in each study river, the percentages which were positive for otters and the number of spraints per sprainting Site were recorded and combined to produce an annual index of population. One western river, naturally recolonized, showed rapid early population growth for 5 years, followed by slower growth, while growth was steadier in 2 catchments which already held some otters at the beginning of the study. Colonization on the eastern rivers was slower, with greater fluctuations over time. Annual population growth rates were estimated at 1-7%, higher in the earlier years. A strategy for annual monitoring of otters is recommended.

1272: +.101

We assess the fate of 100 *Leiopelma pakeka* transferred in two batches from remnant forest on Maud Island to a new site at Boat Bay, 0.5 km away, in 1984-85. Seventy of the original 100 individual frogs were recaptured, plus 35 young recruits into the population. The 43 frogs released in 1984 settled closer to the release site than did the 57 released a year later, suggesting that many of the later arrivals avoided sites already occupied by frogs. Boat Bay frogs became heavier than frogs in the source population, presumably a reflection of lower population density and greater per

capita food supply. Numbers declined initially, but the frog population remained relatively stable after losses of founder individuals began to be offset by local recruitment. The mean annual survival rate after initial settlement was high (97%), indicating an average life expectancy of 33 years.

1273: +.131

Gortyna borelii lunata is a rare species of moth with a widespread, but localised distribution in Europe. In Britain, the moth is restricted to coastal grassland habitats that support its larval foodplant (*Peucedanum officinale*), in the southeast of England. Threats to *G. borelii lunata* in Britain include inappropriate management and sea-level rise. This study investigates how to secure the future of the moth in Britain by managing existing colonies appropriately and determining whether translocations of the species, away from the dangers of flooding, would be feasible. A mowing experiment and a translocation trial were conducted. Results from the mowing experiment indicate that cutting annually in either August or November is detrimental to the abundance of the moth. It is recommended that where sites must be mown this be performed on rotation, leaving much of the site uncut each year. The translocation of the moth and its foodplant to a site away from the threats of flooding was very successful, demonstrating that the species establishes well and can survive on higher ground. It is concluded that to secure the future of the moth in Britain, a sustainable network of interconnected sites for the species should be created. Also, an appropriate management plan should be formulated for each site.

1274: +.100

There is a scarcity of data on the seedling establishment success of plants inhabiting the sand coasts of the Mediterranean, despite on increasing interest in the conservation and restoration of dune habitats. A field experiment, in conjunction with a series of laboratory germination tests, was conducted to (1) determine the recruitment capacity of *Pancregium maritimum*, a perennial dune plant which is declining along the north-western Italian coasts, by natural seed dispersal and (2) test the ability of seeds to tolerate different environmental stress. We planted seeds at different burial depths and found that seeds from greater depths (6, 10 and 15 cm) showed higher emergence (35.0-46.6%) than seeds from a shallower depth (2 cm; 11.6%). On average, less than 18% of seeds remained dormant at the end of the germination period. None of the seedlings that emerged in autumn survived over winter, and 88% of those that emerged in spring died by the start of the second reproductive season as a result of desiccation. Therefore, less than 3% of the seeds resulted in established seedlings. Under laboratory conditions seeds germinated well (87.5-100%) in darkness as well as at 12 h alternating light/dark and showed little dormancy (27-35 days). Germinability of seeds remained up to 70% for at least one year of storage. Temperatures below 10degreesC or over 30degreesC inhibited germination; frost and heat were lethal for most seeds. Germination was totally inhibited by salinity and water stress. Recovery of germination occurred in seeds from solutions below 25% seawater or -0.6 MPa. These data provide useful information for conservation and reintroduction of this species.

1275: +.255

We collected genetic and behavioural data on hihi (*Notiomystis cincta*, an endangered New Zealand bird) after reintroduction to Mokoia Island to assess the effect of extrapair copulation on effective population size (N_e), and investigate the potential for increasing N_e through behavioural management. DNA fingerprinting revealed that 46% of chicks ($n = 188$) resulted from extra-pair paternity, and 82% of broods ($n = 56$) had at least one extra-pair chick. Of the extra-pair young,

34% (n = 89) were from unpaired males, and the remainder were from paired males. Variance in reproductive success (VRS) among individuals changed between years, and the relative variance among males and females depended on the sex ratio. VRS increased when measured over longer time scales, the variance in recruits being three times higher than the variance in the number of hatchlings. Extra-pair copulation increased VRS by 150% in 1 year and decreased it by 30% in another year, but this only caused a 4% decrease and 8% increase, respectively, to $N-e/N$. Although there is potential to manage VRS in this species through behavioural management, a more important factor is adult lifespan, which is the main correlate of lifetime reproductive success as well as the determinant of generation time. The high annual mortality rate in Mokoia hihi (females = 64%, males = 52%) has prevented the population from growing, so the key factors limiting N and $N-e/N$ are the same.

1276: +.119

Captive populations can exhibit more behavioral variation than their wild counterparts as a result of relaxed selective pressures in the captive environment. This increased variation can translate into decreased survivorship upon reintroduction to native habitats. Data show that captive populations of oldfield mice (*Peromyscus polionotus subgriseus*) exhibit such an increase in variation. Motivated by these results, we developed a series of calculations for a "release ratio" that can be used to determine the number of captive-bred animals needed to compensate for the increased variance. We present calculations of release ratios for behavioral and morphological variables with different distributions and illustrate the functional relationship between release numbers, increased variation, and change in average behavior and morphology. Our calculations indicated that the release of 130-150 captive-bred oldfield mice is equivalent to the release of 100 wildlike animals. Release ratios will vary among species, however, and perhaps among different populations of the same species and should be calculated separately for each situation. Development of the release ratio is the first rigorous effort to incorporate behavioral and morphological changes due to captivity into reintroduction planning. Release ratios will help conservation biologists ensure that the appropriate number of animals is released, thus increasing the success of reintroduction programs.

1277: +.168

In Europe at the beginning of 20th century, there were only four isolated areas where an estimated stock of about 2,000 beavers, *Castor* sp., lived. Many projects of beaver reintroduction and protection enabled the population to increase in size to grow up to approx. 400,000 or more individuals today. Further planned and partially achieved reintroduction projects (in Scotland, Great Britain, Bulgaria, and Italy), which were carried out without any regard for the formerly autochthonous distribution of the beavers, and were neither following the IUCN (The World Conservation Union) guidelines for the reintroduction of animals, contributed to a mixed beaver population and therefore to a mixed genetic potential. There are no exact data on the survival of *Castor fiber* in mixed populations. The genetic pool of some original subspecies of *Castor fiber* is therefore in danger. Legal and illegal releases of North American beaver, *Castor canadensis*, took place in some European countries. The protection status of the beavers varies according to the country from total protection (endangered species status) to seasonal protection or protection in selected areas. This is why, in the states with legal beaver hunting, the rules and laws may vary and an international agreement is necessary. There are conflicts of interests between protectionists and "regulators" in central and western Europe where the countryside is intensively used and mostly cultivated. Renaturation of water systems and flowing-stream networks in river basins would be an important demonstration for an optimal share in ecological revalorization which,

supra-regionally, will be most important. The beaver as a symbolic animal of progressive nature protection is a subject for discussion. We need a new management and control-system for beavers in the future.

1278: -.069

The presence of top predators can affect prey behaviour, morphology and life history, and thereby can produce indirect population consequences greater and further reaching than direct depredation would have alone. Raptor species in the Americas are recovering since restrictions on the use of dichlorodiphenyl-trichloroethane (DDT) and the implementation of conservation measures, in effect constituting a hemisphere-wide predator-reintroduction experiment, and profound effects on populations of their prey are to be expected. Here, we document changes in the behaviour of western sandpipers (*Calidris mauri*) at migratory stopover sites over two decades. Since 1985, migratory body mass and stopover durations of western sandpipers have fallen steadily at some stopovers in the Strait of Georgia, British Columbia. Comparisons between years, sites and seasons strongly implicate increasing danger from the recovery of peregrine falcons (*Falco peregrinus*) as a causal factor. A decade-long ongoing steep decline in sandpiper numbers censused on our study site is explained entirely by the shortening stopover duration, rather than fewer individuals using the site. Such behavioural changes are probably general among migratory shorebird species, and may be contributing to the widespread census declines reported in North America.

1279: +.080

The Javan gibbon is one of the rarest species of gibbons, restricted as it is to the western half of the densely populated island of Java, Indonesia. Based on a study from 1994-2002 it was found that the Javan gibbon has a larger distribution range than previously assumed. It is not restricted to the forests of the province of West Java and significant populations occur in the central part of the island. To establish the presence of gibbons in an area focused research is needed and in the past certain populations were missed in rapid presence-absence surveys. Javan gibbons occur at population densities of c. 2.6 groups km⁻² (8-9 individuals km⁻²) in lowland and hill forest <1000 in asl and less than one group km⁻² (1.5 individuals km⁻²) in montane forest between 1000-1750 in asl. Based on the extent of remaining habitat in 15 of the largest populations of Javan gibbons, a conservative density estimate of one group km⁻², and exclusion of floaters (sub-adults that have not yet established a territory), it is estimated that some 4000-4500 Javan gibbons remain in the wild. This conservative estimate is considerable higher than assumed by conservation authorities. Given that large-scale deforestation on Java (the main threat to the survival of the species) dates back more than a century and has slowed down over the last decades, this suggests that the present IUCN status of Critically Endangered seems untenable. Following IUCN guidelines the species should therefore be down-listed to Endangered. As still considerable populations remain in unprotected areas of natural forest it is argued that, in order to effectively protect the species and in an attempt to increase its survival prospects, increased protection of these forest areas is the key to the survival of the species. It is recommended not to resort to expensive and intrusive captive-breeding programmes and reintroduction initiatives as this will inevitably divert the attention away from in-situ conservation. Any programme that costs a great deal of money over the years will inevitably seek to portray itself as necessary and relevant, and if caution is needed it is in the evaluation of current management options, based on the best possible information irrespective of previous investments.

1280: +.004

The quali-quantitative inventoried data of apprehended species made by environmental authorities of Rio Grande do Sul State (RS) are presented in this work. We have assessed the wildlife avian apprehension protocols. One of those protocols have been registered by Batalhao de Policia Ambiental (BPA) from Brigada Militar do Estado do Rio Grande do Sul in the 1999-2000 term at Porto Alegre/RS metropolitan area. The other one has been registered by Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renovaveis (IBAMA) in the 1998 to June 2000 term, in relation to RS. As result of birds apprehension analysis made by IBAMA and BPA, they had been accounted the total amount, from 1998 to 2000, of 3797 specimens distributed in 26 families, 66 genus and 93 species. The most apprehended species was *Paroaria coronata* (red-crested cardinal) with 1088 individuals representing 28.7% of the total. The most apprehended family was Emberezidae, in a total of 2756 specimens, representing 72.6% of the total. We can infer that the bird's translocation is sufficiently considerable, especially because a parcel of the trafficked species is not reached by the authorities and gets at its destination. From the apprehended parcel, at least 93 distinct species are part of the roll of birds that is attractive to the illegal commerce. Amongst these, the singing birds and the parrots are distinguished.

1281: +.039

A multidisciplinary research focused on characterizing the genetic diversity and reintroduction of the micropropagated plants in a rare and endangered taxon; *Syzygium travancoricum* Gamble was undertaken. Random Amplified Polymorphic DNAs (RAPDs) and Single Primer Amplification Reactions (SPARs) genetic markers revealed a high percentage of polymorphism (>81%) and similar mean genetic distances (0.39 to 0.28) among the selected populations. Clustering based on UPGMA and SHAN indices revealed minimum genetic differentiation between the populations. Micropropagated plants derived through axillary bud proliferation were hardened in the forest nurseries and reintroduced in the wild with the help of the forest department and the local communities with limited success. This study emphasizes that maintaining current levels of genetic diversity substituted with in vitro approaches for rapid multiplication, and involvement of local communities are effective means for conservation and reintroduction of many endangered species.

1282: +.208

Extinction of tree snails of the genus *Partula* on Moorea, following introduction of the predatory snail *Euglandina rosea*, has challenged conservation biology during years of successive captive breeding of small rescued populations. An experimental release of three *Partula* species into a predator-proof patch of native forest on Moorea was designed to test: effectiveness of physical and chemical methods of predator exclusion and to evaluate behavior of animals bred for up to six generations in highly artificial environments. At the close of the experimental release, there had been multiple incursions of *E. rosea*, and too few *Partula* spp. remained to assess effects of captive breeding on ecological responses. However, results demonstrated the effectiveness of the enclosure under ideal maintenance and monitoring. Captive breeding methods were validated by reproduction and growth to sexual maturity in the wild as well as retention of genetic variability in the form of persistent color polymorphism in one species.

1283: +.070

Introduced mammals are a major driver of extinction and ecosystem change, particularly on islands. Feral goats *Capra hircus* have been introduced to numerous islands worldwide and have had wholesale impacts on ecosystems. Techniques are now available, however, to eradicate goat

populations from islands, providing a powerful conservation tool. Goats were removed from Pinta Island, Galapagos, Ecuador after a 30-year eradication campaign, the largest removal of an insular goat population using ground-based methods. Over 41,000 goats were removed during the initial hunting effort (1971-82). In the following decade the island was twice wrongly declared free of goats. During this period, the island was visited irregularly but no monitoring programme was implemented. A revised campaign over 1999-2003, which included improved hunting techniques and monitoring, removed the final goats from the island. The use of Judas goats was critical in locating the remaining goats and as a tool to confirm eradication. A systematic monitoring programme is critical for confirming eradication and preventing future reintroductions. An earlier monitoring programme would probably have resulted in earlier eradication and significant financial savings. Given limited resources, island conservation programmes elsewhere should strive to increase eradication efficiency and learn from past campaigns.

1284: +.156

From 1998 to 2000 we used radio telemetry to study habitat use by greater rheas *Rhea americana* in rural areas. Captive-born greater rheas preferred pastures to grasslands and did not use crops. No differences in habitat use were found between wild and captive-born greater rheas. Wild individuals preferred pastures, showed less preference for grasslands, and did not use crops. Rheas used pastures and grasslands for nesting but they did not use crops. No differences in nesting success was detected between these habitats. Our results show that agroecosystems that include grasslands and pasture production would strongly contribute to the conservation of this species. However, poaching must be controlled to ensure long-term persistence of wild populations of greater rheas.

1285: +.106

The conservation status of 23 Hawaiian endemic palms, *Pritchardia* spp., is reviewed. Field survey reports, recovery plans, herbaria holdings and observations have been utilized to assess each taxon's current range and status. Eleven species are categorized as Critically Endangered, nine Endangered, two Vulnerable and one as Data Deficient when subject to the IUCN Red List criteria. Conservation management options are discussed. A large proportion of this genus is on the verge of extinction and will continue to decline in the wild without active conservation management. Recommendations involving long-term management include maintaining and protecting the existing wild populations, establishment of effective ex situ populations, reintroduction into the wild, and the establishment of procedures to deal with invasive plants and animals.

1286: +.035

Interspecific competition is one of several constraints that might prevent an individual from maximising its energy intake. When an interspecific competitor is introduced, an individual is often forced to shift its diet according to the intensity of the competitive pressure. In this paper, we explore whether the introduced American mink (*Mustela vison* Schreber) shifts its diet when the density of its potential competitor, the Eurasian otter (*Lutra lutra* L.), is increased. We compared the diets of otter and mink at the same location but at two moments in time when the relative densities of these two species were different while controlling for the abundance of aquatic prey. Mink and otters are semi-aquatic mammals belonging to the same guild of mustelids and otters are expected to be the dominant competitor because they are larger and better at hunting underwater. The diets of otters and mink overlap to a great extent but while otters specialise mainly on aquatic

prey, mink are able to exploit both aquatic and terrestrial prey. These observations prompted the hypothesis investigated in this work that at higher otter densities the diet of mink should change to include a higher proportion of terrestrial items. This hypothesis was supported by the data and at higher otter densities mink diet was observed to consist of a higher proportion of mammals and birds while fewer fish were present, although this pattern was present only in winter while no changes were observed in spring. Meanwhile the diet of otters remained basically unchanged. In the second part of the study, we investigated whether niche breadth and niche overlap between otter and mink changed at different otter densities. We found that niche overlap declined as the density of otters increased, in agreement with the prediction of habitat selection theory.

1287: -.065

Competition is considered to be a major evolutionary driving force within assemblages of related and morphologically similar species, but it is notoriously difficult to test and quantify especially amongst species that cannot be easily manipulated in a laboratory or in the field. By exploiting a re-introduction of Eurasian otters (*Lutra lutra*) in the Upper Thames catchment (UK) in 1999 we performed an experiment to test whether there was evidence of competition between otters and American mink (*Mustela vison*). Mink and otters are semi-aquatic mustelids belonging to the same guild. Otters are expected to be the dominant competitor because they are larger and better adapted at exploiting aquatic resources. Our hypothesis was that mink declines when the density of otters increases. We measured the effect of competition at the population level, by observing whether mink distribution and densities changed in an area of 1353 km² in association with the arrival of its putative competitor. We estimated distribution and densities by means of sign surveys and trapping. The results showed that otters were associated with a significant and rapid reduction in the densities of mink, while mink occupancy remained approximately the same in an area of 2464 km² that was used as a control. We observed that the spatial distribution of the mink population throughout its decline was influenced by the yearly cycle of mink activities, with areas being temporarily re-colonized during the dispersal season. Mink is an invasive species in the UK threatening the survival of some native species. Our findings suggest that the re-establishment of otter populations is likely to lead to a decline of mink that may, in turn, be beneficial to native species threatened by this invasive.

1288: +.003

1. Literature on the wolf *Canis lupus*, brown bear *Ursus arctos* and lynx *Lynx lynx* is reviewed to determine if sufficient semi-natural habitat exists in the UK for a viable population of any of these species and to assess the potential risks to human safety, livestock and economically valuable wildlife. Public attitudes to the recovery and reintroduction of some other mammals are also briefly reviewed. 2. The large home range sizes and low population densities of large carnivores mean that the Scottish Highlands is the only UK region with the potential to support a viable population. Human population density is also lower in the Highlands and the density of wild ungulate prey higher than in many parts of Europe where large carnivores survive. 3. Attacks on people have been recorded in Europe for healthy bears and for rabid bears and wolves but there are no reports of attacks by lynx. Bears are more carnivorous in the north of their range than in the south and although wild mammals seldom appear to be important prey serious predation of livestock can occur. Livestock predation is also reported for the wolf and the lynx but they appear to prefer wild prey if available. However, mass kills of up to 100 or more sheep are occasionally recorded for wolves. 4. Attitudes to reintroductions and carnivores generally tend to be favourable amongst the general public, but negative amongst those most likely to be adversely affected. Fears for human safety and significant livestock predation with bears and wolves, respectively, suggest

that reintroduction of these species is unlikely to be acceptable in the foreseeable future. Reintroduction of the lynx may be feasible but habitat suitability and potential impact on vulnerable native wildlife need to be assessed. Socio-economic and legal issues also need to be addressed before such a reintroduction is considered.

1289: +.174

South Island Saddlebacks *Philesturnus carunculatus carunculatus* were once found throughout the South Island of New Zealand, but by the early 1960s were confined to the island of Big South Cape, in the extreme south of the country. All subsequent reintroduced populations of South Island Saddlebacks are derived from 36 surviving birds from this relict population. The aim of this study was to compare the breeding success of three recently reintroduced populations of Saddlebacks relative to their distance from, and habitat similarity to, the relict population. The three study islands show a latitudinal cline with Ulva, Breaksea and Motuara Islands located 60, 190 and 810 km north of Big South Cape, respectively. Saddlebacks on Ulva and Breaksea appeared to prefer to establish breeding territories in coastal scrub, the dominant habitat feature of Big South Cape. The area of coastal scrub habitat was much smaller on Motuara, where breeding territories were instead scattered through broadleaf forest habitat. Nesting success, calculated using Mayfield's method, was significantly greater on Ulva (73%) than on Breaksea (32%) or Motuara (19%) owing primarily to higher egg fertility and hatching success. Although egg failure rates were highest on Motuara, the island least similar to Big South Cape, they were also relatively high on Breaksea where the habitat was similar to Ulva and Big South Cape. Therefore, the results only partially support the hypothesis that nesting success should decrease with increasing habitat difference associated with increasing latitudinal distance from the source population. The data from this 1-year study lay the groundwork for examining further hypotheses on the effects of reintroducing endangered species outside their contemporary range, but within their historical range.

1290: +.190

Knowledge of scarlet macaw (*Ara macao*) biology during the post-fledging period is limited, yet information about this important life stage is critical to developing effective conservation strategies. We used radiotelemetry to study the post-fledging movements and behavior of scarlet macaws from an isolated and threatened population in Costa Rica. Our results indicate that monitoring and protection of young macaws during the initial 14 days post-fledging is a critical conservation measure. We identify coastal mangrove as an important habitat for the species during the post-fledging period. Young scarlet macaws gradually developed flight and feeding skills, learned behaviors and movement patterns from their parents, and were integrated into social groups during the post-fledging period. Our results underscore the challenges facing management programs based on captive rearing and stress the importance of in situ conservation focusing on nest cavity management and protection in cooperation with local communities. 1291: +.103

The Po'ouli (*Melamprosops phaeosoma*), a Hawaiian honeycreeper endemic to Maui, has a population of only three known individuals; no breeding pair currently exists, and their home ranges are too far apart for breeding to occur. Without timely intervention this monotypic genus will likely go extinct. Conservationists have faced a dilemma: facilitate breeding amongst the known individuals, manage their ecosystem to benefit uncounted Po'ouli, or a combination of both? Po'ouli biology is poorly known - but their remote home ranges are closely monitored. A

State and Federal Environmental Assessment in 1999 recommended that one Po'ouli be translocated into the home range of another in an attempt to facilitate breeding. This first manipulative recovery action was achieved in April 2002, and provided valuable new information for future captive management efforts, but upon release, radio telemetry confirmed that the translocated bird returned to its own home range after one day. We describe the recent progress that has been made to recover the Po'ouli, and critically evaluate the Po'ouli case study and the lessons learned from it that can help expedite recovery of other birds of extreme rarity. (C) 2003 Elsevier Ltd. All rights reserved.

1292: +.150

The decline of rabbit (*Oryctolagus cuniculus*) populations in Mediterranean Spain has been shown to be one of the main threats to rabbit-specialist predators such as the Iberian lynx (*Lynx pardina*) and the Spanish imperial eagle (*Aquila adalberti*), two species which are in serious danger of extinction. Consequently, corrective measures such as increasing rabbit populations by restocking have been carried out to help the recovery of predator populations. In order to determine the general applicability of rabbit restocking for predator conservation, we performed three experimental restockings and evaluated their success in relation to season, habitat quality and the number of animals introduced. Rabbits were released either in large or small numbers in all four seasons of the year, and in habitat types defined as 'poor' or 'rich' according to the food availability for rabbits. For each restocking we evaluated rabbit survival, degree of residency and expected population increase. As a rule, the highest restocking success occurred whenever smaller number of rabbits were released in the richest quality habitat. Restocking during the breeding season was less successful than in other seasons. Problems concerning intraspecific competition, reproductive failure and diseases are discussed. (C) 2003 Elsevier Ltd. All rights reserved.

1293: -.039

Collecting tortoises for the pet trade is one of the factors threatening species of *Testudo* in the Mediterranean area. The collection of *Testudo graeca graeca* for pets is described in southeast Spain, where the main European population of this subspecies coincides with an area where keeping tortoises in captivity is a long-established custom. This present paper, based on inquiries made to children, reveals that this practice continues to be a common activity, and estimates a captive population in the order of tens of thousand of tortoises. Tortoises are collected as a result of chance encounters with wild animals by local inhabitants, and without any commercial objectives. The captive breeding and the release of tortoises without any institutional control is also common. These activities could be an important threat for the species. Implications for conservation are discussed and a critical review of the conservation strategies developed in relation to this threat (trade control and re-introduction programmes) are presented. We suggest that environmental education programmes are necessary to reduce casual collection and to change the social perception of tortoises as pets. (C) 2003 Elsevier Ltd. All rights reserved.

1294: -.003

We analyse the spatial and temporal variation in non-natural mortality during a 40-year period of strong contraction of the geographic range of the Iberian lynx (*Lynx pardinus*), which shrank from 40,600 to 22,300 km². We recorded 1258 lynx deaths, an average of 31.5 losses per year over the study period. Given the reduced lynx population size, especially later in the period (around 1100 individuals), this level of non-natural mortality may have contributed significantly to the quick decline of the Iberian lynx. Non-natural mortality was not spatially correlated with, and

probably did not shape the pattern of, relative abundance of lynx across its core range, but may have reduced its absolute density. Lynx losses were caused mainly by traps set not only for predator control but also for rabbits (*Oryctolagus cuniculus*), the lynx's staple food. We did not find evidence that non-natural mortality was higher in small lynx populations through edge effects. The highest mortality levels were recorded in regions where small game was a valuable economic resource compared with other activities. Mortality decreased throughout the period because of changes in the prevailing game regimes rather than because of legal protection. The Iberian lynx is now critically endangered and effective protection should be urgently enforced, especially in small game estates, which are environmentally favourable for rabbits but risky for lynx due to predator control. Lynx reintroductions would be better attempted in traditional rabbit hunting areas. Some big game estates where small game is not exploited and predators are not controlled may be good candidates for lynx reintroduction too, provided that habitat is managed towards a suitable interspersed of woody cover and grassland. (C) 2003 Elsevier Ltd. All rights reserved.

1295: +.027

A native fish strategy has been initiated to rehabilitate native fish populations in the Murray-Darling Basin, Australia. The reintroduction of large woody debris (LWD) into the Basin's large lowland rivers is one of the restoration activities in the strategy. The results from three separate studies undertaken on the Murray River between Yarrawonga and Tocumwal are presented on the relationship between carp (*Cyprinus carpio*), native species, and LWD to examine whether native species and carp compete for LWD habitat. The first study reports on the relative abundance of carp and native fish in a river reach. Since 1995 carp abundance has declined, whereas the abundance of native fish populations has remained relatively constant providing little support for the hypothesis that competition for LWD habitat is having effects at the population level effects. The second study reports on the relationship between LWD, river channel position, and its use as habitat by carp and native species. A statistically significant relationship was observed between native fish, LWD, the location within a meander, and curvature of the meander. There was no statistically significant relation between carp and any of these parameters indicating that carp utilise a variety of riverine habitats, whereas native species were strongly associated with LWD. The third study reports on an experiment that tested the response of carp to the placement of new LWD habitat. The response from carp was statistically inconclusive. The combination of these studies suggest that it is unlikely that carp and native species are directly competing for LWD habitat and it is unlikely that carp will inundate restored LWD habitats and preclude native species.

1296: +.103

1. Although many reintroduction schemes for the Eurasian lynx *Lynx lynx* in Germany have been discussed, the implications of connectivity between suitable patches have not been assessed. 2. We introduce an individual-based, spatially explicit dispersal model to assess the probability of a dispersing animal reaching another suitable patch in the complex heterogeneous German landscape, with its dense transport system. The dispersal model was calibrated using telemetric data from the Swiss Jura and based on a map of potential lynx dispersal habitat. 3. Most suitable patches could be interconnected by movements of dispersing lynx within 10 years of reintroduction. However, when realistic levels of mortality risks on roads were applied, most patches become isolated except along the German-Czech border. Consequently, patch connectivity is limited not so much by the distribution of dispersal habitat but by the high mortality of dispersing lynx. Accordingly, rather than solely investing in habitat restoration, management efforts should try to reduce road mortality. 4. Synthesis and applications. Our approach illustrates

how spatially explicit dispersal models can guide conservation efforts and reintroduction programmes even where data are scarce. Clear limits imposed by substantial road mortality will affect dispersing lynx as well as other large carnivores, unless offset by careful road-crossing management or by the careful selection of release points in reintroduction programmes.

1297: +.013

The Japanese regional population of the Oriental white stork (*Ciconia boyciana*) became extinct in 1986. Mitochondrial DNA (mtDNA) D-loop region from 20 mounted specimens preserved at public facilities in Toyooka City, Hyogo Prefecture, Japan and its vicinity ($n = 17$), the area inhabited by the last of the Japanese population, and samples originating from China ($n = 3$) which were kept at a zoo was analyzed. After extracting DNA from small pieces of skin from mounted specimens, a 1210-bp region of the mtDNA D-loop region was analyzed. The haplotypes among 11 specimens of storks captured or found dead at Toyooka City just before the population became extinct were completely identical. Four haplotypes observed among the mounted specimens preserved in the vicinity of Toyooka City were differentiated from those of captive storks originating from China and Russia in a previous study. Therefore, the last Japanese population might have been a genetically unique group. However, phylogenetic analysis using the maximum likelihood method showed that haplotypes found in the Japanese regional population were closely related to the Chinese and Russian lineages (sequence difference = 2.1%). One mounted specimen collected in 1935 at Izushi village, in the vicinity of Toyooka City, showed the same haplotype as the captive storks from China, suggesting that genetic flow may have historically occurred between the populations of Japan and the continent. Recently, reintroduction for the Oriental white stork has been planned in Toyooka City. The planning for the recovery of extinct populations should not only involve translocation of species to the range from which it disappeared, but also reconstruction of regional populations while considering the genetic lineage between the extinct and introduced populations.

1298: +.009

In the Sonoran Desert of North America, populations of the desert tortoise (*Gopherus agassizii*) occur in rocky foothills throughout southwestern Arizona and northwestern Mexico. Although tortoise populations appear to be isolated from each other by low desert valleys, individuals occasionally move long distances between populations. Increasingly, these movements are hindered by habitat fragmentation due to anthropogenic landscape changes. We used molecular techniques and radiotelemetry to examine movement patterns of desert tortoises in southern Arizona. We collected blood samples from 170 individuals in nine mountain ranges and analyzed variability in seven microsatellite loci to determine genetic differentiation among populations. Gene flow estimates between populations indicate that populations exchanged individuals historically at a rate greater than one migrant per generation, and positive correlation between genetic and geographic distance of population pairs suggests that the limiting factor for gene flow among populations is isolation by distance. Life history traits of the desert tortoise, a long-lived species with delayed sexual maturity, may severely constrain the ability of small populations to respond to disturbances that increase adult mortality. Historic gene flow estimates among populations suggests that recovery of declining populations may rely heavily on the immigration of new individuals from adjacent mountain ranges. Management strategies compatible with the evolutionary history of gene flow among disjunct populations will help ensure the long-term persistence of Sonoran desert tortoise populations.

1299: +.175

We integrated genetics and demography into population modeling in the context of species restorations, in which both the origin of released individuals and the management strategy may influence the success of introduction. Through an explicit individual-based simulation approach, we investigated the effects of the age of released individuals by exploring the relative merits of releasing juveniles or adults to establish populations. We included the effect of genetic variability responsible for inbreeding depression and mutational meltdown. Our general analysis uncovered an interaction between the age of founders and the extent of intrapopulation fitness variability, which substantially influenced the efficiency of selection in populations founded by juveniles and had subsequent positive consequences for long-term persistence compared with the case in which adults were released. We then applied the model to the case of the reintroduction of the Griffon Vulture (*Gyps fulvus fulvus*) to southern France, for which post-release data were available. The demographic aspects of this reintroduction were already analyzed and published, suggesting that it is more efficient to release adults than juveniles, despite an observed reduction of demographic parameters following the release of adults. In that context, the inclusion of genetic considerations qualitatively changes the conclusion, predicting reduced long-term extinction risk if juveniles rather than adults are released.

1300: +.172

We investigated how large carnivores, herbivores, and plants may be linked to the maintenance of native species biodiversity through trophic cascades. The extirpation of wolves (*Canis lupus*) from Yellowstone National Park in the mid-1920s and their reintroduction in 1995 provided the opportunity to examine the cascading effects of carnivore-herbivore interactions on woody browse species, as well as ecological responses involving riparian functions, beaver (*Castor canadensis*) populations, and general food webs. Our results indicate that predation risk may have profound effects on the structure of ecosystems and is an important constituent of native biodiversity. Our conclusions are based on theory involving trophic cascades, predation risk, and optimal foraging, on the research literature; and on our own recent studies in Yellowstone National Park. Additional research is needed to understand how the lethal effects of predation interact with its nonlethal effects to structure ecosystems.

1301: +.063

Re-introduction is a technique widely used in the conservation of threatened bird species. With advances in aviculture the use of captive-produced individuals as the release stock is becoming more commonplace, and ideally, survival of captive-produced, released individuals should be no different from their wild-bred counterparts. During the late 1980s the Critically Endangered Mauritius kestrel (*Falco punctatus*) was successfully re-introduced into the Bambous mountain range, Mauritius, some 30 years after its local extinction. Between 1987 and 2001 the developing population was closely monitored enabling us to construct re-sighting histories for 88 released and 284 wild-bred kestrels. We used age-structured models in the survival analysis software program MARK to determine if an individual's origin influenced its subsequent survival. Our analysis indicated no compelling evidence for reduced survival among juvenile captive-reared and released individuals, relative to their wild-bred counterparts, across the majority of cohorts and only limited evidence of a cohort-specific effect. This study illustrates that despite the lack of a formal experimental approach it is still feasible to conduct an assessment of re-introduction outcomes and techniques. (C) 2003 Elsevier Ltd. 1302: +.180

The objective of this project was to collect scientific data to assist in the development of guidelines for the humane relocation of threatened and endangered arboreal non-human primate species. A troop of 31 Lowland Sykes monkeys (*Cercopithecus mitis albotorquatus*) was habituated to fruit bait for capture in a village and relocation to a previously selected suitable site in a protected forest reserve approximately 30 km away. Sixty-five percent ($n = 20$) of the animals were captured and relocated. This subgroup comprised one adult male, eight adult females, two subadult females, three juvenile males, four juvenile females and two infant males. Although the relocated group originated from one single group, post-translocation telemetry signals demonstrated that it split into two groups, which established themselves approximately 2-4 km apart in their new territory, the adult male eventually became solitary. The factors of importance for the successful capture and relocation of forest primates were found to include: proper understanding of troop home-range utilisation and of social bond organisation within the troop, method and period of habituation, method of release, suitability of the new habitat with respect to the ecological niche requirements of the species in question, and the period of post-relocation monitoring.

1303: +.071

Reintroduction of captive-bred animals is a key approach in conservation attempts for many endangered species, however, post-release survival is often low. Rearing conditions may be unlike those encountered upon release and the animals may not have had experiences necessary for survival in the wild. Animals may also habituate in captivity to stimuli that may pose a danger after release and/or there may be selection for behavioural traits, in particular reduced fearfulness, that may not be suited for the wild. Here, variation in boldness was assessed in captive-bred swift fox (*Vulpes velox*) and tested for influence on survival after release. Radio-tracked individuals that died in the 6 months following release were those judged previously as bold. In the presence of novel stimuli in captivity, they had left their dens more quickly, approached more closely to the stimuli and shown more activities indicating low fear than did those that survived. These individuals were less suited for release. Future selection of release-candidates on the basis of behavioural variation should enhance the success of reintroduction programmes.

1304: +.179

Adequate monitoring of amphibian populations will be increasingly important if global declines are to be understood and, where possible, reversed. The natterjack toad, *Bufo calamita*, is the rarest British amphibian and has been the subject of substantial conservation efforts. Monitoring strategies have aimed to quantify both the total numbers of populations and the status of individual populations. Between 1970-1999 the number of natterjack populations increased from 43 to 48 because successful translocations (11) outnumbered extinctions (6). Efforts to monitor individual populations increased over the period 1970-1999. Between 1990-1999 there were no detectable trends in *B. calamita* population size or breeding success in Britain, although power to detect any trends over 10 years was low. Calling activity and short-term trends in spawn counts were unreliable predictors of long-term population viability in the absence of extra information such as toadlet production. Long periods (> 10 years) of spawn counts are needed to demonstrate trends that are reflective of real population changes at the national level. Efforts to develop reliable methods for monitoring *B. calamita* in Britain could provide useful guidelines for work on some other declining species of amphibians.

1305: +.149

Although population dynamics of giant pandas *Ailuropoda melanoleuca* remain poorly known,

basic principles can be safely transferred from studies of, and experience with, similar species. Without minimizing the importance of continued study of demographics, genetics, and behavior of pandas, I offer the following generalizations from our understanding of carnivore population biology in North America. First, elasticity analyses confirm that pandas have evolved life-histories that prioritize high survival of adult females. In comparison, reproductive rates are unimportant. Increases in survival of adult females will yield approximately 5 times the conservation benefit of proportional increases in reproductive output. Second, under circumstances likely to characterize most panda populations, survival rates of males (even adults) are also relatively unimportant. Thirdly, notwithstanding its well-deserved reputation as a slow breeder, giant panda populations are mathematically capable of growing surprisingly quickly, if habitats (and associated survival rates) allow. Finally, reintroductions of endangered species in western North America remind us of the critical role of maintaining large patches of unfragmented habitat. Wolves *Canis lupus*, extirpated from the western U.S. before the mid-20th century, have made a rapid and surprisingly painless recovery because wild areas and prey populations remained abundant. In contrast, black-footed ferrets *Mustela nigripes*, lost from the wild more recently, have encountered great difficulty in becoming reestablished, despite tremendous scientific efforts. It appears that ferrets may simply no longer have sufficient wild habitat (i.e., prey) to persist. The best science will not be capable of saving pandas if sufficient habitat is not available.

1306: +.040

Present population structure and patterns of genetic diversity in forest trees have been influenced by past anthropogenic activities and the major aim of this review is to assess the scale and timing of this influence within Europe. Very little 'natural' forest (defined as areas that have not experienced a break in forest continuity because of cultural activities since conditions became suitable for tree growth) remains in Europe. Yet many contemporary European forests have developed by natural regeneration from local stock, so despite a massive anthropogenic impact, one can predict a survival of the 'natural' patterns of genetic diversity despite a general reduction in total diversity. Systematic interference with forests was closely associated with the spread of agriculture from south-east to north-west Europe during the last 10,000 years. It has been suggested that the spread of trees of early economic importance was linked to local agricultural development. However, closer analyses of spreading dynamics and comparisons with comparable spreading in the USA does not fully support this hypothesis. Indeed, modelling the present and past range limits (if forest trees has suggested that climate change is the major driving force for range changes, implying that genetic composition is primarily governed by natural processes. Anthropogenic activity did catalyse the spread of *Fagus sylvatica* through increasing the rates of forest disturbance. By the Roman period, there are documented cases of introduction of e.g. *Aesculus hippocastanum* and *Castanea sativa* to many parts of Europe. Countries with colonial histories have been importing undisputedly 'exotic' species for several centuries. Occasionally there is doubt over exotic status owing to lack of documentation or possible prehistoric introduction, e.g. *Arbutus unedo* in western Ireland. The translocation of native species with the aim of improving production potential is a relatively recent practice often documented in national histories of forestry. Thus despite considerable widespread and long-term intervention with European forest ecosystems, many of the observed patterns of genetic diversity observed in naturally regenerated forests primarily originate from natural processes. However, given the enormous recent increase in the long-distance translocation of seeds, this situation is rapidly changing in regions with intensive forest management. (C) 2004 Elsevier B.V. 1307: +.102

Brosimum alicastrum Sw. is a multi-purpose species and it is dominant in some American tropical forests. In Western Mexico, forests dominated by *B. alicastrum*, called *mojoteras*, have been dramatically altered. The present work aims to supply basic elements for the reintroduction of *mojoteras* in the Sierra de Manantlan Biosphere Reserve. The question we posed was: Are there nursing species for the reintroduction of *B. alicastrum* seedlings in secondary tropical dry forest? A hundred randomly chosen 2-year-old *B. alicastrum* seedlings were planted in five treatments: under the covering of 80 individuals belonging to four species (*Tabebuia chrysantha* (Jacq.) G. Nicolson, *Thouinia serrata* Radlk., *Acacia macilenta* Rose and *Acalypha cincta* Muell. Ara.) and 20 on open ground. After 1 year, the survival of *Brosimum alicastrum* seedlings was significantly different among the treatments ($G(2) = 12.11$; $P < 0.05$). The treatments with the highest significant *B. alicastrum* seedling survival rate were under the covering of *Acalypha cincta* and *Thouinia serrata* (55 and 40%, respectively), whereas under the covering of *Acacia macilenta*, *Tabebuia chrysantha* and on open ground, the survival rate was the lowest (<5%). (C) 2004 Published by Elsevier B.V.

A total of 436 logs were used to create 20 engineered log jams (ELJs) in a 1.1 km reach of the Williams River, NSW, Australia, a gravel-bed river that has been desnagged and had most of its riparian vegetation removed over the last 200 years. The experiment was designed to test the effectiveness of reintroducing woody debris (WD) as a means of improving channel stability and recreating habitat diversity. The study assessed geomorphic and ecological responses to introducing woody habitat by comparing paired test and control reaches. Channel characteristics (e.g. bedforms, bars, texture) within test and control reaches were assessed before and after wood placement to quantify the morphological variability induced by the ELJs in the test reach. Since construction in September 2000, the ELJs have been subjected to five overtopping flows, three of which were larger than the mean annual flood. A high-resolution three-dimensional survey of both reaches was completed after major bed-mobilizing flows. Cumulative changes induced by consecutive floods were also assessed. After 12 months, the major geomorphologic changes in the test reach included an increase in pool and riffle area and pool depth; the addition of a pool-riffle sequence; an increase by 0.5-1 m in pool-riffle amplitude; a net gain of 40 m³ of sediment storage per 1000 m² of channel area (while the control reach experienced a net loss of 15 m³/1000 m² over the same period); and a substantial increase in the spatial complexity of bed-material distribution. Fish assemblages in the test reach showed an increase in species richness and abundance, and reduced temporal variability compared to the reference reach, suggesting that the changes in physical habitat were beneficial to fish at the reach scale. 1309: +.256

Plant species richness in rural landscapes of northern Europe has been positively influenced by traditional management for millennia. Owing to abandonment of these practices, the number of species-rich semi-natural grasslands has decreased, and remaining habitats suffer from deterioration, fragmentation, and plant species decline. To prevent further extinctions, restoration efforts have increased during the last decades, by reintroducing grazing in former semi-natural grasslands. To assess the ecological factors that might influence the outcome of such restorations, we made a survey of semi-natural grasslands in Sweden that have been restored during the last decade. We investigated how plant species richness, species density, species composition, and abundance of 10 species that are indicators of grazing are affected by (1) the size of the restored site, (2) the time between abandonment of grazing and restoration, (3) the time elapsed since

restoration, and (4) the abundance of trees and shrubs at the restored site. Only two factors, abundance of trees and shrubs and time since restoration, were positively associated with total species richness and species density per meter square at restored sites. Variation in species composition among restored sites was not related to any of the investigated factors. Species composition was relatively similar among sites, except in mesic/wet grasslands. The investigated factors had small effects on the abundance of the grazing-indicator species. Only *Campanula rotundifolia* responded to restoration with increasing abundance and may thus be a suitable indicator of improved habitat quality. In conclusion, positive effects on species richness may appear relatively soon after restoration, but rare, short-lived species are still absent. Therefore, remnant populations in surrounding areas may be important in fully recreating former species richness and composition.

1. We used field and experimental data to test if white grub parasites (Diplostomatidae) are costly to White Sands pupfish (*Cyprinodon tularosa*), a threatened species restricted to four sites in the Chihuahuan desert, New Mexico. 2. Of the four populations of *C. tularosa*, two are native and two are introduced. The two native populations (Malpais Spring and Salt Creek) are genetically distinct and have been isolated historically in dissimilar aquatic habitats (brackish spring and saline river, respectively). Two populations were established c. 1970 from translocation of Salt Creek fish to another saline river (Lost River) and another brackish spring (Mound Spring). 3. Physid snails (Physidae) occur in the two brackish spring habitats but not the saline river habitats. These snails are first intermediate hosts for white grubs (Diplostomatidae). Therefore, the two freshwater populations are infected by diplostomatids. For the Mound Spring population, the ecological relationship of *C. tularosa* and diplostomatids has only recently occurred. 4. In 1995, a population crash occurred for *C. tularosa* at Mound Spring, associated with a parasite outbreak. Diplostomatids were the presumptive cause of this crash, but this was inferred from observation of infection in collected fish. 5. Two years of seasonal sampling of the two populations revealed that all collected fish were infected. Parasite intensities were significantly lower in winter compared to summer, suggesting that heavily infected fish were lost from the population on a seasonal basis. 6. We conducted an artificial infection experiment to assess the costs of parasitism for previously uninfected *C. tularosa* females for various life-history traits. Under experimental conditions, diplostomatid infection caused increases in *C. tularosa* mortality and decreases in growth and fat storage. Individual-level costs of parasitism may translate to population-level patterns of parasitism for *C. tularosa* populations. Results from this study suggest that parasites may impact host overwinter survival, which is consistent with lower parasite intensities found during winters in wild populations.

1311: +.076

A comparison of four pollination treatments revealed that *Antirrhinum valentinum* is self-incompatible but shows low levels of spontaneous self-fertility. Seed sets, after hand cross-pollination and spontaneous self-fertilization, were significantly fewer than in control flowers, but fruit and seed mass were not significantly different. Pollen tube growth was slower after selfing than crossing, being arrested in the stigmata or in the upper part of the style. Multilocus outcrossing rates ($t(m)$) were high and $t(m) - t(s)$ ($t(s)$ = single-locus outcrossing rate) small, indicating low levels of biparental inbreeding. Despite that, the estimated neighborhood sizes were from six to seven individuals, which can be considered low because the number of seeds per fruit ranges between 150 and 200. This apparent incongruence is explained by the small size of populations together with the multiallelic gametophytic control of self-incompatibility, making

possible crossing between half-sibs. On the basis of these data, recommendations to develop reinforcement or reintroduction programs as well as for in vitro propagation of plants are given.

1312: +.064

Although the Mexican axolotl (*Ambystoma mexicanum*) is well known as a popular laboratory and aquarium animal, in the wild it is almost extinct and confined to the remnant canals of Lake Xochimilco on the edge of Mexico City. Loss of habitat, introduced fish, pollution and illegal collection for food and medicines have all played a role in its decline. Capitalizing on its high profile within local culture, a multidisciplinary conservation programme is being developed using the axolotl as a flagship species for the wider Xochimilco system. The programme is focusing on raising the profile of the axolotl and other species by promoting nature tourism and conservation education within the local community. Complementing these socio-economic initiatives is biological research on population ecology, survey methods and threat mitigation. The axolotl has been bred in captivity very successfully both in Mexico and elsewhere. However, reintroduction to Lake Xochimilco will not be a realistic option until the threats facing the species have been addressed. Equally, the disease and genetic risks posed by the release of captive bred stock need to be evaluated prior to any reintroduction.

1313: +.189

The hare, *Lepus europaeus*, production in 25 enclosures was monitored from 1999 to 2003. The average surface of the enclosures was 3.4 +/- 1.3 (SD) ha (range 1.1-6.6). Annually, 2 adult males and 3 adult females, preventively captured in protected areas, were randomly assigned to each enclosure in January. The hares produced in the enclosures were captured in October/December for restocking. The enclosures were cultivated with non-harvested crops. Every enclosure was surveyed with a GPS system. A total of 675 hares were produced in the enclosures with 165.4 produced hares for 100 introduced hares. A linear regression analysis showed that the % woodland, % bush-land and clay content of the soil negatively affected the hare production, while the % mixed-hay fields, % undersowed cereals, number of "small-fields" per ha, enclosure surface, Shannon index, number of cultivated-plant species and sand content of the soil seemed to have a positive affect. A stepwise selection of the environmental characteristics reduced the effect-variables to "year", "surface", woodland-incidence (negative factor), clay-content (negative factor), and mixed-hay fields-incidence (positive factor). Semi-natural rearing seems to be a valuable system to produce hares for restocking and reintroduction, but the success of this technique seems to be linked to the environmental characteristics and crop management of the enclosures.

1314: -.039

Several species of wild animals are endangered with extinction in Cameroon. The ostrich, *Struthio camelus*, which is one of these animals, has been protected since 1994. In 2000, there were about fifty individuals left in the Waza National Park, in the far northern part of the country. The number of ostriches has steadily decreased in the park despite more than half a century of protection. This repressive management method has progressively evolved into a participative management method. The primary cause of this drop in number is poaching, which is carried out by the local populations searching for eggs whose shells are sold to tourists, and for adult animals killed for their meat, and even more so for their bone marrow which is widely used in traditional medicine. Commercial hunting is carried out by foreigners, the skin being used in the fabrication of hand-crafted objects. In addition to these problems, natural predation occurs, mostly by jackals, Can is

aureus, and hyenas, *Hyaena hyaena*, which targets the hatchlings often already weakened by the harsh climactic conditions. One of the alternatives for the conservation of this species is the introduction of its breeding in "game ranching" or "game farming" near the park and urban centers where there are consumers of the products taken from this animal. The products of such breeding farms or ranches could be used as animals for reintroductions into the wild, improving the visual tourism, and be valorized on the national meat- and craft markets.

1315: +.205

Community Based Natural Resource Management (CBNRM) has made its contribution to the Environment and Development Agenda of most Southern African countries, and perhaps even in other parts of the world. In Namibia, it has gained its merit and widespread support in the wildlife sector, through the internationally-acclaimed Conservancy Programme. This Programme was launched in 1998 and has demonstrated that wildlife stands a better chance of success and growth by giving the wildlife resource economic values to those who live and interact with the wildlife on a day-to-day basis. These economic values are realized through usufruct rights given to rural communities through a strong policy and legislative framework, which defines, clarifies and guarantees such rights. The result is a vibrant community-driven programme, encompassing over 60 communities mobilized into governance and wildlife management bodies, called Conservancies, involving over 200,000 people (in both registered and emerging Conservancies). This represents over 10% of the total population of Namibia, and close to 20% of the rural population. The 29 registered Conservancies alone involve 95,000 people and cover over 7 million hectares of land. This accounts for 22% of communal land and close to 9% of the total land area. Communities are not only empowered to manage the wildlife, but are also in a position to reap direct financial and other benefits as a result of their management effort. Financial and non-financial benefits accrued to Conservancies from wildlife and wildlife-based tourism, have nearly doubled annually since 1998. In 2003, Conservancies earned over US\$ 2,430,000 from a diversity of wildlife and tourism ventures. The Ju/'hoansi San of Nyae Nyae in northeastern Namibia is one of the Namibia's most poverty-stricken and marginalized communities. This community created a 9,030-km² Conservancy in 1998. Largely as a result of the game reintroduction effort made since 1999, the game numbers increased, contributing significantly to the livelihoods of the members. The Conservancy provided 28% of all jobs (n=97) and about 44% of all incomes (US\$ 341,390) during 2003. The CBNRM has the potential of broadening community rights and benefits beyond wildlife to also include other natural resources, but this will require careful consideration and planning when integrating wildlife with other forms of land use, and further advancing the CBNRM as mainstream strategy for rural development. Considering the current inequities in the agricultural sector between the elites and the rural poor, the major future stake of rural communities in the wildlife sector will be to safeguard the fundamental principles of the CBNRM.

1316: +.080

This report covers the results of the western pond turtle head-starting and reintroduction project for the period of October 2003 - September 2004. Wild hatchling western pond turtles from the Columbia River Gorge were reared at the Woodland Park and Oregon Zoos in 2003 and 2004 as part of the recovery effort for this Washington State endangered species. The objective of the program is to reduce losses to introduced predators like bullfrogs and largemouth bass by raising the hatchlings to a size where they are too large to be eaten by most of these predators. Sixty-nine turtles were over-wintered at the Woodland Park Zoo and 69 at the Oregon Zoo. Of these, 136 head-started juvenile turtles were released at three sites in the Columbia Gorge in 2004. Two were

held back to attain more growth in captivity. Thirty-four were released at the Klickitat ponds, 19 at the Klickitat lake, 21 at the Skamania site, and 62 at Pierce National Wildlife Refuge (NWR). This brought the total number of head-start turtles released since 1991 to 246 for the Klickitat ponds, 114 for the Klickitat lake, 167 for the Skamania pond complex, and 250 at Pierce NWR. In 2004, 32 females from the two Columbia Gorge populations were equipped with transmitters and monitored for nesting activity. Twenty-one of the females nested and produced 85 hatchlings. The hatchlings were collected in September and October and transported to the Woodland Park and Oregon zoos for rearing in the head-start program. Data collection for a four-year telemetry study of survival and habitat use by juvenile western pond turtles at Pierce NWR concluded in 2004. Radio transmitters on study animals were replaced as needed until all replacements were in service; afterward, the turtles were monitored until their transmitters failed. The corps of study turtles ranged from 39 in August 2003 to 2 turtles at the end of August 2004. These turtles showed the same seasonal pattern of movements between summer water and upland winter habitats observed in previous years. During the 2004 field season trapping effort, 345 western pond turtles were captured in the Columbia Gorge, including 297 previously head-started turtles. These recaptures, together with confirmed nesting by head-start females and visual resightings, indicate the program is succeeding in boosting juvenile recruitment to increase the populations. Records were also collected on 224 individual painted turtles captured in 2004 during trapping efforts at Pierce NWR, to gather baseline information on this native population. Bonneville Power Administration (BPA) funded approximately 60% of program activities in the Columbia River Gorge from October 2003 through September 2004.

1317: *-.001*

Crested Ibis *Nipponia nippon* is an Endangered species that has experienced a severe but short-lived population bottleneck in recent years. Only one wild population and two captive populations exist in China today, all of which were probably initiated from two breeding pairs rediscovered in 1981. This paper represents the first study of the genetic diversity of Crested Ibis by analysing sequence variation of a fragment spanning domains II and III of the mitochondrial DNA (mtDNA) control region of both wild and captive populations. Two haplotypes were identified in both wild and captive populations, and the captive population had a bias towards haplotype 1. The species as a whole demonstrated an extremely low level of genetic diversity, with a haplotype diversity and nucleotide diversity of 0.386 ± 0.074 and $0.069\% \pm 0.013\%$, respectively. Despite the rapid increase in numbers of birds under intensive management, the paucity of genetic diversity remains a real threat to the species. The mtDNA control region variations detected in the present study could provide significant information additional to the studbook data of Crested Ibis; therefore we suggest that special attention be paid to individuals with haplotype 2 when considering captive breeding management. Overall, great care should be taken in the selection of reintroduction sites for this rare bird, as species with low genetic diversity are thought to be more limited in their ability to tolerate a wide range of environmental extremes and diseases.

1318: *-.072*

Historical data on the distribution and status of the purple gallinule (*Porphyrio porphyrio*) in Portugal were collected by bibliographic research, from museum catalogues and from questionnaires to wetland managers, ornithologists and birdwatchers. The population suffered severe decline and range contraction at the end of the 19th century and most of the 20th century, due mainly to habitat loss and degradation and excessive hunting. However, the population has begun to recover in the last decade mainly through direct protection of the species and of the remaining habitat, together with creation of artificial wetlands and a reintroduction programme,

and probably also due to immigration from Spain. The population size has increased about 10-fold and the range has expanded to most of its former area. The estimated Portuguese breeding population in 2002 was 49-67 pairs. Densities varied between 0.05 and 7 individuals/ha in recently colonized areas and stable (saturated) areas, respectively. Although the population is recovering, its small size, high fragmentation and several natural and anthropogenic threats lead us to consider it still a species of major concern in Portugal. 1319: +.064

Although the Mexican axolotl (*Ambystoma mexicanum*) is well known as a popular laboratory and aquarium animal, in the wild it is almost extinct and confined to the remnant canals of Lake Xochimilco on the edge of Mexico City. Loss of habitat, introduced fish, pollution and illegal collection for food and medicines have all played a role in its decline. Capitalizing on its high profile within local culture, a multidisciplinary conservation programme is being developed using the axolotl as a flagship species for the wider Xochimilco system. The programme is focusing on raising the profile of the axolotl and other species by promoting nature tourism and conservation education within the local community. Complementing these socio-economic initiatives is biological research on population ecology, survey methods and threat mitigation. The axolotl has been bred in captivity very successfully both in Mexico and elsewhere. However, reintroduction to Lake Xochimilco will not be a realistic option until the threats facing the species have been addressed. Equally, the disease and genetic risks posed by the release of captive bred stock need to be evaluated prior to any reintroduction.

1320: +.101

The reintroduction of gray wolves to Yellowstone National Park (YNP) provides a natural experiment regarding the effects of top predators on scavenger species. Fieldwork on the Northern Range of Yellowstone indicates that wolves facilitate carrion acquisition by scavengers, but it is unclear whether this represents a transient or permanent effect of wolf reintroduction. Here we present a wolf-elk model with human elk harvest and use it to investigate the long-term consequences of predator-prey dynamics and hunting on resource flow to scavengers. Our model shows that while wolves reduce the total amount of carrion, they stabilize carrion abundance by reducing temporal variation in the quantity of carrion and extending the period over which carrion is available. Specifically, the availability of carrion is shifted from reliance on winter severity and elk density to dependence on the strength of wolf predation. Though wolves reduce the overall abundance of carrion by lowering the elk population, this reduction is partially offset by increases in the productivity of an elk population invigorated by removal of the weakest individuals. The result of this is higher carrion production per elk in the presence of wolves. In addition, this yields an ecological explanation for the phenomena that predators increase the robustness of their prey: namely that by reducing the effect of density-dependent resource competition among elk, those that remain, even some of the older animals, are better fed and healthier as a result. Our model also suggests that human hunting has no effect on the distribution of carrion across the year but is crucial in determining the long-term abundance of carrion because of the effect of hunting on elk population levels. By reducing the proportion of cows in the annual hunt, which have historically been high in order to control the number of elk migrating north of the park, managers can allow an adequate supply of carrion without substantially reducing hunter take. The effects of a more tractable food resource is likely to benefit scavengers in Yellowstone and other areas of the world where wolves have been or are currently being considered for reintroduction. 1321: +.166

The white-winged guan *Penelope albipennis* (Aves, Cracidae) is a Critically Endangered bird endemic to northern Peru. We surveyed a protected area suitable for its reintroduction north of the species' current range. Following IUCN guidelines, four factors were evaluated: diversity and quantity of plant species that are part of the white-winged guan's diet, year-round water sources, resting and roosting cover, and extent of undisturbed forest. Several suitable small valleys or quebradas were inspected, but our evaluation focused on three. We identified all shrub and tree species to compare with habitat currently used by the guan. Cover for nesting places was assessed visually. We found species composition and microhabitat types to be similar to habitat presently used by wild guans. Thus, all habitat components are favourable for reintroduction. The high degree of protection of the area makes it particularly suitable as a reintroduction site. We recommend experimental extension of the species current range to mitigate the risk of extinction posed by catastrophic events.

1322: +.185

Echinacea laevigata (Boynton and Beadle) Blake, Asteraceae, smooth coneflower, is a federally listed endangered species native to the piedmont of the southeastern United States. The majority of known populations occupy roadsides and utility rights-of-way, and the few undisturbed populations are declining in number and size as succession shades out the understories. The recovery plan for *E. laevigata* calls for reintroduction to the wild and safeguarding throughout the range of the species. In an experimental reintroduction, we tested several planting methods to determine the optimal method for establishing populations in the wild including transplanting seedlings bare-root versus rooted in potting soil, clustering seedlings versus planting them individually, and planting adult plants (1-3 year old) versus seedlings. Treatments were tested at two sites typical of *E. laevigata* habitat. The high survival rates and comparable growth among plants from all planting methods that we observed suggests that reintroduction is a promising conservation strategy for the species and that there are various options for introducing populations. Therefore, reintroduction practitioners may weigh logistical costs and benefits on a case-by-case basis when choosing reintroduction methods for *E. laevigata*. Based on theoretical predictions and our findings, we suggest that an optimal method for establishing populations is to plant adult plants (older than one year) in the spring, without soil amendment.

1323: +.013

There are two recognized subspecies of impala in sub-Saharan Africa: the common impala (*Aepyceros melampus melampus*) - widespread in southern and east Africa - and the vulnerable black-faced impala (*A. m. petersi*) - found naturally in only a small enclave in southwest Africa. The Etosha National Park (NP) in Namibia harbours the largest and only protected-area population of black-faced impala, numbering some 1500 individuals. Due to translocations of the exotic common impala to commercial farms in Namibia during the past decades, the black-faced impala in Etosha is faced with the potentially serious threat of hybridization posed by secondary contact with the common impala inhabiting bordering farms. Using eight microsatellite DNA markers, we analysed 127 black-faced impala individuals from the five subpopulations in Etosha NP, to determine the degree, if any, of hybridization within the park. We found that (a) the black-faced impala were highly genetically differentiated from the common impala (pairwise theta-values ranged from 0.18 to 0.39 between subspecies; overall value = 0.27) and (b) black-faced samples showed high levels of genetic variability [average expected heterozygosity (H-E) = 0.61 +/- 0.01 SE], although not as high as that observed in the common impala (average H-E = 0.69 +/- 0.02).

SE). (c) No hybridization between the subspecies in Etosha was suggested. A Bayesian Markov Chain Monte Carlo approach revealed clear distinction of individuals into groups according to their subspecies of origin, with a zero level of 'genetic admixture' among subspecies.

1324: +.066

1. In a population with Allee effects a positive relationship exists between fitness and population size or density. Allee effects may result in extinction thresholds and are therefore crucial in conservation and management. It has been shown theoretically that Allee effects can be driven by predation; however, there are few empirical data. Previous empirical work on Allee effects has emphasized that taxa with life-history characteristics such as co-operative breeding may be prone to such effects. Because predation is a general ecological mechanism, Allee effects may be more widespread than previously thought. 2. We used a series of simple heuristic models to develop a theoretical framework for understanding predation-driven Allee effects as a function of predator functional and aggregative responses. 2. Predators can create an Allee effect if they have a type I (linear) or type II (saturating) functional response without a type III (sigmoid) aggregative response, or vice versa. In addition, predation must be the main driver of prey dynamics, and prey must have little spatial or temporal refuge from predation. 4. We highlighted several, mainly unrecognized, examples of predation-driven Allee effects from the literature, the majority of which came from systems that had been perturbed by exploitation or introduced predators. 5. Synthesis and applications. Allee effects can arise from a general ecological process under a variety of different combinations of functional and aggregative responses. Allee effects may thus be present in a broad spectrum of different taxa with different types of life history, not only those taxa, such as broadcast spawners and co-operative breeders, on which empirical work has focused thus far. Conservation biologists and managers working with heavily exploited or threatened populations, or attempting reintroductions, should be aware of the possibility of a threshold population size or density below which extinction is likely. These thresholds can occur regardless of species life history, if predation is a major source of mortality and spatial and temporal predation refuges are limited.

1325: +.315

In the UK, research has improved our understanding of amphibian populations, their habitats, threats and the effectiveness of conservation measures. The greatest research effort has been directed to the protected and declining species, notably *Triturus cristatus*, *Bufo calamita* and *Rana lessonae*. However, several challenges arise when attempting to employ research findings as a tool to shape policy. Wild populations and threats to them are not often simple systems that invite straightforward investigation. Extrapolating from small studies to more comprehensive application can also generate problems, especially with widespread species. The standards of confidence commonly used in science may not be directly transferable to conservation policy, as in conservation it is often desirable to apply the precautionary principle. When constructing policies, it is important to be realistic about the constraints that may be imposed due to factors beyond the control of conservation agencies and researchers, notably those of a legislative or socioeconomic nature. There is a need for conservation practitioners to engage more closely with scientists, with a view to identifying the current knowledge gaps that hinder the achievement of conservation gains. The increasing success of *B. calamita* reintroductions provides an excellent illustration of such an application of scientific knowledge.

1326: +.024

The dramatic decline of amphibian populations worldwide is an urgent conservation issue. The root causes underlying many amphibian declines are unknown. One Michigan species of Special Concern, the Blanchard's cricket frog (*Acris crepitans blanchardi*), is declining at an alarming rate in the northern portions of its range. In May 2004, the National Amphibian Conservation Center (NACC) at the Detroit Zoo initiated a translocation project to reintroduce Blanchard's cricket frog to three manmade wetlands at the northern extent of its range. Calling surveys in south-east Michigan revealed several robust populations of cricket frogs including one site slated for development in the fall of 2004. Working with the developer and the Department of Environmental Quality, we successfully removed about 1,050 frogs and tadpoles from the threatened breeding ponds. The animals were released into two Michigan Department of Natural Resource restored lake plain prairie complexes with wetland features, and into a restored wetland near the NACC in fall of 2004. These translocated populations will be monitored in subsequent breeding seasons to assess the success of the translocation project.

1327: +.036

Zoos, by nature, are breeding grounds for high numbers of rodents. The use of poisons and traps has been the main tool for rodent control. By acquiring and reintroducing avian predators, specifically barn owls, into a zoo setting, the rodent population could be controlled naturally. Barn owls (*Tyto alba*) once flourished in Pennsylvania and surrounding areas, particularly in old wooden barns, but the development of new prefabricated barns has left the owls with fewer places to nest. This study focuses on installing several man-made nest boxes for three avian predators on the grounds of the Pittsburgh Zoo & PPG Aquarium and surrounding areas. In time, it is hoped that the owls will begin to breed and higher densities will be achieved, as well as a suppressed rodent population.

1328: -.213

An introduced pathogen, white pine blister rust (*Cronartium ribicola*), has caused declines in five-needled pines throughout North America. Simultaneously, fire exclusion has resulted in dense stands in many forest types, which may create additional stress for these generally shade-intolerant pines. Fire exclusion also allows fuels to accumulate, and it is unclear how affected populations will respond to the reintroduction of fire. Although white pine blister rust and fire exclusion are widely recognized threats, long-term demographic data that document the effects of these stressors are rare. We present population trends from 2168 individuals over 5-15 years for an affected species, sugar pine (*Pinus lambertiana*), at several burned and unburned sites in the Sierra Nevada of California. Size-based matrix models indicate that most unburned populations have negative growth rates (λ range: 0.82-1.04). The growth rate of most populations was, however, indistinguishable from replacement levels ($\lambda = 1.0$), implying that, if populations are indeed declining, the progression of any such decline is slow, and longer observations are needed to clearly determine population trends. We found significant differences among population growth rates, primarily due to variation in recruitment rates. Deaths associated with blister rust and stress (i.e., resource competition) were common, suggesting significant roles for both blister rust and fire exclusion in determining population trajectories. Data from 15 prescribed fires showed that the immediate effect of burning was the death of many small trees, with the frequency of mortality returning to pre-fire levels within five years. In spite of a poor prognosis for sugar pine, our results suggest that we have time to apply and refine management strategies to protect this species.

1329: +.142

Captive breeding of animals is widely used to manage endangered species, frequently with the ambition of future reintroduction into the wild. Because this conservation measure is very expensive, we need to optimize decisions, such as when to capture wild animals or release captive-bred individuals into the wild. It is unlikely that one particular strategy will always work best; instead, we expect the best decision to depend on the number of individuals in the wild and in captivity. We constructed a first-order Markov-chain population model for two populations, one captive and one wild, and we used stochastic dynamic programming to identify optimal state-dependent strategies. The model recommends unique sequences of optimal management actions over several years. A robust rule of thumb for species that can increase faster in captivity than in the wild is to capture the entire wild population whenever the wild population is below a threshold size of 20 females. This rule applies even if the wild population is growing and under a broad range of different parameter values. Once a captive population is established, it should be maintained as a safety net and animals should be released only if the captive population is close to its carrying capacity. We illustrate the utility of this model by applying it to the Arabian oryx (*Oryx leucoryx*). The threshold for capturing the entire Arabian oryx population in the wild is 36 females, and captive-bred individuals should not be released before the captive facilities are at least 85% full.

1330: +.083

We developed an interactive management model for wild and captive populations of the ploughshare tortoise or angonoka, *Geochelone yniphora*. Interactive management is based on the translocation of individuals between wild and captive populations to simulate a metapopulation. Demographic parameters of one captive and two wild populations of this rare tortoise were used to conduct a metapopulation viability analysis (MVA). The effectiveness of the conservation strategy proposed for this species was then evaluated by modifying the probability of extinction and growth of the metapopulation over a fixed period of time. Several alternative scenarios of interactive management were then tested and ranked in terms of their effect on the viability of the metapopulation. The model predicted that catastrophic events such as bush fires would likely have a negative effect on the future of remaining wild populations. However, the model also predicted that the use of captive-born offspring to establish additional wild populations would decrease the risk of extinction of the metapopulation as a whole. We believe that, when supported by sound knowledge of the demographic parameters of a species, the use of MVA as part of an interactive management program can be an effective conservation tool that allows assessment of the probable response of both captive and wild populations to different management alternatives. One of the most interesting aspects of this interactive management approach is the link between in situ and ex situ conservation. (C) 2004 Elsevier Ltd. All rights reserved.

1331: +.297

The maintenance of wild populations of Greater Rhea (*Rhea americana*) through effective management requires an understanding of their habitat requirements in terms of vegetation composition and field configuration. We studied the relative influence of some anthropogenic variables (presence of route, house and fences) and resource variables (presence of water source, composition and coverage of plant species, vegetation height and bare soil), on the habitat use by a population of rheas in a cattle ranch of Buenos Aires Province, Argentina. Habitat use was determined indirectly by documenting the number of faeces in summer, autumn-winter and spring 1999. The presence or absence of faeces was related to the measured variables through discriminant analysis that allowed the elaboration of predictive models of habitat use by this species. Contrary to what was expected, those variables related to human activity showed a low

predictive value on the habitat use by rheas when compared with resource variables. Rheas preferentially selected the stream area in all seasons and sites with great percent cover of *Bupleurum* sp., *Phyla canescens*, *Sida leprosa*, *Plantago lanceolata*, *Trifolium repens*, *Lolium multiflorum*, *Stipa* spp., and *Stenotaphrum secundatum*. Low vegetation height was another important component of rhea's habitat in summer and autumn-winter. The high accuracy level obtained by validation tests of this model supports its utility for the management of rhea populations in other cattle ranches of the region, and to analyze the suitability of other ranches for reintroduction programs. (C) 2004 Elsevier Ltd. All rights reserved.

1332: +.274

To assess the feasibility of restoring an extirpated species, it is crucial to identify the method of reintroduction that optimizes juvenile survival and growth so that adequate adult populations may be established. Because Atlantic salmon *Salmo salar* fry are relatively expensive to rear, we compared the efficacies of two embryo-stocking methods and one fry-stocking method in producing age-0 Atlantic salmon parr in the Salmon River, New York. As measured by resulting part-densities, there were no differences in survival rates between embryos stocked with and without protective hatching boxes; the mean Survival of embryo-stocked fish to late summer was less than 0.01 %. Fry stocking produced significantly greater densities of late-summer parr than did embryo stocking, with site-specific Survival ranging from 0 to 8%; the mean survival of fry was 2%. Considering the hatchery costs of rearing each life stage, the labor involved in stocking, and the resulting late-summer parr abundances, we recommend planting fry rather than embryos as a method of reintroducing Atlantic salmon. Additional studies are needed to evaluate the success of stocking older life stages of Atlantic salmon in the Salmon River, although factors other than juvenile survival are probably important in establishing and maintaining a spawning Population.

1333: +.108

Conservation efforts in the United Kingdom have increasingly sought to restore the populations and ranges of birds affected by changes to their habitat or by direct human persecution. One approach is reintroduction, although this is likely to be appropriate in only a limited set of circumstances, involving a small number of species. This paper reviews the use of reintroduction as a tool for conserving birds associated with lowland farmland, highlighting the benefits of this approach to conservation, as well as the potential dangers. Two case studies are presented to illustrate how different reintroduction techniques are required, depending on the species involved and the donor stock available. The internationally agreed, though not legally binding, IUCN guidelines for reintroduction projects are summarized, together with the requirements of The Wildlife & Countryside Act (1981) in relation to the release of birds into the wild in Britain. Potential changes to current legislation are suggested, to prevent inappropriate and potentially damaging reintroduction projects from being carried out in the future.

1334: +.187

To organize and prioritise species-specific conservation efforts, we delineate 'functional conservation units' for the threatened Alcon Blue butterfly *Maculinea alcon* in Belgium. We used detailed distribution data on the butterfly, its host plant and its habitat, present-day population sizes and its mobility and colonization capacity to determine functional conservation units (FCUs) on different spatial scales: FCU-1, i.e., the 12 presently occupied habitat patches plus the area within a range of 500 m surrounding them (the maximum local movement distance, based on mark-release-recapture data), FCU-2, i.e., the areas within a range of 2 km around the occupied habitat

patches (the maximum observed colonization capacity) and FCU-3, i.e., potential re-introduction sites (sites where *M. alcon* went extinct recently). We suggest different management and planning measures for each type of functional conservation unit and discuss translocation and re-introduction as 'intensive care' conservation measures for this threatened and sedentary species. (C) 2004 Elsevier Ltd. All rights reserved.

1335: +.007

The bearded vulture *Gypaetus barbatus* is a large, long-lived osteophagous vulture whose abundance and breeding range have drastically declined during the last century, making it one of the most endangered European bird species. We evaluated the extinction risk of the bearded vulture population in Corsica (a small, isolated breeding population of 8-10 pairs), one of the last extant populations in Western Europe, and estimated its probability of extinction to be 0.165 over the next 50 years. A sensitivity analysis to assess the influence of uncertain demographic rates showed that it is critical to estimate precisely the values of pre-adult survival. Neither the type nor the parameters of density dependence acting on fecundity and survival rates influenced much the extinction risk of the Corsican population. We evaluated the effect of four realistic conservation actions that could be implemented on the Corsican bearded vulture population and rank them in terms of their respective decrease of the current extinction risk faced by this population. We found that the release of two juveniles every other year for 12 years and the increase of fecundity due to selective food provisioning would reduce by more than one-half the current extinction risk of Corsican bearded vulture population. In contrast, even substantial increases in the carrying capacity through large supplemental feeding produced very modest decreases in the extinction risk, thus calling into question the efficacy of one of the main pan-European conservation strategies for this species. Reestablishing a population network within the Mediterranean could be a potentially better strategy, though its efficacy depends on natal dispersal among populations that is currently unknown. (C) 2004 Elsevier Ltd. All rights reserved.

1336: +.255

Knowledge of the causes of success or failure in introductions may provide information to help improve the chances that re-introductions succeed. However, the utility of this information will be influenced by the comparability of sets of introduced and re-introduced species. Here, we assess the extent of this similarity using recent historical data on introduced and re-introduced birds. Introductions are less often threatened than expected and have larger ranges and earlier ages at maturity than re-introductions. Introductions also generally have 'weedy' life-history characteristics relative to family-typical values, whereas those of re-introductions more closely conform to these typical values. However, introductions and re-introductions do not differ in migratory behaviour, mating system or dichromatism, nor do they show statistically consistent differences in body mass, incubation time or annual fecundity. The taxonomic composition of the lists of introductions and re-introductions is similar, with more species than expected on both lists. Overall, these results suggest that the characteristics of introductions and re-introductions are sufficiently similar that conclusions from studies of the former may reasonably be used to inform studies of the latter.

1337: +.159

Island populations are an interesting dichotomy in conservation biology. On the one hand, they can be a refuge for species where mainland populations have been decimated by loss of habitat and predation by exotic predators. On the other hand, island populations usually have reduced genetic

diversity and are more susceptible to extinction through genetic and demographic processes. Genetic variation and morphological characters were measured for island and mainland populations of *Parantechinus apicalis*, small dasyurid marsupials, restricted to southwest Australia. Genetic variation at seven microsatellite loci revealed low levels of heterozygosity ($H_e = 0.20 - 0.44$) and high levels of inbreeding ($F_e = 0.40 - 0.72$) in island populations compared with the mainland population ($H_e = 0.73$). A nested clade analysis revealed that allopatric fragmentation was probably responsible for the association between geographical location and control region haplotypes, which is consistent with the isolation of populations on islands and indicative of two main populations of *P. apicalis* representing separate conservation units for management. While these results are typical of many island populations, they have important implications in terms of the conservation of threatened species in Australia and around the world, where island populations are a common source of founders for captive breeding and translocation to mainland sites.

1338: +.179

The endemic pink pigeon has recovered from less than 20 birds in the mid-1970s to 355 free-living individuals in 2003. A major concern for the species' recovery has been the potential genetic problem of inbreeding. Captive pink pigeons bred for reintroduction were managed to maximise founder representation and minimise inbreeding. In this paper, we quantify the effect of inbreeding on survival and reproductive parameters in captive and wild populations and quantify DNA sequence variation in the mitochondrial d-loop region for pink pigeon founders. Inbreeding affected egg fertility, squab, juvenile and adult survival, but effects were strongest in highly inbred birds (F greater than or equal to 0.25). Inbreeding depression was more apparent in free-living birds where even moderate levels of inbreeding affected survival, although highly inbred birds were equally compromised in both captive and wild populations. Mitochondrial DNA haplotypic diversity in pink pigeon founders is low, suggesting that background inbreeding is contributing to low fertility and depressed productivity in this species, as well as comparable survival of some groups of non-inbred and nominally inbred birds. Management of wild populations has boosted population growth and may be required long-term to offset the negative effects of inbreeding depression and enhance the species' survival.

1339: +.023

Large blue (*Maculinea*) butterflies are highly endangered throughout the Palaearctic region, and have been the focus of intense conservation research(1-3). In addition, their extraordinary parasitic lifestyles make them ideal for studies of life history evolution. Early instars consume flower buds of specific host plants, but later instars live in ant nests where they either devour the brood (predators), or are fed mouth-to-mouth by the adult ants (cuckoos). Here we present the phylogeny for the group, which shows that it is a monophyletic clade nested within *Phengaris*, a rare Oriental genus whose species have similar life histories(4,5). Cuckoo species are likely to have evolved from predatory ancestors. As early as five million years ago, two *Maculinea* clades diverged, leading to the different parasitic strategies seen in the genus today. Contrary to current belief, the two recognized cuckoo species show little genetic divergence and are probably a single ecologically differentiated species(6-10). On the other hand, some of the predatory morphospecies exhibit considerable genetic divergence and may contain cryptic species. These findings have important implications for conservation and reintroduction efforts.

1340: +.063

Published data, recent surveys and studies of museum specimens are combined to provide a list of

84 fishes for South Australia in five drainage divisions. The list includes 58 native species (44 restricted to freshwater) and 26 alien species. Seven endemics are recognised, namely *Chlomydogobius eremius* (Zeitz), *Chlomydogobius gloveri* Larson, *Craterocephalus dalhousiensis* Ivanstoff & Glover, *Craterocephalus eyresii* (Steindachner), *Craterocephalus gloveri* Crowley & Ivanstoff, *Mogurnda thermphila* Allen & Jenkins and *Neosilurus gloveri* Allen & Feinberg. New records are reported for *Craterocephalus stercusmuscarum* (Gunther), *Galaxias trutaceus* Valenciennes and *Neochanna cleaveri* (Scott), and a terapontid of uncertain status also is noted. Range extensions are reported for *Nannoperca obscura* (Klunzinger), *Nannoperca australis* Gunther and an undescribed species of *Hypseleotris*, and the presence of *Galaxias olidus* Gunther and *Galaxias brevipinnis* Gunther in particular regions is confirmed. Possible extirpations are reported for *Ambassis agassizii* Steindachner, *Gadopsis marmoratus* Richardson, *Galaxias rostratus* Klunzinger, *Maccullochella macquariensis* (Cuvier), *Macquaria australasica* Cuvier, *Mogurnda adpersa* (Castelnau), *Neochanna cleaveri* and *Prototroctes maraena* Gunther. There is need for further evaluations of fish distributions, better systematic frameworks, clarifications of conservation status, reviews of the introduction and impacts of alien species and development of protective measures for fish species and communities and their ecosystems.

1341: +.038

The Tuamotu Sandpiper or Titi is the only surviving member of the Tribe *Prosoboniini* and is confined to eastern Polynesia. Formerly distributed throughout the Tuamotu Archipelago, it has been decimated by mammalian predators which now occur on nearly all atolls of the archipelago. Isolated sandpiper populations are currently known from only four uninhabited atolls in the Tuamotu. Only two of these are currently free of mammalian predators, such as cats and rats, and the risks of rat invasion on them are high. This paper outlines tasks necessary in the short term (within five years) to secure the species, together with longer term actions needed for its recovery. Short-term actions include increasing the security of existing populations, surveying for other potential populations, eradicating mammalian predators on key atolls, monitoring key populations, and preparing a recovery plan for the species. Longer term actions necessary for recovery include reintroductions, advocacy and research programmes.

1342: -.092

Line-transect surveys were conducted at a small remnant of semideciduous Atlantic Forest to estimate primate density and population size. The Mata Sao Jose has about 230 ha and it is located between Rio Claro and Araras (Sao Paulo State, southeastern Brazil). This forest fragment holds 23 non-volant mammal species distributed in seven orders and 13 families. From July 1999 to January 2001, a total of 125 km were walked and three primate species were recorded. The densities were estimated based on Distance software. Brown capuchin monkey *Cebus nigritus* (Goldfuss, 1809) (Cebidae) presented the highest population density (24.5 individuals/ km², ranging between 19.6 and 32.6 individuals/ km²). Titi monkeys *Callicebus nigrifrons* (Spix, 1823) (Pitheciidae) and tufted ear marmosets *Callithrix aurita* (E. Geoffroy, 1812) (Callitrichidae) presented 3.5 individuals/ km² (ranging between 2.8 to 4.6 individuals/ km²). Total population size of brown capuchin monkeys was 56 individuals (ranging between 45 to 75 individuals) and the titi monkeys and tufted ear marmosets were eight individuals (ranging between six to 10 individuals). Titi monkeys and tufted ear marmosets are vulnerable to extinction and both persist at Mata Sao Jose, but at low population densities. These primate species are at local extinction risk, because populations at low densities are more susceptible to stochastic events, inbreeding depression and environmental variation. Translocation is the only plausible management action that could avoid local extinction of these primates.

1343: +.118

Recent losses and fragmentation of tallgrass; prairie habitat to agriculture and urban development have led to corresponding declines in diversity and abundance of plants and birds associated with such habitat. Mowing and burning are alternative management strategies for restoring and rejuvenating prairies in fragmented landscapes, but their specific, comparative effects are the subjects of ongoing evaluation. We compared the responses of plant and bird communities on four sets of mowed, burned, and untreated sites of small (3-10 ha), fragmented tallgrass prairies at the DeSoto National Wildlife Refuge (DNWR), Iowa, U.S.A., during May-July in 1998 and 1999. Species richness and diversity of plants, resident grassland birds, and communities of birds associated with grassland edges (edge species) were independent of treatment. Although not affecting species richness and diversity in plant communities, mowed sites ranked lower in total plant coverage and total forb coverage than burned sites or untreated sites. In contrast, untreated sites had more coverage by shrubs, suggesting that mowing and burning did retard shrub encroachment. Overall, abundance and diversity of plants and birds were generally insensitive to management strategies. Small, fragmented sites of rare habitat may not respond in the short term to management treatments and may not be capable of supporting highly diverse communities, no matter how intensively manipulated. It is more probable that diversity of native prairie communities can be enhanced and restored only through long-term efforts, acquisition of large land units capable of supporting stable populations, and deliberate reintroduction of species of high conservation value.

1344: +.119

In the past, the otter (*Lutra lutra*) was a predator in Dutch freshwater ecosystems. Due to hunting, fishing, destruction and fragmentation of its habitat, pollution, traffic mortality and disturbances due to recreation, the otter became extinct. Fourteen years after extinction, the otter has been reintroduced in the Weerribben, an area in the northwest of Overijssel province. There was much discussion about releasing otters in the Netherlands. This paper discusses the reintroduction project in the light of the IUCN (international Union for Conservation of Nature and Natural Resources) guidelines, which are internationally recognized and applied in many reintroduction projects. The IUCN guidelines stress the importance of biodiversity and public nature conservation awareness (important in a highly populated country as the Netherlands). The guidelines stipulate that the former causes of death should have been removed or minimised in the release area and that the chances of a spontaneous recolonisation by otters, sufficient to establish a viable population, should be small. Capturing otters for reintroduction should not have negative effects, the released otters should be genetically similar to the extinct otter population and the project has to be monitored. Assessment of the project to reintroduce otters into the Netherlands shows that that the IUCN guidelines were followed.

1345: +.177

1. Species undergoing reintroduction offer a unique opportunity for clarifying their specific niche requirements because they are likely, if sufficiently mobile, to colonize the most suitable habitats first. Information drawn from the individuals released first might thus be essential for optimizing species' policy as reintroductions proceed. 2. Bearded vultures were extirpated from the European Alps about a century ago. An international reintroduction programme using birds reared in captivity was launched in 1986; up to 2003, 121 individuals had been released at four different locations. Subsequent dispersion throughout the range has been far from homogeneous, resulting in a clumped occurrence of the first breeding pairs within three main zones that do not necessarily

coincide with release areas.³ In order to discern ecological requirements we performed a geographical information system (GIS) analysis of bearded vulture sightings collected in Valais (Swiss Alps) from 1987 to 2001. This area harbours no release site, is situated in the core of the Alpine range and has been visited by birds from all four release points.⁴ During the prospecting phase (1987-94, mostly immature birds), the most important variable explaining bearded vulture distribution was ibex biomass. During the settling phase (1995-2001), the presence of birds (mostly maturing subadults) correlated essentially with limestone substrates, while food abundance became secondary.⁵ The selection of craggy limestone zones by maturing bearded vultures might reflect nesting sites that are well protected against adverse weather, as egg laying takes place in the winter. Limestone landscapes, in contrast to silicate substrates, also provide essential finely structured screes that are used for bone breaking and temporary food storage, particularly during chick rearing. Finally, limestone substrates provide the best thermal conditions for soaring.⁶ Synthesis and applications. Extrapolated to the whole Alpine range, these findings might explain both the current distribution of the subadult/adult population and the absence of breeding records for bearded vultures around release sites in landscapes dominated by silicate substrates. As reintroduced bearded vultures tend to be philopatric, we suggest that population restoration would be more efficient if releases were concentrated within large limestone massifs. This case study of the bearded vulture illustrates the need for continual adaptive management in captive release programmes.

1346: +.105

The National Trust for the Cayman Islands has been implementing conservation efforts for *Cyclura lewisi* since 1990. Commencing with small-scale captive breeding, the program has expanded to include field research, large-scale captive breeding and head-starting, reintroduction and restocking, habitat protection and management, education, and awareness activities. A formal species recovery plan is in place. In the past 12 years, the size of the wild population appears to have declined from 100-200 to 10-25 animals and is functionally extinct. Principal causes for the decline are habitat loss, predation by introduced mammals, road kills, and continued exploitation by humans. Reproduction in the wild by animals released from the captive breeding population has been confirmed. However, in order to assure the greatest possible genetic diversity within the captive population, wild individuals with potentially distinct genetic constitutions must be captured and assessed before their genes become diluted as a consequence of interbreeding with released animals. Goals of 100 hatchlings and approximately 100 two-year-old iguanas for release annually are being approached. Options for restoring self-sustaining wild populations are limited to habitat islands, for which perimeter fencing will be essential to restrain iguanas and exclude predators. The recovery program is operating on institutional grants, program-generated income, and private donations, but we hope that this charismatic lizard will become able to support its own survival through carefully managed tourism activities and related commerce.

1347: +.086

The use of relocations, repatriations and translocations as amphibian and reptile conservation strategies has received much debate. In the case of endangered species, their use may outweigh the potential negative consequences. We performed an experimental repatriation of the eastern massasauga (*Sistrurus catenatus catenatus*), which has experienced range-wide population declines and extirpations. The experiment included measures to minimize negative conspecific effects to the donor populations as well as inter-species effects on the release and donor sites. Snakes released during late July had lower mortality rates, larger home ranges, and gained more mass than snakes released in early September. The July release cohort also successfully reproduced, while no

breeding activity was observed with September release snakes. Results of this study suggest that repatriation may be a viable method of restoring eastern massasauga populations. We hope the methods and conservation measures used in this experiment will serve as a template for future repatriations.

1348: +.057

The need for an individual-based approach in genetic management for game species has been identified and generally welcomed by a wide spectrum of stakeholders in the South African game industry. Different levels of "intensive breeding" exist in the game industry. At the one extreme would be the closely controlled captive breeding programmes for carnivores such as white lions, *Panthera leo*, cheetah, *Acinonyx jubatus*, and wild dogs, *Lycaon pictus*. It is generally acknowledged that a system approaching a domestic stud book would be justified for these programmes, and such databases are already in place for some species. At the other end of the scale are the game-farm populations of moderately valuable antelope species, for example tsessebe, *Damaliscus lunatus*, and nyala, *Tragelaphus angasi*, where individual genetic information is probably neither necessary nor feasible. It is in the area between these two extremes where the concept of individual genetic information was investigated. Examples are the white rhino, *Ceratotherium simum*, African buffalo, *Syncerus caffer*, and the valuable populations of species from the Hippotraginae, roan antelope, *Hippotragus equinus*, and sable antelope, *Hippotragus niger*. An accurate National Genetic Database for game species based on individuals can contribute to issues such as the retention of genetic diversity, avoidance of hybridization, the conservation of evolutionary significant units (ESUs), regulation of translocations, avoidance of inbreeding and to parentage verification. The database contributes to the development and application of cross-species and species-specific microsatellite marker sets, the expansion of a national BIOSSTORE and the application of these tools for the forensic analyses of poaching cases. It can also ultimately result in a reference sequence database for all game species at a national level.

1349: +.060

Pre-Euro-American settlement forest structure and fire regimes for Jeffrey pine-white fir, red fir-western white pine, and lodgepole pine forests in the Lake Tahoe Basin (California and Nevada, USA) were identified using stand structural analysis and fire scars based on measurements of stumps of trees that were cut in the 19th century. Comparisons of the presettlement reference with contemporary conditions were then used to determine how and why contemporary conditions deviate from presettlement conditions and to guide ecological restoration. Contemporary forests varied in different ways compared to the presettlement reference. Contemporary Jeffrey pine-white fir forests have more and smaller trees, more basal area, less structural variability, and trees with a more clumped spatial distribution than presettlement forests. The mean presettlement fire-return interval for Jeffrey pine-white fir forests was 11.4 yr, and most (>90%) fires burned in the dormant season; no fire was recorded in the study area after 1871. Similar differences were identified in the structural characteristics of contemporary and presettlement red fir-western white pine and lodgepole pine forests. However, 19th-century logging changed the composition of red fir-western white pine forests, and these forests now have more lodgepole pine than red fir or western white pine. Comparison of contemporary forests with the presettlement reference suggests that restoration treatments in Jeffrey pine-white fir forests should include: (1) density and basal-area reduction, primarily of smaller diameter trees; (2) reintroduction of frequent fire as a key regulating disturbance process; and (3) increasing structural heterogeneity by shifting clumped tree distributions to a more random pattern. Restoration treatments in red fir-western white pine

forests should include: (1) a shift in species composition by a density and basal-area reduction of lodgepole pine; and (2) increasing structural heterogeneity by shifting tree distributions to a more random pattern. In lodgepole pine forests the restoration emphasis should be: (1) a density and basal-area reduction of small-diameter trees; and (2) an increase in structural heterogeneity that shifts tree spatial patterns from clumped to a more random distribution. Reintroduction of fire as a regulating process into high-elevation red fir-western white pine and lodgepole pine forests can be viewed as a longer-term restoration goal. The method for quantifying presettlement reference conditions from stumps complements, or is an alternative to, methods based on dendroecology or repeat photography.

1350: +.121

The White-winged Guan (*Penelope albipennis*) is a cracid endemic to the Northwestern Peruvian dry forests that is critically endangered due to poaching pressure and habitat loss. In the year 2000, a species reintroduction program was established which consisted in the release of captive born and raised animals from the Barbara D'Achille captive breeding center. The guans were released in areas where the species had disappeared and that were safe for reintroduction and conservation. Between September 2001 and July 2003, 20 White-winged Guans were released at the Chaparri Private Conservation Area, Lambayeque, Peru. The bird's adaptation to the area was measured through its dispersion, survival and reproduction. Based on the measured dispersion distance, it has been found that it is actually feasible to link the reintroduced population with the surrounding wild populations. Survival has been established at 55 %, measured two years after the animals were released. With respect to reproduction, 3 wild-born chicks were born from reintroduced parents.

1351: +.149

Case studies are presented for the western ringtail possum, *Pseudocheirus occidentalis*, and the quokka, *Setonix brachyurus*. The ringtail case study summarises information from a recent review of the species' distribution and conservation status, collates information on ringtail populations within the areas covered by the Department of Conservation and Land Management's (CALM) fauna recovery program, Western Shield, and draws extensively on the recent findings from translocation programs. Critical to the case study is the finding that (i) monitoring of the response to fox control programs is poor, or non-existent, at all known sites, with the exception of research specific translocation sites. This may reflect the difficulty in censusing and monitoring this species; and (ii) translocation success has not been demonstrated at any translocation release site and the primary translocation site, Leschenault Peninsula Conservation Park, has suffered a significant population decline. Hypotheses are proposed to explain this decline and, in the absence of demonstrated translocation success, critical components for monitoring western ringtail possum translocations are recommended. Monitoring protocols are also recommended for other extant populations within the species' geographic range. The quokka case study also summarises information from a recent review of the species' distribution and conservation status and collates information on quokka populations within the areas covered by Western Shield. The case study also draws extensively on the findings from recent research from the northern jarrah forest. As for the ringtail case study, the quokka case study found monitoring is non-existent or poor, or, ad hoc at best, at all known sites, with the exception of research specific sites within the northern jarrah forest. Consistent with recently published research findings, intervention management is recommended at these northern jarrah forest sites. An active adaptive management framework, using fire as a tool to create the preferred structural habitat mosaic, is recommended. Both case studies highlight the need to review data collection, collation, analyses and reporting processes to

ensure data are collected in a manner to allow objective analyses and scrutiny. Under this proposed scenario, any conservation gains can be quantified and documented. Conversely, in circumstances where desired outcomes have not been met, the failure to meet set goals can be identified and mechanisms can be implemented to improve conservation management.

1356: +.050

The effects of seasonal prescribed fire on the belowground ectomycorrhizal community and live fine root biomass were investigated before, 1 year after, and 2 years after prescribed underburning. Ectomycorrhizas were sampled from four replications of three treatments (fall underburning, spring underburning, and a nonburned control) in a randomized complete block design. Samples were separated in two subsamples representing the upper 5 cm and lower 5 cm of a soil core. Molecular tools were used to distinguish 140 restriction fragment length polymorphism (RFLP) species of fungi directly from the ectomycorrhizas. Prior to underburning, the number of RFLP species and amount of live root biomass were similar among treatment units and between upper and lower core samples. Fall underburning largely removed live root biomass to a depth of 10 cm and significantly reduced ectomycorrhizal species richness compared with spring underburning and the nonburned control for at least 2 years. RFLP species richness and live root biomass following spring underburning were generally similar to the nonburned treatment. The successful reintroduction of fire to the ecosystem to retain high species diversity of ectomycorrhizal fungi and achieve the desired future condition of large-tree ponderosa pine retention with low fuel loads may require more than underburning in a single season.

1357: +.038

Translocation of European wild rabbit *Oryctolagus cuniculus* L. is one of the most frequent management tools to increase rabbit density in Spain, both as prey of several predators that are threatened with extinction and for sport hunting. Nevertheless the elevated short-term mortality by predation makes translocations unsuccessful and increases their biological cost. Information on the factors affecting the short-term survival and dispersal of translocated rabbits is required to improve release management and increase performance of translocated rabbits, and to avoid the use of non-selective lethal methods for predator control. In this study we tested electric fencing and night-shooting as alternative to traditional release protocols, and the effects of vegetation cover and warren fencing on short-term survival and dispersal of rabbits. Night shooting performed during the first nights after release increased significantly the survival of rabbits, by hindering the activity of carnivores in the release area. The use of an electric fence enclosure also increased the performance of rabbits, but was not efficient to constraint rabbit dispersal. Rabbits released in areas with low vegetation cover showed higher mortality and dispersal distances than rabbits released in high cover areas. Warren fencing decreased both the dispersal of rabbits and the adverse impact of predation in low cover areas, but had no effect in high cover areas. Selection of high cover areas or warren fencing in low cover areas seem to be the most advantageous release conditions to decrease the short-term predation impact, reducing the biological cost of rabbit translocations and the risks for endangered predators derived from the use of traditional predator control practices during translocations. 1358: +.073

There is increasing evidence that culture is an important determinant of behavior in some non-human species including great apes and cetaceans (whales and dolphins). In some cases, there may be repercussions for population biology and conservation. Rapidly evolving "horizontal" cultures,

transmitted largely within generations, may help animals deal with anthropogenic change and even allow them to exploit it, sometimes with negative consequences for both the animals and humans. In contrast, stable "vertical" or "oblique" cultures, transmitted principally between generations, may impede adaptation to environmental change, and confound range recovery, reintroductions and translocations. Conformist stable cultures can lead to maladaptive behavior, which may be mistaken for the results of anthropogenic threats. They can also structure populations into sympatric sub-populations with distinctive cultural variants. Such structuring is common among cetaceans, among which sympatric sub-populations may face different anthropogenic threats or respond to the same threat in different ways. We suggest that non-human culture should be integrated into conservation biology when considering populations with such attributes, and also more generally by refining definitions of evolutionarily significant units and considering how cultural attributes may change our perspectives of non-humans. (C) 2004 Elsevier Ltd. All rights reserved.

1359: +.111

Pond-breeding amphibians require aquatic and terrestrial habitats to complete their lifecycles, and preservation of both habitats is necessary for maintaining local populations. Current wetland regulations focus primarily on aquatic habitats, and criteria to define critical upland habitats and regulations to protect them are often ambiguous or lacking. We examined the association between the presence of seven pond-breeding amphibian species and the landscape composition surrounding 54 wetlands located within the Till Plains and the Glaciated Plateau ecoregions of Ohio, USA. We quantified landscape composition within 200 m of the wetland ("core terrestrial zone") and the area extending from 200 m to 1 km from the wetland ("broader landscape context zone"). We constructed binary logistic regression models for each species, and evaluated them using Akaike Information Criterion. Presence of spotted salamanders (*Ambystoma maculatum*), Jefferson's salamander complex (*A. jeffersonianum*) and smallmouth salamanders (*A. texanum*) was positively associated with the amount of forest within the core zone. Presence of wood frogs (*Rana sylvatica*) was positively associated with the amount of forest within the core zone and the amount of forest within the broader landscape context zone. Presence of tiger salamanders (*A. tigrinum tigrinum*) was negatively associated with the cumulative length of paved roads within 1 km of the site, and presence of red-spotted newts (*Notophthalmus v. viridescens*) was negatively associated with the average linear distance to the five nearest wetlands. Overall salamander diversity was positively associated with the amount of forest within the core zone, and negatively associated with the presence of predatory fish and cumulative length of paved roads within 1 km of the site. Our results confirm the strong association between the structure of surrounding upland areas and amphibian diversity at breeding ponds, and stress the importance of preserving core terrestrial habitat around wetlands for maintaining amphibian diversity. (C) 2004 Elsevier Ltd. All rights reserved.

1360: +.191

In this paper we discuss the history of the koala and possum fur trade in Queensland, based mainly on material in Queensland Government archives, and review the development of legislation and wildlife management practices. The koala and possum harvests arose in response to a large increase in the abundance of koalas and possums in mid to late 19th century. A marked increase in skin prices in the early 20th century provided further stimulation to the harvests. Harsh rural conditions and economic downturns further raised interest in harvesting and the government regularly came under pressure to open trapping seasons for economic reasons. Regulated koala harvests operated intermittently from 1906 to 1927, whereas possum harvests were held more

frequently and over a longer period, from 1906 to 1936. Fluctuation in demand was a major influence on the industry, leading to the expansion of the industry after 1900, and the eventual demise of the possum industry in the 1930s. Strong demand over about three decades resulted from a range of factors influencing the international fur markets, associated in particular with warfare and economic conditions after World War I. Successive Queensland governments supported the harvest because of its economic value, despite having serious concerns about the viability of the koala harvest. The legislation to control the harvest was aimed at protecting possums and koalas from extinction and establishing a sustainable industry. The principal legislative devices used to manage the harvest were close seasons and establishment of sanctuaries, supported by various other measures. Animals were taken by baiting (cyanide), snaring and shooting. Control measures were ineffective in preventing breaches of the regulations, and widespread take occurred during close seasons. The Department of Agriculture and Stock attempted to manage the trade as a sustainable harvest, with annual assessment of populations, and determination of open seasons in response to population levels and market conditions. The harvest was supported by population conservation measures including the establishment of reserves and attempts to conserve populations with a restocking (translocation) program for both koalas and possums in areas thought to be over-harvested. Koalas and possums were translocated to a number of mainland sites and onto islands. The take of possums ranged from about 400,000 to 3,000,000 per annum and that of koalas from about 450,000 to nearly one million. In good seasons, top quality skins could bring at least 60 shillings per dozen. The poorest quality skins brought as little as 2(1)/(2) pence each. The industry was of considerable economic value, generating personal incomes substantially greater than the income from wages of many workers, and total returns comparable to those of the annual sales of gold for the State. The total number of trapping permits issued in a season varied from about 8,000 to over 9,000. Governments had serious reservations about the koala harvest, but supported the possum harvest much more strongly. Possum harvests were held more frequently, generated more income, and made an important contribution to the economy. Strong community opposition to koala harvests first arose in 1919, effectively signalling the end of the harvest for that species. By 1936, community opposition to the possum seasons had also become established. There was a market downturn at the same time and the possum harvest came to an end. Significant community opposition to harvests of both species arose in both urban and rural areas, the latter mainly because harvests were seen as interfering with grazier interests, causing death of stock from cyanide baits and disturbance to stock by shots and spotlights.

1361: +.107

Alagoas Curassow *Mitu mitu* has long been subjected to taxonomic discussions as to its validity as a full species or as a member of a polytypic assemblage which includes the Razor-billed Curassow *Mitu tuberosum*. In this paper we review the history of this highly threatened taxon (now extinct in the wild) endemic to north-eastern Brazil, including summarising and mapping known localities for the species. We analyse and discuss all previously published proposed diagnostic characters for *M. mitu* and confirm its validity as a full species based on diagnostic characters of a bicoloured bill, bare auricular patch, tawny-tipped tail and nearly all-black central rectrices (molecular evidence also support this conclusion). We detail surveys carried out in north-eastern Brazil in October-November 2001 which were unsuccessful in finding extant populations of *M. mitu* but encountered widespread hunting and some wood extraction in the few remaining forest blocks. There is, however, landowner Support for protecting the remaining forests in the majority of areas. The captive population history and management is given including information on current location and provenance. Before reintroduction of *M. mitu* to the wild is possible many conservation measures will be needed at the chosen forest location, including better protection, monitoring, and educational work with local people.

1362: +.127

Small founder populations of whooping cranes are managed to maximize egg production for the purpose of reintroducing young to the wild. This results in an excessive number of hatched chicks that cannot be naturally reared by parents. Hand-rearing techniques have been developed to raise the additional hatches. However, hand rearing may affect the behavior of the birds and their chances of survival later in life. The objectives of this study were to determine the impact of rearing practices on the behavior of whooping crane chicks. The birds were reared under three commonly used rearing techniques: parent reared (PR), hand reared (HR), and hand reared with exercise (HRE). Fifty-six whooping crane chicks were observed by focal animal sampling from hatch to 20 weeks of age. During these observations, occurrences of comfort behavior, aggression, foraging, nonvigilance, sleep, vigilance, and other types of behavior were collected. Data were analyzed using mixed models repeated measures analysis of variance (ANOVA). Behavior was affected by rearing treatment, age, and time of day. PR birds spent more time being vigilant than HR and HRE birds. An inverse correlation was found between percentage of time foraging and vigilant ($r = -0.686$, $P < 0.0001$). However, there were no differences in the behavior of birds reared in HR or HRE programs. (C) 2004 Published by Elsevier B.V.

1363: +.059

Aims This study was designed to compare levels of genetic variation and its partitioning in three related species of *Antirrhinum*, *A. subbaeticum*, *A. pertegasii* and *A. pulverulentum*, and to check the hypothesis that species with small total population size have lower levels of genetic variability than those with bigger ones. This information should contribute to the development of conservation strategies of rare endemic species of *Antirrhinum*. **Methods** One hundred and seventy-seven plants were screened for variability at 14 allozyme loci by means of horizontal starch gel. Parameters of genetic diversity, and its partitioning, were calculated. An indirect estimate of gene flow was based on the equation: $N_{ut} = (1 - G(ST))/4G(ST)$. **Key Results** Genetic variabilities in *A. subbaeticum* and *A. pertegasii* were found to be the lowest known for the genus, the within-population genetic diversity being correlated with population size in both species. The distribution of genetic diversity is strikingly different among species, with 85% of the total variation distributed among populations in *A. subbaeticum*, 6% in *A. pertegasii* and 23% in *A. pulverulentum*. Estimated levels of gene flow were negligible for *A. subbaeticum* (0(.04), high for *A. pertegasii* (3(.92), and substantial for *A. pulverulentum* (0(.83). Genetic and geographic distances were negatively correlated in *A. pertegasii*, whereas no significant correlation was found in the other two species. **Conclusions** Levels of total genetic diversity agree with the hypothesis that species with small total population size have lower levels of genetic variability than those with bigger ones. Strategies for the conservation of the species are recommended, such as preservation of natural populations and avoidance of possible causes of threat, as well as ex situ preservation of seeds, reinforcement of small populations of *A. subbaeticum* with plants or seeds from the same population, and avoidance of translocations among populations. (C) 2004 Annals of Botany Company.

1364: -.114

We used radioimmunoassay to determine fecal corticoid concentrations and assess potential stress in 10 endangered whooping cranes (*Grus americana*) undergoing reintroduction to the wild. Fecal samples were collected shortly after hatching at a captive facility in Maryland, during field training in Wisconsin, and throughout a human-led migration to Florida. After a 14-day decline following hatching, fecal corticoid concentrations stabilized at baseline levels for the duration of

the captive period, despite exposure to potentially stressful stimuli. Shipment of the cranes to the field training site was correlated with an eight- to 34-fold increase in fecal corticoid concentrations, which returned to baseline levels within 1 week. Increases were positively correlated with age but not body weight at the time of shipping. Fecal corticoid concentrations during the training period increased slightly and exhibited greater variation than levels observed at the captive facility, but were well within expected norms based on previous studies. Fecal corticoid concentrations increased twofold following premigration physical examinations and placement of radiotransmitters, and persisted for up to 4 days before they returned to baseline levels. Though fecal corticoid concentrations and variation during the migration period were similar to training levels, there was an overall decline in fecal corticoid concentrations during the artificial migration. Acute stressors, such as capture, restraint, and severe storms, were associated with stress responses by the cranes that varied in accordance with lasting physical or psychological stimuli. The overall reintroduction process of costume-rearing, ultralight aircraft habituation, training, and artificial migration was not associated with elevations in fecal corticoid concentrations suggestive of chronic stress.

1365: -.152

Conserving genetic diversity of rare and endangered species and their evolutionary potential is one of the long-term goals of ex situ conservation. Some potential genetic risks in ex situ conservation in botanical gardens are presented. The preserved species may lack genetic representativity because of poor sampling. Inappropriate plantations, inadequate records and unclear kinships jeopardize endangered species to genetic confusion, inbreeding depression or outbreeding depression. Artificial selection and habitat conversion also potentially result endangered plants in adapting to ex situ conservation, which had been usually overlooked. All the genetic risks can decrease the success of reintroduction and recovery. Therefore, appropriate genetic management should be carried out in botanical gardens to decrease or avoid genetic risks in ex situ conservation.

1367: +.115

A team of biologists and field assistants conducted, between January 2002 and May 2003, a survey on the status of the Iberian lynx in Portugal. The survey was performed on previously identified lynx areas, during studies carried out in the 1970-s and 1990-s. Intensive search for lynx scats, for DNA analysis, and camera trapping provided a basis for identifying potential lynx areas. Over 4200 km were covered during a global searching effort of 1975 man-hours. This effort resulted in the collection of 168 potential scats that were submitted to genetic validation with no positive lynx amplifications. Camera trapping was applied in a total effort of 5647 camera days, in three lynx potential areas. No positive detections were achieved. At the same time, a study on wild rabbit distribution reveals that most historical nuclei do not support lynx viable populations. Although we can not confirm extinction, the scenario is highly pessimistic. The Iberian lynx is presently in the verge of extinction. Intensive rabbit regression and massive habitat destruction are identified as the main causes of decline in recent decades. In the Portuguese lynx historical range, we could only identify significant areas suitable for lynx in the South-eastern part of the country, particularly in the Andalusian border, where we lack on recent evidence of lynx presence. Being aware of the considerable difficulties pointed above, the ICN developed a Conservation Action Plan for the Iberian lynx in order to provide a consistent and effective approach to conserve the species in Portuguese territory. This proposal describes guidance that retains future options, provides management consistent, offers necessary flexibility, in order to achieve the maximum goal of conserving the lynx in Portugal. Conservation measures have the goal of provide guiding

lines for conservations agents in order to conduct actions that can positively affect lynx and/or to help avoid negative impacts through thoughtful planning of activities. The proposal of Action Plan will be applied in all the areas located in the lynx historical distribution geographic area, that present suitable characteristics for the species presence or landscape features that can be optimized for lynx survival and that can be relevant for the species life-cycle, independently of their protection status. The goal of this plan is to apply pre-release strategic reintroduction activities to make possible, in a long-term, the reintroduction of Iberian lynx, in order to assure the viability of the species, as a fundamental element of Mediterranean ecosystems. For achieving this goal it will be necessary to establish a suitable connection between ex-situ and in-situ actions.

1368: +.239

In the article the state of international bison's total number has been demonstrated and the threat and actual problems of species preservation have been shown. The main conception of National Belorussian program on conservation, resettlement and using of the European bison (Program 'Bison') have been expounded. The metapopulation model of free-living bison's subpopulations with different status and regimes including main fund (insured) - for bison's from nature reserves and national parks and reserve fund - for animals inhabiting territories of general economic usage, are recognized more optimal and realistic. The results of first stage of program fulfilment have been summed up. In 1994 -2000 78 bison were caught in National park "Byelaya Vezha forest" and became the founder of 5 new centers of free-living subpopulations. The bison's reintroduction was successful. In centers bison's number has been reached 226 individuals in 2004. There are 610 individuals in Belarus compared with 347 before the start of the Program "Bison".

1371: +.165

American black bears (*Ursus americanus*) have been extirpated from all but a few areas in southwestern Alabama, and the remaining habitat is being rapidly lost to development. Remnant bear populations exist near extensive (> 125,000 ha) bottomland hardwood forests in the Mobile-Tensaw Delta (MTD), but those bottomland areas are rarely used by bears. Reintroduction of black bears to the MTD may improve viability of the remaining bear populations in southwestern Alabama. To evaluate the suitability of this area for bears, we compared habitat conditions at the MTD with similar alluvial habitats at White River National Wildlife Refuge (White River NWR), where bears are numerous. We measured overstory, midstory, and understory vegetation in the MTD and on the North and South management units at White River NWR. We used principal components analysis and principal variable selection to identify 9 variables associated with 5 principal components (hard mast, soft mast, cavity tree availability, large tree availability, and total basal area) that best explained variation among study areas. Differences among the study areas were associated with hard mast, soft mast, and cavity tree availability ($P \leq 0.001$). Hard and soft mast production in the MTD was lower than at White River NWR, but we believe it was adequate. However, suitable den trees, which may be a critical habitat component given the duration and severity of winter flooding, appeared to be lacking in the MTD.

1372: +.195

Few studies have documented intestinal parasites in populations of Neotropical primates, and many of those have been carried out on captive animals. This essay reviews the state of knowledge of intestinal parasites in primates focusing on Neotropical species. The factors that affect gastrointestinal infections in wild primates are presented, and the implications on the conservation of primates are discussed. The main factors that affect parasitic infections include primate density,

behaviour, age, reproductive condition and diet, as well as humidity and habitat fragmentation of the habitat. It is recommended that primate management and translocation programmes consider the age class structure of the groups and the availability of medicinal plant species as food. It is also important to determine which season is most appropriate for the translocation of primates. Taking these factors into account when designing management programs and making decisions about translocating primate groups will help deter the negative effects of intestinal parasitic infections and contribute to the successful conservation of primates.

1373: +.057

The grey partridge *Perdix perdix* species is divided into at least eight subspecies (Table 1), of which two exist in Finland. In this study, which is presented more detailed in English elsewhere (Liukkonen 2005), the mitochondrial DNA (mtDNA) control region I (CR1) of 138 wild and 36 captive grey partridges (Table 2, Fig. 2) was sequenced. Two separate mtDNA haplotype lineages were found hereafter referred to as the eastern and the western lineage. The dominant Finnish haplotype differed from the dominant European haplotype by 15 nucleotide substitutions (3.7%, Fig. 1). Both lineages included one core haplotype. The Finnish lineage dominated in the wild population (131/138 birds, 94.9%), whereas the European lineage dominated in the captive stock (32/36 birds, 88.9%). The eastern core haplotype was observed in 53 wild individuals (38.4 % of all wild bird samples) and it dominated in the South-Ostrobothnia subpopulation 42/90 individuals). Four birds of this haplotype were also found in the subpopulations of North Ostrobothnia and South Finland and three birds in subpopulation of SW Finland. Five western haplotypes were found among the farmed birds, and three among the wild birds in this addition to the dominant western haplotype. The greatest differences between populations were found between the wild and captive subpopulations (Table 3). The highest nucleotide and haplotype diversities were found in South Finland and in North Ostrobothnia, where individuals representing both lineages were found. The lowest nucleotide and haplotype diversities were found in South Ostrobothnia (Table 3). The analysis of molecular variance showed that 79.8% of the total variance was explained by the variation of birds within subpopulations and 20.2% by the variation between the different subpopulations. When the captive stock was included in the analysis, 67.0% of the variation was explained by the variation between the different subpopulations and 33.0% by the variation of birds within the subpopulations. According to the significant pair wise [PHI], STS (Table 3) captive birds differed from all the wild populations. South Ostrobothnia was different from the North Ostrobothnia and Southern Finland subpopulations, and SW Finland was different from North Ostrobothnia. These results clearly show that DNA CR1 in the native stock in Finland differs from that in the farm stock. No clear geographical structuring could be found in the distribution of separate haplotypes into different subpopulations. Some common haplotypes were found (ip, i8, Li, i11, Fig. 1), but several unique haplotypes were also found (i3, iS, i15). The pattern of one core, some common and several unique haplotypes is similar to that found in the Finnish capercaillie *Tetrao urogallus* subpopulations. There were two common western Lp (19 individuals) and L6 (9 individuals) in the captive population. In addition to this, the captive stock also included four single haplotypes (L1, L2, L4 and L.7). Four eastern birds were also found in the captive stock, two of which represented the core haplotype ip, one was i9-type and one, ipt1, was unique and not found in the wild. The captive rearing and releasing of grey partridges in Finland has previously been carried out to increase the game bag. Recently, it has become more and more common to do this in order to strengthen natural populations and to reintroduce the species into areas where it has disappeared. However, the survival rate of released partridges has been poor. It is worth mentioning that despite the frequent releases of birds representing the European lineage into the subpopulation South Ostrobothnia only one bird (1, 90) of this lineage has found in this area. The lack of success in introductions may result from the maladaptation of

the European grey partridges to the climatic conditions of the release areas in Finland. Although the survival of the released partridges seems to be poor, it is possible, that some released birds survive in the wild and later breed. The tame birds breed better in captivity. As a result, because European grey partridges have been captive-bred in Finland for generations, it has become obvious that the farm stock has adapted to life in aviaries. These birds breed easily and produce a great amount of offspring. In contrast, if wild birds are taken into farms, they are generally unsuccessful because of the stress and fear they experience caused by human presence, and their numbers therefore decrease in farm stock. Genetic adaptation to captive conditions is recognised as a severe problem if captive populations are used for reintroductions. Avoiding genetic adaptation to captive conditions and preserving genetic variation in the farm stock are without any doubt the major challenges of captive rearing. Captive stock may to some extent be "improved" by introducing individuals from the wild, but this may not always be possible or expedient. It has become increasingly desirable to only captive-rear birds with native origin in Finland. Captive-rearing itself includes many pitfalls that have to be solved in order to produce "good-quality" birds for reintroductions. In this study I have clearly shown one pitfall in captive-rearing, i.e. the possibility of genetic differences between wild and the captive stocks. Introducing alien species or subspecies is not considered reasonable from the conservational point of view. This has already been taken into account in the management of the grey partridge at a national level. However, habitat protection and improvement of the environment, as well as hunting restrictions, will still be of high importance in the conservation of the Finnish grey partridge populations.

1374: +.053

IMPACTS OF TSUNAMI IN 2004 (Updated to May 2005) The earthquake of December 26 2004 that struck 30km beneath the Indian Ocean off the Northwestern coast of Sumatra, Indonesia, affected 10 countries that share the waters of the Indian Ocean. It triggered massive tsunamis which caused extensive devastation on land and unprecedented loss of lives, and will go down as one of the worst human tragedies in history. Four out of the 10 Southeast Asian countries were affected by the December 26, 2004 earthquake and tsunami - Indonesia, Thailand, Malaysia and Myanmar, all with coastlines lying within the Indian Ocean. **Indonesia** The northern sections of the island of Sumatra suffered the most severe damage. Pre and post-tsunami satellite images of northern Sumatra show considerable changes to the coastline morphology, including changes to the bathymetry of the surrounding waters. The tsunamis infiltrated several kilometers in to mainland in many areas, destroying not just coastal areas but entire cities and villages. An early estimate of coral reef damage falls in the range of 30%. **Thailand** A total of six provinces were affected by the tsunami [long dash] Phuket, Ranong, Phang-Nga, Krabi, Trang and Satun, with Phang-Nga experiencing the greatest impact. A total of 174 sites covering the six affected provinces were assessed. 12% of the sites showed severe impact; with 47% of the sites showing low to moderate impact and 41% of the sites had no visible impact from the tsunami. **Malaysia** The tsunamis reached the northwestern coast of Malaysia 2-3 hours following the earthquake. Coral reefs along the northwestern region of Malaysia were assessed in March 2005, and no tsunami related damage was observed at all sites surveyed, including Pulau Langkawi, Pulau Paya and Pulau Perak. **Myanmar** Official government reports that followed stated that Myanmar was only mildly affected by the tsunami, and subsequent assessments by NGOs and unofficial reports by tour operators and tourists substantiated the government reports. An assessment of the coral reefs of western Mergui Archipelago by Reef Check Europe and WorldFish Center in March 2005 indicated that the reefs were literally untouched by the tsunami waves with little environmental damage. **CURRENT STATUS OF CORAL REEFS Cambodia** Coral reefs are distributed along the offshore islands and rocky coastlines of Cambodia, covering a total reef area of approximately 28.065 km². Seven sites have been identified and established for long term monitoring. **Diversity**

studies have indicated that 111 species of hard coral, 17 species of soft corals and 9 species of seafans and seawhips are present in Cambodian waters. The average live coral cover at the seven monitoring sites range from 23% to 58%. Indonesia Indonesia is a large archipelagic nation with about 14% of the world's coral reef area. Results form coral monitoring activities between 1993 to 2003 showed an overall improvement in coral reefs in "poor" condition, while reefs in the good and excellent condition remained relatively stable and unchanged. However, progressive degradation of coral reefs within the last 10-15 years in several areas has been recognized. The best reefs were mostly restricted to remote areas or areas with some level of active management in place.

Philippines Changes in the percent cover of different benthic lifeform categories on coral reefs in the Philippines that are in excellent condition indicate that the reefs may be experiencing a steady state of decline (from 5% to 3% to >1% of reefs in excellent condition). However, reefs in good condition are still present in the Celebes Sea, Southern Philippine Sea, Sulu Sea and the Visayas biogeographic regions. About 15% of the reefs surveyed in South China Sea and Sulu Sea sustained very high fish biomass. Singapore Singapore is a small island state with an estimated 54km² of coral reefs. Almost the entire coastline of the main island, particularly the southern half have been altered by land reclamation and many of the southern offshore islands merged by reclamation to form larger islands. Coral reefs, once abundant along the southwest coastline of the main island have been lost to coastal reclamation and are now restricted to narrow fringing bands and patches among the southern offshore islands. Despite the limited reef area and high anthropogenic impacts, some reefs still support good coral cover (50% - 70% coral cover) and diversity (over 150 species of corals).

Thailand The coastal areas of Thailand between latitudes 6[degree] and 13[degree]N offer suitable environmental conditions for coral reef development. Three types of coral distribution are recognized in Thailand - coral communities with no true reef structure; developing fringing reefs; and early formation of fringing reefs. The surveys of coral reefs in certain provinces during 2002-2004 showed obvious changes condition of some reefs within the Gulf of Thailand, while the condition of coral reefs in the Andaman Sea have remained relatively unchanged.

Vietnam Coral reefs are distributed within the shallow waters of the main coastline and around the offshore islands. Coral reefs in better condition are found within the central coastal areas and around the southeastern islands, where temperatures are normally greater than 20[degree]C, and where the reefs experience some offshore influences. Recent coral survey data indicate a dominance of reefs with fair to poor condition (18% and 30% hard coral cover respectively at 50 monitoring sites). Declining abundance of key invertebrate and fish indicators also indicate a reduction of economically important reef organisms. Reefs in better condition were only recorded at some reefs in Ninh Thuan and Phu Quoc.

China The lack of warm water along much of China's coast has inhibited coral reef growth. Typical fringing reefs occur mainly on part of coasts of Hainan Island and Taiwan Island. Before 1984, coral reefs in China were in good condition with more than 70% in coral cover. In the 1990s, coral reef conditions declined occurred in great pace due to the fast social-economic growth. Coral percent cover was 32% in Daya Bay in 1991 and 38% in Luhuitou, Sanya, in 1994. During the recent surveys in 2002 in China, coral percent cover was still low as 35% in Daya Bay and 19% in Luhuitou. However, some areas have higher coral percent cover such as 68% in Yongxing Island, Xisha Island.

Hong Kong Coral Communities are mainly found in the eastern and northeastern coasts of Hong Kong. There are currently four marine parks and one marine reserve in Hong Kong and all the MPAs are now being monitored for various physical parameters and biodiversity and abundance of corals, fish, other invertebrates and algae. The corals within the marine parks in the northeast are so far, generally healthy and some increase in coral cover has been registered over the last four years.

Taiwan Coral reefs are found in all the waters around Taiwan except in the sandy area on the west coast. No significant changes in coral cover among years were found between 1997 and 2004, because both increasing and decreasing trends were observed. However, more increasing trends at reef slope and more decreasing trends at reef flat were found, suggesting that the reef flat biota was more

frequently influenced by anthropogenic disturbances than that of the reef slope. Japan Corals widely distribute from Ryukyu Islands to northern islands of Japan including Kyushu, Shikoku and Honshu. Although most of the coral have been recovered gradually in 10 to 20 years after the outbreak of crown of thorns starfish (COTs), the number of COTs has been increasing again in 2000's. After the catastrophic bleaching event in 1998, relatively small scale bleaching occurred in 2001, 2002 and 2003. On the other hand, coral coverage is increasing in the northern islands because of elevated water temperature in winter relaxing the limits for coral growth in the area.

Korea Korean waters do not have any typical coral reefs by reef building corals, because of the low water temperature. Only the area around Jeju Island affects the influence of warm current and has temperate, subtropical and tropical marine species. 134 of soft and hard coral species are found in Korea including 15 species of stony corals. Most of researches have been conducted on soft corals mainly in Jeju Island

THREATS TO CORAL REEFS

Cambodia There are many anthropogenic impacts to coral reefs including destructive fishing practices, over-fishing, coastal development, agricultural run-off, sedimentation and seaweed farming on reefs. Reef fish and invertebrates densities are low due to over-fishing.

Indonesia Many coastlines are being rapidly degraded mainly through inappropriate land development. Rapid population growth, land-based industry, domestic waste and tourism have resulted in a wide range of environment and resource management problems. The marine resources are severally threatened by destructive fishing methods such as dynamite, cyanide, compressors, fish traps, reef gleaning and over fishing.

Philippines Philippines has a large coastal population that is highly dependent on reef resources for their livelihoods. Over-fishing and destructive fishing practices are by far the greatest threats to the reefs, followed by coastal development and land-based activities.

Singapore Ongoing land reclamation since the early 1970's has resulted in elevated sedimentation. Regular dredging of shipping lanes and the offshore dumping of dredged spoils contribute to the sediment load. This chronic impact has resulted in the decline in reef condition since 1986, with a marked reduction in the vertical growth zone along the reef slopes.

Thailand The first tsunami disaster in the history of Thailand occurred on December 26, 2004. 13% of the reef monitored showed "high impact", with around 40% showing "no impact". 21%, 17% and 9% of the reefs showed "very low", "low" and "moderate" impact respectively.

Vietnam There were serious outbreaks of the Crown-of-Thorns starfish in Van Phong and Nha Trang bays, while algal bloom killed almost all the coral reefs in Ca Na bay (Binh Thuan province), with the recovery occurring slowly after the event. Sedimentation continues to have a strong impact in Ha Long and Cat Ba islands.

China Overfishing and destructive fishing practices have badly damaged coral communities around Hong Kong and Xisha islands, causing most high-value fish species to become locally extinct. Blast fishing has been widely practiced in Hainan Island. Cyanide fishing is carried out by large-scale commercial operators who take fish from remote areas such as Xisha Island and Nansha Island. Cyanides are also used for collecting aquarium fishes. Sedimentation, freshwater incursion, and sewage outflows have adversely impacted China's reefs, particularly near the mainland. Failure in proper managing the land resources have caused problems of siltation. Local governments has bombed out Mabian Zhou, Daya Bay for oil industry in late 1990s, although coral reef transplantation has been carried out to reduce the reef destruction, the damage to coral reefs is still great.

Hong Kong Occasional bleaching, predation, human or storm disturbances have been observed in Hong Kong waters. High sedimentation due to dredging and land reclamation, high nutrients due to effluence of untreated sewage and high heavy metal contents due to industrial effluence are some of the main marine pollution problems in Hong Kong. Extensive mortality of corals was reported in South Ninipin attributable to heavy siltation brought about by dredging in Tung Long Wan Borrow area. Hong Kong waters are generally considered as being overfished.

Taiwan Soil erosion and landslides frequently occur in coastal areas especially after storms, and these runoffs have carried large amounts of sediment and nutrients to reef areas. Sewage of most towns and villages in coastal areas are often ill-treated and discharged to reef areas. This induces serious nutrient

enrichment to reef ecosystems especially in northeastern and southern Taiwan, and Hsiao-liuchiu. Although blast and poison fishing methods have been officially banned, there are still sporadic reports on these illegal fishing methods. Anchor damages could be found sporadically on most reefs. Bottom-trawlers, with their heavy gears sweep over reef surface, have caused severe damage to coral reefs in Penghu Islands. Trampling and mechanical breakage of coral skeleton by divers and tourists have been a serious problem at diving hotspots in Lutao, Penghu, and southern Taiwan. Construction of fishing ports and coastal highway in northeastern and eastern Taiwan has caused damage to coral reefs. Extensive coral bleaching was observed in southern Taiwan, Penghu Is., and Hsiao-liuchiu reefs following heavy rainfalls associated with typhoons in June and July, 2004. Outbreak of a sea anemone, *Condylactis nanwanensis*, was noticed in Nanwan Bay, southern Taiwan and caused severe damage to coral reefs since it destroys coral tissue and weakens coral skeleton. Typhoon is another disturbance on corals in Taiwan. Coral communities at Chitou, Penghu Islands and Tiaoshi, Nanwan Bay were heavily damaged (up to 90% coral mortality) by Typhoon in 2001, and have not recovered since then. Japan The number of COTs has been increasing again in southern part of Japan since 2000's. After the catastrophic bleaching event in 1998, relatively small scale bleaching occurred in 2001, 2002 and 2003. Soil runoff by the coastal development is also one of the major threats on the reefs in Okinawa and mainland Japan. The corallivorous gastropod, *Drupella* is still major predator of corals in northern islands. Korea The increase of tourists for SCUBA diving and tourist submarine have become the cause of reef destruction. CORAL REEF MANAGEMENT Cambodia The Cambodian government has very limited human resources, infrastructures, and finances for scientific research and monitoring. There are no laws that relate to the protection of coral reefs, with the exception of a Fisheries law. A national action plan that integrates coral reef management and conservation, capacity building and maintenance, infrastructure and institutional development, improved legislations, better administrative framework and enforcement, public awareness, communication, education, and participation, biodiversity assessments and regular monitoring is urgently needed. Indonesia The new 1999 legislation (Autonomy laws No. 22/1999 and No. 25/1999) effectively integrated all previous legislations concerning marine management. The ministry of Forestry's Directorate General for Protection and Nature Conservation (PKA) is the agency responsible for nature conservation in Indonesia. The government has set a target to establish 10 million ha of marine conservation area; however, only some 5.8 million ha has been officially declared, which includes 37 marine conservation area. Coral reef rehabilitation and Management Program (COREMAP) have conducted public communication programs for the last two years. All target sites were positively affected by the campaign. Philippines The Department of Environment and Natural Resources (DENR) and the Department of Agriculture, Bureau of Fisheries and Aquatic Resources (DA-BFAR) are the two national government agencies that have the mandate to establish MPAs or fishery refuges. Under the 1998 Philippine Fisheries Code, at least 15% of the total coastal areas in each municipality should be identified as fish sanctuaries. Of over 600 MPAs that have been established in the Philippines, only around 10% of these MPAs are actually being managed effectively. A National Coral Reef Strategy is currently being prepared to provide a clear and integrated management framework for the protection, conservation and rehabilitation of the coral reefs in the country. Singapore There are no marine protected areas covering coral reefs, although proposals to protect identified reefs have been made. Currently, only two legislated nature areas have marine components, but they do not contain reefs. The establishment of the Biodiversity Center within the National Parks Board in 2004 has increased the focus on the marine environment. Artificial reefs and coral translocation activities have been initiated since the mid-1990's to address the issue of coral reef remediation. Thailand There are numerous institutions involved in coral reef monitoring and management, coordinated through the Department of Marine and Coastal Resources and several universities. A National Coral Reef Strategy: Policies and Action Plan was adopted by the cabinet in 1992. All the major coral reefs in Thailand are assigned

to one of four management categories - general use zones, intensive tourism zones, ecotourism zones and ecosystem reserve zones. The majority of coral reefs are classified as ecotourism zones. There have been a few studies on community-based management of coral reefs in Thailand, such as Had Chaolao in Chantaburi Province where local people manage coral reefs for tourism. Vietnam National government and international agencies have supported the development of a network of marine protected areas in Vietnam. A national action plan for coral reef management is being developed under the framework of UNEP GEF/SCS project. China Coral reefs are protected and managed by the regulations, such as; the State Law of Marine Environment Protection issued in 1983 and new revised edition issued in 2000; the Hainan Province Regulation of Coral Reef Protection issued in 1998; and the State Law of Ocean Use Management issued in 2001 demand that all coastal development programs need accord with the Division of Marine Functional Zonation made by government. There are 3 Marine Coral Reefs Reserves in mainland of China and more MPAs are in the planning process. Marine Coral Reefs Reserves are "no-take" areas where only scientific research is allowed within the boundaries. A program named "Restoration of Coral Reef Ecosystem and Protection and Management of Its Biodiversity in South China Sea of China" is one of the priority programs of 21 Century Ocean Agenda of China. Hong Kong The most important legislature that has a direct bearing on the protection of coral communities is the Marine Parks Ordinance that enacted in 1995 and took effect in July 1996. This Ordinance provides for the designation, control and management of marine parks and marine reserves under the Country and Marine Parks Authority of the Agriculture and Fisheries Department (AFD). The Agriculture, Fisheries and Conservation Department (AFCD, former AFD) of the Hong Kong SAR Government is the lead agency overseeing the protection of Hong Kong marine parks. The Authority is advised by the Country and Marine Parks Board that is made up of representatives from different government departments, the academia, NGOs and the public. There are currently four Marine Parks and one Marine Reserve in Hong Kong. AFCD provides the funding for research teams from tertiary institutions to monitor the parks. Taiwan Most coral reefs in Taiwan are within national parks, national scenic areas or coastal conservation zones and these areas are protected by the National Park Law and the Coastal Environmental Protection Plan. However, the current laws are inadequate to protect coral reefs. The revision of laws and the planning of MPAs with effective management are currently processing by governmental administrations. Japan There are several management practices conducted in the local communities to control the disturbances, such as COTs and Drupella. The government has established the Law for the Promotion of Nature Restoration and focus on integrated coastal management involving different stakeholders for coral conservation. There are two programs of Nature Restoration Projects targeting coral conservation. Korea Southern coast of Jeju-do were designated as MPA in the name of Wetland Protection Areas by Ministry of Maritime Affaires and Fisheries (MOMAF) as well as Man and Biosphere (MAB) by UNESCO in 2002. There are some overlapping between designation of protected area and development plan in different level (agencies) and they made local stakeholders confused. Legislation in local/national level needs to be well coordinated in complementary integration

1375: -.094

This project's goal was to restore populations of four rare fishes into Abrams Creek, Blount County, TN. These species, all on the US Endangered and Threatened Wildlife List, include two catfishes, the smoky madtom (*Noturus bailey*) and the yellowfin madtom (*N. flavipinnis*), the duskytail darter (*Etheostoma percnurum*) and the spotfin chub (*Erimonax monachus*). Captive propagation, reintroduction, and non-invasive monitoring techniques were used for this restoration effort, which began in 1986. By 2000, there was evidence of reproduction for all four species. As of 2003, the number of these species stocked in Abrams Creek was 3167 smoky madtoms, 1574 yellowfin madtoms, 3430 duskytail darters, and 11,367 spotfin chubs. Increasing population sizes

were indicated for three of the four fishes, and smoky madtom and duskytail darter abundances were nearly comparable to native populations in Citico Creek, Monroe County, TN.

1376: +.080

Diuris species exhibit a large amount of morphological variation, resulting in a lack of unique characters and hence difficulties in assessing phylogenetic relationships. This study used direct sequencing of the nuclear ITS and plastid trnT-F regions for assessment of the phylogenetic relationships among some closely related Diuris species from the state of Victoria, Australia. Yellow and purple-flowered Diuris species formed well-supported monophyletic sister clades. Relationships within the purple-flowered clade, including Diuris fragrantissima, were unresolved and purple-flowered species in the "punctata" group sampled for this study are genetically very closely related. This Study will have implications for the conservation of Diuris fragrantissima and the location of a suitable mycorrhizal symbiont for reintroduction of this critically endangered species.

1377: +.144

Laelia lobata (Lindl.) H.J. Veitch is among the 24 endangered orchid species of Rio de Janeiro city. This species, endemic to Rio de Janeiro state mountains, was known to occur out), at the top of the most-visited mountains in town, on Pao de Acucar rock and Pedra da Gavea rock. Today the Pao de Acucar rock population may well be extinct because of over-collecting practices, but some plants can still be found at Pedra da Gavea rock, in spite of past over-collecting at the Site. Currently the CORES (Coastal Orchid Restoration) Project has adopted a conservation strategy that covers both ex-situ and in-situ conservation of the species. Following the action plan for conservation, developed by the IUCN Orchid Specialist Group, the project has three objectives: (1) Determine the conservation Status of Laelia lobata, analyzing Population demography, floral biology, and population genetics of three samples (Pao de Acucar rock, Pedra da Gavea rock, and ex-situ propagates); (2) Micro-propagate this Species using symbiotic and asymbiotic germination of seeds; and (3) Educate climbers on the need to preserve the orchid's native habitat on the two hills. Reintroduction will be attempted only if necessary. By pursuing these objectives, we attempt to achieve the main purpose of the project, which is to remove Laelia lobata from the Red List of endangered orchids.

1378: +.197

Some 221 species of native orchids have been recorded in Singapore. Of these, however, ca. 170 orchid species are considered to be extinct, and only four are viewed as common. The orchid conservation program at the Singapore Botanic Gardens aims to monitor these species, to explore ways to conserve their germplasm, and to increase their number for subsequent reintroduction into appropriate habitats, including managed parks and roadsides. Thus far, we have successfully reintroduced Grammatophyllum speciosum, Bulbophyllum vaginatum, and Bulbophyllum membranaceum. Recently, we initiated the Orchid Cryo-Seed Bank Project, and have managed to successfully store seeds of four native species. They are Dendrobium crumenatum, Spathoglottis plicata, Bulbophyllum vaginatum, and Dendrobium anosum.

1379: +.037

Ex situ conservation may be the immediate solution for endangered species, but prolonged captivity poses problems as populations adapt to man's environment. Here we present all historical

and biological overview of such problems, and we end with a word for caution as to their efficacy when reintroduction is desired.

1380: +.236

Current Species Status: Blackburn's sphinx moth (*Manduca blackburni*) is federally listed as endangered (U.S. Fish and Wildlife Service 2000a). This taxon is currently known to occur on three of the seven major Hawaiian Islands. No known Blackburn's sphinx moth populations are entirely protected from the numerous factors threatening the species' recovery, and the moth is endangered throughout its range. **Habitat Requirements and Limiting Factors:** Blackburn's sphinx moth is currently found in association with topographically diverse landscapes that contain low to moderate levels of non-native vegetation. Vegetation types that support Blackburn's sphinx moth include dry to mesic shrub land and forest from sea level to mid-elevations. Soil and climatic conditions, as well as physical factors, affect the suitability of habitat within the species' range. Impacts to the moth's habitat from urban and agricultural development, invasion by non-native plant species, habitat fragmentation and degradation, increased wildfire frequency, ungulates, and direct impacts to the moth from non-native parasitoids and insect predators have significantly reduced the species' range (A. Medeiros, U.S. Geological Survey-Biological Resource Division, pers. comm., 2001; E. Van Gelder and S. Conant, in litt., 1998). **Recovery Objectives:** Needed conservation and recovery activities include protection, management, and restoration of habitat including out-planting of native *Nothocestrum* sp. (*aiea*) (confirmed and presumed) host plants (two of which are federally listed: *N. breviflorum* and *N. peltatum*); a Blackburn's sphinx moth captive breeding and/or translocation program; and research. This plan identifies 3 recovery units comprised of 13 management units which are geographic areas recently documented to contain Blackburn's sphinx moth populations and/or Blackburn's sphinx moth host plant populations and which shall be the focus of recovery actions. The three recovery units and their component management units contain habitat considered necessary for the longterm survival and recovery of Blackburn's sphinx moth (e.g., networks of suitable habitat patches and connecting lands). The overall objective of this recovery plan is to ensure the species' longtermconservation and to conduct research necessary to refine recovery criteria so that Blackburn's sphinx moth can be reclassified to threatened status, and eventually delisted. **Goals include:** (1) protect habitat known to support extant populations and high-quality habitat known to have supported moth populations in the past; (2) stabilize moth populations within their known distributions; and (3) conduct research necessary to refine recovery criteria to include threat information. **Downlisting Criteria:** One Blackburn's sphinx moth population on each island of Hawaii, Kahoolawe, and Maui must be well-distributed, naturally reproducing, and stable or increasing in size through one to two El Nino events or for at least 5 consecutive years of average rainfall conditions before downlisting may be considered. This criterion assumes future genetic studies (see recovery action 3.5 and 3.6) will confirm the species currently consists of multiple populations. If additional research reveals the species is actually comprised of one population, this criterion will need to be revised. **Stable** Blackburn's sphinx moth populations are defined in this recovery plan as those in which observed population declines are followed by a population increase to pre-decline levels. These criteria should provide for the maintenance of genetic variation that occurs in natural populations of Blackburn's sphinx moth by protecting all known, natural populations and the habitats upon which they rely. Furthermore, these criteria should provide some assurance that a single catastrophic event will not destroy all populations of this species. More specific downlisting criteria can be developed when completion of some of the recovery actions provides necessary information on the life history and ecology of this species and its host plants. **Delisting Criteria:** Before delisting of Blackburn's sphinx moth can be considered, all of the following four requirements must be met: (1) one moth population, within one management unit, must be naturally reproducing and stable or

increasing in size, through one to two El Nino events or a minimum of 5 consecutive years of average rainfall within the Kauai-Oahu Recovery Unit; (2) four moth populations, within four management units, must be naturally reproducing and stable or increasing in size, through one to two El Nino events or a minimum of 5 consecutive years of average rainfall on three different islands within the Maui Nui Recovery Unit (of those four, one within windward and one within leeward Maui Island); (3) two moth populations, within two management units, must be naturally reproducing and stable or increasing in size, through one to two El Nino events or a minimum of 5 consecutive years of average rainfall within the Big Island (Hawaii Island) Recovery Unit; and (4) a post-delisting monitoring plan and agreements to conduct post-delisting monitoring are in place and ready for implementation at the time of delisting. These criteria assume genetic studies (see recovery actions 3.5 and 3.6) will confirm the species currently consists of multiple populations. If additional research actually reveals the species is comprised of one population, these criteria will need to be revised. More specific delisting criteria can be developed when completion of some of the recovery actions provides necessary information on the life history and ecology of this species and its host plants. **Specific Actions Needed:** 1. Protect, manage, and restore habitat and control threats. 2. Expand existing wild *Nothocestrum* sp. host plant populations. 3. Conduct additional research essential to recovery of Blackburn's sphinx moth. 4. Develop and implement a detailed monitoring plan for Blackburn's sphinx moth. 5. Reestablish and augment, through captive propagation if necessary, wild Blackburn's sphinx moth populations within its historic range. 6. Develop and initiate a public information program for Blackburn's sphinx moth. 7. Validate recovery objectives. 8. Develop a detailed Post-Delisting Monitoring Plan for Blackburn's sphinx moth.

1381: +.108

We examined the public process used to develop the 1996-2001 Fortymile Caribou (*Rangifer tarandus*) Herd Management Plan adopted by state and federal management boards. The process differed from most government-supported planning processes because it was initiated by residents of Alaska and Yukon, and not by an agency. State, federal, and territorial agencies were asked to participate in and support development of a management plan that would include a broad range of interest groups. We describe the planning effort, issues addressed by the planning team that posed significant challenges during both the planning and implementation phases, and then identify unforeseen costs and benefits derived from the process. Critical decision points in plan development and implementation are discussed.

1382: +.245

Alstroemeria (Alstroemeriaceae), the Incas lily, an exclusively South American genus comprises near 90 species ranging from Venezuela (31 North) to Tierra del Fuego, Argentina (531 South). *Alstroemeria* species and hybrids have gained world-wide importance as cut flower crop due to its attractive flowers and the excellent keeping quality of them. Nevertheless, they are also suitable for growing in pots and for garden and landscape uses. The recent taxonomic revisions of the group for Brazil (Assis, 2001), Argentina (Sanso, 1996), and Chile (Bayer, 1987), the biosystematic research (Aagesen and Sanso, 2003; Sanso and Xifreda, 1998, 1999, 2001, 2003) and the chromosome studies (Sanso and Hunziker, 1998; Sanso, 2002) have facilitated the identification of the taxa and improved the basic knowledge of the genus. The nomenclature of the species, their geographical distribution, ecological characteristics and the interspecific relationships are now better understood. Many wild taxa, that are scarcely known so far, carry genetic traits that open possibilities for improvement and development of more attractive new varieties. For example, some of the Brazilian taxa have an important potential value in breeding

programmes because of their showy flowers and the rigid leaves, instead of the very tender foliage that possess most of the species; some Patagonian ones have rather short plant height, which is important for potted plants. Several species of the wild populations are nowadays threatened and with risk of extinction. Most of the species occupy reduced geographical areas. Species that inhabit plain regions are vulnerable because those fields are burned and cultivations are introduced. Patagonian species especially need to be protected, against the grazing of the animals. The cultivation of the native plants would help to the ex situ conservation. Reintroduction in some natural areas might also play an important role in order to maintain the landscape value.

1383: +.352

A population of *Cicindela patruela patruela* DeJean (Coleoptera: Carabidae: Cicindelini) existed until at least 1950 in a small area of eastern Washington, D.C., and adjacent Prince George's County, Maryland, USA. Suitable habitat for this population consisted of open sandy barrens with soils derived from Cretaceous sediments of the Potomac Group and vegetation characterized by oak and pine species, particularly *Quercus marilandica* Munchhausen and *Pinus rigida* Miller. This habitat was eliminated in the Washington area by extensive suburban housing construction, which was driven by rapid growth in the human population. Recommendations are provided for the reintroduction of *C. patruela* and for the restoration of suitable habitat at remnant natural areas.

1384: +.128

A micropropagation protocol was developed for the conservation of critically endangered Serbian perennial *Nepeta rtanjensis* (Lamiaceae). Rooted shoots were obtained from one-node stem segments and shoot tips on a half-strength Murashige and Skoog (MS) medium without growth regulators. The best pH of the medium for axillary buds induction and for rooting of shoots was found to be at 7 and/or 7.2 respectively. The addition of cytokinins to the culture medium did not significantly stimulated axillary bud production as compared to the control. On the contrary, on media supplemented with high cytokinin concentrations, only dwarf shoots with rudimentary roots were obtained. All tested concentrations of 6-benzylaminopyrine (BAP) and kinetin (Kn) in combination with 0.1 mg l⁻¹ indole-3-acetic acid (IAA) negatively affected the elongation and rooting of shoots. Plants micropropagated on hormone free medium and rooted in vitro were successfully acclimatized in greenhouse and in open field conditions. The result of successful acclimatization was the production of more than 7000 plantlets with normal sexually reproduction. They flowered, fruited and produced seeds which exhibited 47% germination. The survival rate of plants that were transferred to the open field for the acclimatization and exposed to the winter chill was 99%. The reintroduction of *N. rtanjensis* occurred in May 2004. One thousand plantlets were planted within the historic range of this plant species. The survival rate was also 99%.

1385: +.116

The great bustard is a globally-threatened species needing conservation action across Europe. This paper discusses key issues in the case for reintroducing the bird to Britain. Great bustards became extinct as a breeding species in Britain in 1832 probably as a result of hunting, agricultural change and inclement weather. The factors that caused the loss are no longer thought to operate. Suitable habitat exists in pockets across England and especially on Salisbury Plain where a large area is protected for military training and conservation purposes. The Plain combines short grass areas for lekking, long grassland for feeding and adjacent arable land for nesting. Pilot studies on arthropods in long grassland suggest that their density is sufficient for chick-rearing but the precautionary creation of additional food-rich areas among arable crops is recommended. Genetic

studies indicate that Britain's bustards probably belonged to the central European group and that restocking should not use birds from Iberia. Only Russia has sufficient birds to supply a reintroduction project and losses there through nest destruction are high. By rescuing eggs, artificially incubating them and transporting chicks to Britain, the project should have zero detriment to the donor population. Modelling indicates that 40 chicks will need to be brought to Britain for 5-10 years to build a founder population of 100 birds. Although focused on direct action in Britain, the project will promote grassland conservation across Europe and serve as a model for translocating bustards elsewhere.

1386: -.136

We radio-tagged and released 49 captive-reared Hispaniolan Parrots (*Amazona ventralis*) in Parque Nacional del Este (PNE), Dominican Republic, during 1997 and 1998. Our primary objective was to develop a restoration program centered on using aviary-reared birds to further the recovery of the critically endangered Puerto Rican Parrot (*A. vittata*). Hurricane Georges made landfall over the release area on 22 September 1998 with sustained winds of 224 km/h, providing us with a unique opportunity to quantify responses of parrots to such disturbances. Quantitative data on such responses by any avian species are scarce, particularly for *Amazona* species, many of which are in peril and occur in hurricane-prone areas throughout the Caribbean. Mean home ranges of 18 parrots monitored both before and after the hurricane increased ($P = 0.08$) from 864 ha (CI = 689-1039 ha) pre-hurricane to 1690 ha (CI = 1003-2377 ha) post-hurricane. The total area traversed by all parrots increased > 300%, from 4884 ha pre-hurricane to 15,490 ha post-hurricane. Before Hurricane Georges, parrot activity was concentrated in coastal scrub, tall broadleaf forest, and abandoned agriculture (conucos). After the hurricane, parrots concentrated their activities in areas of tall broadleaf forest and abandoned conucos. Topographic relief, primarily in the form of large sinkholes, resulted in "resource refugia" where parrots and other frugivores foraged after the hurricane. Habitat use and movement patterns exhibited by released birds highlight the importance of carefully considering effects of season, topography, and overall size of release areas when planning psittacine restorations in hurricane-prone areas.

1387: +.269

Determining whether animals select some habitats over others provides basic information about how animals meet their requirements for survival and reproduction. Habitat selection is therefore an important component of conservation research. Studies involving the release and establishment of threatened species on island refuges can be particularly insightful because breeding pairs should be able to select habitat of the highest quality within the range available. This study uses GIS technology to investigate the spatial distribution of breeding territories in relation to overall habitat availability of two threatened passerines, South Island saddlebacks (*Philesturnus carunculatus carunculatus*) and Stewart Island robins (*Petroica australis rakiura*) two years after their release onto predator-free Ulva Island. Both species established breeding territories around the periphery of the island in coastal forest fringe habitat and away from mature forest in the interior of the island. Compositional analysis suggested that both species prefer dense, fringe-type habitat with open ground cover and deep litter layers and avoid more mature forests, especially with moss cover. Thus habitat structure is likely to be more important for both species than plant-species composition. However, the possibility exists that the preference of coastal fringe habitat could represent an 'ecological trap', where habitat preference does not correspond to better quality habitat in terms of reproductive fitness. It will be useful to continue monitoring saddlebacks and robins to obtain data on survival and fecundity as the density of birds increases, and breeding pairs are forced to establish territories in what is presently perceived to be less preferred habitat in the

interior part of the island.

1388: +.025

One of the greatest challenges for biologists today is to protect biodiversity against a backdrop of widespread habitat loss. *Helenium virginicum* Blake (Virginia sneezeweed) is a federally threatened herb associated with sinkhole margins and wet meadows in the Shenandoah Valley of Virginia and in the Ozark Highlands of Missouri. In this study we evaluated the influence of seed source (maternal line), planting site, water regime, and weed exclusion on survivorship, growth, and fecundity of *H. virginicum* with the objectives: (1) to establish two viable populations on public land in Missouri, and (2) to formulate reintroduction protocols for the species. We collected seed from the one known population in the state of Missouri. Seeds were germinated under controlled conditions and then transplanted to two sites on public land. Maternal line was found to have no significant effects on seed germination or seedling survivorship in the greenhouse for the first year. Maternal line, site, water regime, and weed exclusion cloth had no effects on the survivorship of *H. virginicum* at field sites. Maternal line, along with site, water regime, and weed exclusion cloth had significant effects on height at time of flowering and number of flowers produced by *H. virginicum*. The results of this study address some of the unknowns regarding the biology of *H. virginicum* and will be used to guide future reintroduction projects as well as the ongoing development of state and federal recovery plans.

1389: +.017

Small mammal monitoring using live trapping was done along the upper section of river Drava in 2003-2004, using capture-mark-recapture. Our sample areas were located in a strictly protected alder gallery forest (Lankoci-erdo) and in a neighbouring plot under gradual reforestation which had been clear-cut in 2000. A total of 9 small mammal species were recorded in the two sites, each comprising a 1-hectare sampling grid. The small mammal community revealed here had three characteristic rodent species (*Apodemus flavicollis*, *A. agrarius*, *Clethrionomys glareolus*), and two frequent shrew species (*Sorex araneus*, *Crocidura leucodon*). With the populations assumed to be closed, population sizes of the three dominant rodents were estimated from daily capture data. The highest estimated values were obtained for the two *Apodemus* populations (*A. agrarius* and *A. flavicollis*). Population sizes of the bank vole could be estimated from the protected area only. A spatial analysis with the nearest neighbour method showed that individuals of the more frequent species aimed at an even distribution, both in 2003 when densities were lower, and in 2004 when densities were higher. The more detailed analysis of the spatial pattern in 2004 suggested that by the end of late autumn, the different species are already organised in a pattern of winter survival strategy. It was shown by spatial distribution data that in this period the area of the closed alder gallery forest was occupied by individuals of yellow-necked wood mouse and bank vole. In the inner, larger part of the 1 ha forest section, it was mostly yellow-necked wood mice that established their home ranges. Striped field mice occupied only the reforested areas. Using extensive areas, the reforested area was inhabited also by bank voles, which fact is a proof for population translocation between the two areas in this species.

1390: +.045

The phylogeographic structure of the brown hare (*Lepus europaeus*) was studied by analysing mtDNA control region sequences of 98 individuals from continental and insular Greece, Bulgaria, Cyprus and northern Israel, together with 44 published sequences from Italy and central Europe. We found two distinct clades separated by an average nucleotide divergence of 6.6%, which may

correspond to a Balkan and to an Asia Minor refugium. The estimated time of separation of the two clades was dated back to 105,000-490,000 years ago. These two clades coexist in the area of northeastern Greece and Bulgaria, most likely as a result of a post-glacial northward expansion. Within the southern Balkan refugium, network analyses showed geographical structuring, which supports the hypothesis of several isolated Late Pleistocene populations. The central European and Italian populations appear to have originated from a non-detected northern Balkan population that was genetically closely related to some northern Greek populations, as a result of postglacial expansion, translocations or a combination of both. Moreover, several cases of ancient and recent translocations by humans were detected, especially for some island populations, while the eastern Aegean islands off the Asia Minor coast were most likely colonized naturally through Late Pleistocene land bridge connection. The genetic analysis presented here provided a framework for designing proper conservation and management guidelines for this species. (C) 2004 Elsevier Inc. All rights reserved.

1391: +.196

Translocation—the deliberate, human-mediated movement of organisms—is a useful conservation tool most often employed in attempts to increase persistence of threatened or depleted species. Translocation projects involve difficult management decisions regarding the allocation of animals between sites. This research provides a rational scientific basis for these decisions. We use a stochastic population model and Stochastic Dynamic Programming to determine optimal translocation strategies for theoretical populations, and apply this framework to a case study on the Bridled Nailtail Wallaby (*Onychogalea fraenata*). The translocation problem is defined as follows: in each time step of the translocation program, a set number of individuals are sourced from a captive population and translocated to two sites. Management decisions involve the allocation of these individuals between the two sites, over time. We use a first-order Markov chain stochastic population model to simulate each translocated population. This model follows females only, and does not consider age structure. Translocated populations A and B are limited by carrying capacities $K-A$ and $K-B$, with population dynamics governed by Markov chain transition matrices $A(A)$ and $A(B)$. In the time step of their translocation, translocated individuals are governed by a separate transition matrix $A(T)$ with a higher mortality rate and no reproduction. The Stochastic Dynamic Program (SDP) has three states: the number of individuals in the first site ($n(A) = 0, \dots, K-A$), the number of individuals in the second site ($n(B) = 0, \dots, K-B$), and the time period of the translocation project ($t = 0, \dots, T$). Populations can change state by natural processes—as captured in the transition matrices—or by receiving translocated individuals. With X individuals available in each time step, Population A receives d individuals and Population B receives $X-d$ individuals. The SDP steps backwards from the terminal time T where the final reward, given by an objective function, is received. For each time step all possible decisions—represented by the variable d —are evaluated for every combination of possible population sizes. The optimal decision is the one that produces the highest score, determined by the dynamic programming equation. We compare the results given for two different objective functions. The first is a long-term persistence objective function, which maximises the persistence of translocated populations e time steps after the end of the translocation program. The second is a total population size objective function, which maximises the number of animals present at the end of the translocation program. The SDP is applied to the Bridled Nailtail Wallaby by making each time step equal to four months, and by using realistic population parameters derived from relevant literature. The translocation program is assumed to run for four years (twelve time steps), with two individuals available in each time step. The carrying capacity of each site is set at 50. Population A has an approximate (per capita) growth rate of 1.305, while Population B has a growth rate of 0.87. When using the long-term persistence objective function (with $\epsilon = 128$), the optimal decision for most states is to

translocate both available animals to Population B. These results satisfy the objective function, but are not sensible for a real-life translocation program, as population B has a declining growth rate. This indicates that the long-term persistence objective function considered here does not adequately express the goals of a translocation program. The results for the total population size objective function are more practically applicable. In these results the optimal decisions in each time step are dependent on the number of animals in Population A. The large difference in results between the two objective functions demonstrates the importance of careful consideration when specifying the goals of a project. This applies not only to translocation programs, but any project where clear decision-making is needed.

1392: +.205

Many populations have a negative impact on their habitat, or upon other species in the environment, if their numbers become too large. For this reason they are often managed using some form of control. The objective is to keep numbers at a sustainable level, while ensuring survival of the population. One such population is the koalas (*Phascolarctos cinereus*) of Kangaroo Island, South Australia. Between 1923 and 1925, 18 koalas were introduced to the island as a conservation measure to protect them (they were classified as a threatened species). Today, the Kangaroo Island koalas are considered to be a pest. Their overabundance has had a significant negative impact on the health of the Rough-barked Mannagum (*Eucalyptus viminalis cygnetensis*), along with other high-quality koala habitat. As a response to poor and insufficient habitat, numbers are predicted to decline sharply, and, because of the increased risk of extinction of the koalas and of other species, control and management programs have been proposed. Here we present models that allow population management programs to be assessed. Two common control regimes will be considered: reduction and suppression. Under the suppression regime the population is maintained close to a particular threshold through near continuous control, while under the reduction regime, control (for example culling or sterilisation) begins once the population reaches a certain threshold and continues until it falls below a lower pre-defined level. We discuss how to best choose the control parameters, and we provide tools that allow population managers to select reduction levels and control rates. Additional tools will be provided to assess the effect of different control regimes, in terms of population persistence and cost. In particular we consider the effects of each regime on the probability of extinction and the expected time to extinction, and compare the control methods in terms of the expected total cost of each regime over the life of the population. The usefulness of our results will be illustrated with reference to the control of the koala population. We select a suitable reduction level based on a specified probability of persistence, the genetic diversity of the population and the expected time between control phases. All are important in the management of native fauna. Firstly, while we are aiming to control the population, we wish to ensure the survival of the species without introducing risk additional to that faced prior to control. Next, genetic diversity, which is often overlooked when managing populations, is of utmost importance. The aim is to avoid inbreeding depression and to allow for evolutionary change. We must select a minimum reduction level that ensures a high probability of persistence, while maintaining an adequate level of genetic diversity. We find that a reduction level larger than that derived through these considerations will often be allowable in practice. To aid in selecting the reduction level, we also provide an explicit formula for the expected time between culling phases. Population managers can then select a reduction level so that the time between implementing successive controls is larger than some stipulated minimum (necessitated, for example, by resource constraints). The optimal rate of culling is then obtained by minimizing the cost of each culling phase, before finally selecting the optimal regime for control in terms of the expected cost of control over the life of the koala population. Our results can be easily extended to various control types (for example, sterilisation and translocation), and birth

and death rates other than the ones considered here (for example, we may employ logistic birth rates). Consequently, we anticipate that our approach will be useful in a variety of population management contexts.

1393: +.113

Attempts have been made to reintroduce elk (*Cervus elaphus*) in Ontario, Canada, since the early 1900's. These efforts are on-going and current plans are to establish viable elk populations in 6 pre-selected restoration sites in Ontario. Significant populations of white-tailed deer (*Odocoileus virginianus*) exist in close proximity to some of the proposed restoration sites. Therefore a decision was made to assess the potential impact of restoring elk in white-tailed deer wintering areas in Ontario, prior to the release of elk. The primary concerns regarding white-tailed deer/elk competition are transmission of the meningeal worm (*Parelaphostrongylus tenuis*) from white-tailed deer to elk and the winter carrying capacity of habitat where the restoration is to occur. A review of existing data revealed that significant winter concentrations of white-tailed deer do exist in the vicinity of the Haliburton Highlands elk release site in Southern Ontario. However, that proposed release site is at least 10 km from white-tailed deer wintering areas and restrictive winters occur infrequently in that area. A review of the literature, as well as interviews with Provincial and State biologists and elk managers revealed that although there was anecdotal evidence of competition between elk and white-tailed deer in a few jurisdictions, there was neither quantitative nor qualitative data to support or refute those claims. However, as snow depths increase and elk switch to browse dominated diets, there is potential for white-tailed deer/elk competition for resources if sharing the same winter range, especially during severe winters. The chances that elk and white-tailed deer will share the same winter range will depend on where the released elk decide to settle for the winter, which may be influenced by availability of unused winter habitat and the quality of the available habitat. Therefore, elk will not be released directly into traditional white-tailed deer wintering areas in Ontario. A comprehensive research and monitoring program will be mandatory for future elk releases in Ontario.

1394: +.207

A review of the decline of, and conservation activities for, the adder or northern viper *Vipera berus* within Greater London, the 3,200 sq km London Natural History Society-recording area and with reference to its surrounding hinterland, totalling 6,400 sq km. One hundred and twenty-seven adder sites, approximating to populations, are mapped at the tetrad scale and date from 1800 to 2005. These records are found within the thirty-three London boroughs, and surrounding counties, including the old county of Middlesex, much of Surrey and parts of Essex, Kent, and Hertfordshire. Today in Greater London only five very small populations of adder remain, only two of which are possibly derived from original natural populations. Extinction here has been prevented by protective actions, restocking and introductions/reintroduction over the last twenty years. Outside Greater London and within the London Natural History Society survey area there are around a further eighteen remaining recorded populations most of which are small, many not fully protected and nearly all under threat. The past and present causes of adder decline are described and problems encountered in conserving adders in London over the last thirty years are discussed. Measures needed to conserve adders are described including habitat restoration and creation and management activities to avoid overgrazing by stock and minimize negative influences such as burning of fragmented habitats. Full listing of adder under Schedule 5 of the Wildlife & Countryside Act 1981 is considered appropriate, or protection via other existing or new legislation giving protection to the species and its habitat. New strategic approaches are needed to effectively coordinate suitable nature conservation activities within the adder's highly fragmented

current state.

1396: +.009

Since 2002 hamsters are released in three hamster-friendly managed sites (Sibbe, Amby and Heer) in the most southern part of The Netherlands in the province of Limburg. As a result of these reintroductions, three small hamster populations are established. The management of the sites resulted too in an enormous amount of Field mice (*Microtus arvalis*), which is a favorite prey-species for a lot of predators. Unfortunately, the population of mice collapsed in spring due to agricultural activities. The predators (mainly foxes and marders) than switched to other prey and food, with a disastrous effect on the hamster population. Part of the hamster population escaped predation by moving to surroundings fields with a normal agricultural management. The long time survival of the hamster populations depends on the (im)possibility of creating good hamster-habitat patches within the reserves, in the surrounding of the reserves and between the reserves. In the coming years the management of the three sites must be intensified and crops must be cultivated on larger patches, instead of small stripes. Outside the reserves the main problem seems a shortage of cover and the total absence of food for winter-storage.

1397: +.057

In this chapter, I examined evidence for ungulate impacts on forest biodiversity in the absence of large carnivores. Wild populations from eight species that are distributed worldwide in temperate and boreal forests have been shown to have deleterious effects on biodiversity. Plant species are most often directly affected by ungulates, but additional trophic levels, composed of birds and mammals, are like-wise affected. The closer ungulate populations are to carrying capacity the broader their impact. Biodiversity in forests can be restored following ungulate reduction if conditions are favorable. The reintroduction of large carnivores is one component in a restoration

project that must take into account the potential of the site, invasive species, life history traits of target species, and disturbance regimes. Hunters are not a direct equivalent to large carnivores because they often affect numerical, but not functional, responses in the prey. Large carnivores should not be expected to regulate ungulate populations that are at or above carrying capacity. The culling of ungulate populations prior to carnivore introductions might enhance the ability of carnivores to act as biodiversity "managers." It is preferable to produce large spaces that are variable for both the density of ungulates and plant biodiversity, because microhabitats within the landscape will differ in both their potential for biodiversity and their ability to "shield" ungulates from predation. We have the opportunity to conduct large-scale natural experiments, and these should be used to test the ideas presented in this volume. Forest communities will exhibit a large diversity of responses when placed back under the influence of large carnivores. Whereas it is difficult to predict the response of any one site to reduced ungulate density, it is not hard to predict that the impact over the landscape scale will be significant.

1398: -.124

Unlike many regions in the world where wild pigs (*Sus scrofa*) are threatened, in Australia they are a significant invasive species. As such, the molecular ecology of feral pigs was investigated to understand their social and population genetic structure. Samples from 269 adult animals were collected over their distribution in southwestern Australia. Using 14 highly polymorphic microsatellite markers, we identified 7 inferred feral pig populations that had moderate heterozygosity (mean = 0.580) and displayed a high level of differentiation (mean $R_{ST} = 0.180$). In revealing the genetic structure of feral pigs, we detected anomalies in the putative native origin of some individuals. Samples from these animals were collected from 2 main areas: recently colonized regions that were previously uninfested, and established feral pig populations, where animals from geographically isolated areas had been introduced. In the latter, these corresponded to areas that were in close proximity to public road access and towns. Given the large distances immigrants were found from their population of origin (from 50 to > 400 km), the generally low levels of dispersal of southwest feral pigs, and the grouping and sex of these pigs, we suggest that these individuals have been deliberately and illegally translocated to supplement recreational hunting stocks. Additionally, we could not detect any genetic contribution in these feral pigs from domestic pig herds, suggesting that the deliberate release of domestic pigs to restock feral populations is relatively uncommon. Our molecular data allowed some inferences regarding the success or lack thereof of current management practices, and offered considerable insights into the dynamics of the feral pig populations and identification of "new" approaches that may allow for better control of this highly destructive species.

1399: -.279

A total of 294 sera collected between 1999 and 2001 from eight captive and one free-ranging herds of Arabian oryx (*Oryx leucoryx*) distributed in Saudi Arabia (SA) and the United Arab Emirates (UAE) were assayed for antibodies against 13 selected viral agents. Arabian oryx have been exposed to bluetongue virus (BTV), epizootic hemorrhagic disease virus (EHDV), rinderpest virus (RPV), bovine respiratory syncytial virus (BRSV), bovine adenovirus 3 (BAV-3), cervid herpesvirus-1, foot-and-mouth disease virus, equine herpesvirus 9, and bovine viral diarrhea virus. The high seroprevalence to BTV and EHDV in the UAE and SA indicates that Arabian oryx are likely to be susceptible to infection by these viruses and therefore could act as a source of virus to vectors during the infective stage of infection. Moreover, antibodies were detected against RPV and BRSV in sera from SA and against BAV-3 in sera from the UAE. No antibodies were found against bovine herpesvirus-1, caprine herpesvirus-1, enzootic bovine leucosis virus, and peste des

petits ruminants virus. On the basis of these results, caution should be applied when considering translocation of Arabian oryx, and only those proven to be free of infectious agents that might present a risk to other species should be moved.

1400: +.072

In the present study, we evaluated the genetic diversity of *Panax notoginseng* F H Chen, a domesticated species, and *P. stipuleanatus* H T Tsai et K M Feng, an endangered wild species in southeastern Yunnan and adjacent areas in Vietnam, using sequences of the internal transcribed spacer (ITS) regions of nuclear ribosomal DNA and amplified fragment length polymorphism (AFLP) markers. Twenty-four accessions from three plantations of *P. notoginseng* and 51 samples from eight populations of *P. stipuleanatus* were assayed. A total of 694 bp of partial sequences of 18S, ITS1, 5.8S, ITS2, and partial sequences of 26S were obtained. No sequence variation was detected within *P. notoginseng* and nine sites (1.30%) were variable in *P. stipuleanatus*. Two-thirds of the variable sites were found between Langqiao and other populations. In *P. notoginseng*, four pairs of AFLP primer combinations generated 312 bands, of which 240 (76.9%) were polymorphic and 60.15% of the polymorphisms were harbored within plantations. Approximately 41.0% and 66.9% of bands were polymorphic in population D7 and 5589, respectively. In *P. stipuleanatus*, the same four primer combinations produced 346 bands, of which 334 (96.5%) were polymorphic and approximately 62.14% of polymorphisms were maintained within populations. Considerable variations were observed. The percentage of polymorphic bands ranged from 50.2% to 84.9% and the average over populations was 70.9%. Cluster analysis did not show correlation of genetic differentiation with the distinctive leaf morphology of *P. stipuleanatus* (i.e. one form with bipinnatifid leaflets and the other with undivided leaflets). Because over 40% of genetic variations were maintained among populations and because of the very restricted distribution of *P. stipuleanatus*, all natural populations of this species should be conserved in situ. Considering that there are variations in *P. notoginseng* within and among plantations, we suggest establishing a genetic resource conservation garden or reintroducing *P. notoginseng* into its native habitats in southwestern China. Such reintroduction should be carefully executed after large-scale screening of genetic variation within the species.

1401: +.213

1. Reintroductions provide a good opportunity to study density-dependent population growth, as populations can be studied at a range of densities and the change in density is not confounded with environmental conditions. An understanding of density dependence is also necessary to predict dynamics of reintroduced populations under different management regimens, and assess the extent to which they can be harvested for further reintroductions. 2. We monitored a North Island saddleback (*Philesturnus rufusater*) population for 6 years after reintroduction to Mokoia, a 135 ha island in New Zealand that was made suitable for saddlebacks by eradicating introduced Norway rats (*Rattus norvegicus*). We modelled adult and juvenile survival using Program MARK, and modelled numbers of young fledged per pair using Proc Mixed in SAS with individual female as a random factor. 3. Juvenile survival clearly declined as the population increased, and the decline was closely correlated with the number of breeding pairs. Reproduction also showed a clear decline that was explained by two factors: a difference in quality between territories occupied immediately after reintroduction and those occupied later, and an overall decline as the number of pairs increased. Reproduction was also strongly affected by age, and this needed to be accounted for when modelling density dependence. 4. A stochastic simulation model incorporating these dynamics closely predicted the observed population growth. The equilibrium population size was insensitive to density dependence in reproduction, but highly sensitive to density dependence in

juvenile survival.5. The model is being used to plan management strategies for potential reintroductions of saddlebacks to mainland areas with predator control. The species is currently confined to predator-free islands and one fenced mainland sanctuary.

1402: +.073

In the first attempt to re-establish a population of the red-winged grasshopper, *Oedipoda germanica* (Latr.), threatened with extinction in Germany, 32 adults (19 females, 13 males) were taken from a population in a limestone quarry, individually marked, and translocated to the "Leutratal" nature reserve near Jena, Thuringia, formerly inhabited by the species. A simulation model, with two scenarios was run to determine the probability of re-establishment of this small translocated population. One of the two scenarios indicated that populations of 20 females could survive with optimal life history parameters. In 1994, the year of translocation, during seven nights of observation between July and September, 25 adults were re-observed at least once. About 50% of the females and 70% of the males were found in a 20m radius of the release point, whereas a maximum distance of about 70 m was recorded for a female. Using minimum female life-span and oviposition data from greenhouse experiments, 545 eggs were estimated to have been laid by the initial inoculum in 1994. In the subsequent years 1995 and 1996, only seven and three grasshoppers were observed within 30m of the release point in 1994. However, the translocated population obviously went extinct in 1997 because no *O. germanica* could be found in that or following years. By comparing source and release habitat, the possible causes of the failed re-establishment were elucidated. In the year of release a short mean adult life span of 26 days was observed, assumed to be the consequence of high predation, and resulting in a lower reproductive rate. In the following years, low soil temperature of the release habitat probably delayed egg hatching for about 1 week, delaying phenology and thereby reducing the period over which eggs could be laid. A rapid population decline resulted in only three females found in the year before extinction. (c) 2005 Elsevier GmbH. All rights reserved.

1403: +.186

Himachal Pradesh, in India's North Western Himalayan State, is a global stronghold of two pheasant species; western tragopan *Tragopan melanocephalus*, regarded as the rarest of Himalayan pheasants and cheer pheasant *Catreus wallichii*. Declines in the wild populations of these species are a cause for great concern. Himalayan monal *Lophophorus impeyanus*, the state bird, is also threatened owing to excessive poaching for its colourful crest and meat. Furthermore, Himachal Pradesh is an important area for genetically pure commercially important red junglefowl *Gallus gallus*. Conservation of pheasants has hitherto been limited to captive breeding, resulting only in inbred stock not suitable for any reintroduction programme. The Wildlife Wing of the Himachal Pradesh State Forest Department has instigated the world's largest programme of conservation breeding of four species - western tragopan, cheer pheasant, Himalayan monal and red junglefowl. For ex situ conservation of these pheasants, existing pheasantries at Sarahan, Manali, Chail and Khariun are being redesigned at more appropriate sites. The in situ programme will cover intensive habitat status research in parallel with conservation breeding projects capable of providing 95 - 150 birds of these four pheasants each year. This paper reviews the in situ habitat and population status of all the pheasants found in Himachal Pradesh in relation to the protected area network, the ex situ populations in the pheasantries, and outlines plans for future strategies for the conservation of pheasants in the state.

1404: -.096

A literature review and surveys undertaken between October 2003 and March 2004 in Kaptai National Park, Chittagong Hill Tracts, Lawachara National Park and Satchari forest in Mawlavibazar district, Kurigram in Rajshahi and Sundarbans in Khulna provinces, established that 16 species of Galliformes occur in Bangladesh. Seven were recorded during the field surveys, with the remainder being reported in the literature. Of these species, Indian peafowl, *Pavo cristatus* and green peafowl *P. muticus* are currently extinct. Whitecheeked partridge *Arborophila atrogularis*, rufous-throated partridge *A. ruficularis*, rain quail *Coturnix coromandelica*, blue-breasted quail *C. chinensis* and grey francolin *Francolinus pondicerianus* are the least known species. Black francolin *Francolinus francolinus*, swamp francolin *F. gularis* and grey peacock-pheasant *Polyplectron bicalcaratum* are critically endangered and kalij pheasant *Lophura leucomelana* and Manipur bush quail *Perdicula manipurensis* are locally endangered. Of these, swamp francolin and Manipur bush quail are vulnerable globally. The rest of the species are data deficient. All galliform species are under great pressure from habitat loss, population fragmentation, hunting, environmental degradation and severe human disturbances. Some selected species including extinct ones are recommended for captive breeding and reintroduction. Research including long term monitoring and raising awareness are essential for conservation and the preparation of action plans for the galliform species of Bangladesh. International cooperation and technical support are urgently required.

1405: -.069

The massasauga rattlesnake (*Sistrurus catenatus*) is locally threatened or endangered throughout most of its range. The status of the desert massasauga (*S. c. edwardsii*) is as follows: Arizona, protected; Colorado, Species of Special Concern; Kansas, unknown; New Mexico, no special status; Oklahoma, unknown; Texas, unknown; Mexico, unknown. The desert massasauga is listed as a Species of Special Concern by the Colorado Division of Wildlife primarily because of the limited distribution of well-documented, stable populations. It is listed as a sensitive species by the USDA Forest Service (USFS), Rocky Mountain Region (Region 2), where populations are stable but uncommon in southeastern Colorado and southwestern Kansas. Primary Threats Long-lived, low fecundity animals such as the massasauga are inherently vulnerable to population losses because of limited replacement potential. In Region 2, the primary threat to massasauga populations is habitat loss and degradation due to urbanization, farming, heavy livestock grazing, and water table drawdown due to diversion and well water use. Like other xeric habitats, shortgrass prairie is severely affected by soil disruption (e.g., tilling, overgrazing, urbanization), and the arid nature of this habitat makes recovery following release from disturbance very lengthy and perhaps incomplete, particularly given the growing threat of invasive weeds. Massasauga populations in Colorado have benefited passively from geographic isolation in terms of distance from urban centers, but pressures from Front Range human populations could eliminate this isolation. Like all rattlesnakes, the common result of human encounters is death, and the effects of direct persecution in remote areas are nearly impossible to evaluate. Highway/road mortality is another anthropogenic threat to massasauga population stability and persistence. Conservation easements and public lands (e.g., State Trust lands, National Forest System lands) provide some protection, but presently these do not include areas in the state with the largest desert massasauga populations. Primary Conservation Elements, Management Implications and Considerations Protection and conservation of large, contiguous tracts of native shortgrass prairie habitat will be necessary for the long-term survival of the desert massasauga. Acquisition and management of lands by public agencies (e.g., USFS, Bureau of Land Management) and other groups will help to conserve this fragile habitat. However, much of Colorado is privately owned, often as large ranches (10,000 to 100,000 acres or more), so pursuit of conservation easement agreements with private property owners is likely a more productive means of providing broader protection. It is

further suggested that desert massasaugas rangewide receive protected, no-take status. Direct intervention (e.g., captive breeding, reintroduction) for preservation of Region 2 populations is not indicated or recommended at this time; however, these types of programs are being undertaken in other parts of the species' range. Populations of desert massasaugas in Colorado should be monitored at several levels. Sensitive and robust populations identified by the lead author of this assessment should be surveyed on a regular basis (i.e., 5 to 10 year interval, depending on funding availability) to ensure that new threats to the populations have not arisen. State and federal agencies should monitor land use changes, and if significant changes (e.g., urbanization, till farming, overgrazing) occur in areas occupied by massasaugas, impacts should be evaluated. Massasauga populations on National Forest System lands, in particular in the vicinity of the Baca County locality records, should be surveyed again in the near future with a concerted effort placed on the regions immediately adjacent to and within the Comanche National Grasslands. The Cimarron National Grasslands in southwestern Kansas should be surveyed extensively in late spring and early fall, when the likelihood of encounters is greatest, to determine unequivocally whether or not the desert massasauga occurs there (we expect it to occur there).

1406: +.054

Castilleja levisecta (Scrophulariaceae), the golden paintbrush, is an insect-pollinated herbaceous perennial found in the Pacific Northwest. Currently restricted to two island populations off British Columbia and nine populations (eight on islands) in Washington, *C. levisecta* is a rare species threatened with extinction. Allozymes were used to describe genetic diversity and structure in these eleven populations. Despite its threatened status and small geographic range, exceptionally high levels of genetic diversity are maintained within *C. levisecta*. All sixteen of the loci resolved were polymorphic within the species ($P-s=100\%$), while the mean percentage of loci polymorphic within populations ($P-p$) was 65.7%. The mean number of alleles per polymorphic locus ($AP(s)$) was 2.94 within the species and averaged 2.38 within populations ($AP(p)$). Genetic diversity ($H-s$) was 0.285 for the species, whereas mean population genetic diversity ($H-p$) was 0.213. Smaller populations had, on average, fewer observed alleles and less genetic diversity. A significant negative correlation ($r = 0.72$) was found between genetic identity and geographic distance, indicating reduced gene flow between distant populations. The most geographically isolated population was one of the larger populations, one of the most genetically diverse and the most genetically divergent. A wide range of pairwise population genetic identities ($I = 0.771 - 0.992$) was found, indicating considerable genetic divergence between some populations. Overall, 19% of the total genetic diversity was distributed among populations. Results of this survey indicate that genetic augmentation of existing populations is unnecessary. The high allelic diversity found for the species and within its populations holds promise for conservation and restoration efforts to save this rare and threatened plant species.

1407: +.030

Many populations of turtles (e.g. the European pond turtle *Emys orbicularis* in Poland) and tortoises are endangered. Thus, many protection programs of the animals, including highly manipulative ones (e.g. headstarting), are currently being carried out. Headstarting is a species protection technique that involves raising turtle hatchlings in captivity to an age of a few months up to several years, and then releasing them into a natural habitat. Usually the objective of this procedure is to grow hatchlings to a size at which they are less vulnerable to predators. However, recent analyses of headstarting programs suggest that they are fairly inefficient as tool to increase population size. Analysis suggests that headstarting programs can increase population size only if a large percentage of hatchlings is headstarted, so with large populations it is virtually impossible.

Additionally, if adult survivorship is decreased (even by only 1%), such method will be inefficient. Thus, if the reasons for population decline are not eliminated, a headstarting program cannot save populations from extinction. The real efficiency of such programs, however, also depends e.g. on the length of the headstarting program and the long-term survival rates of wild and headstarted individuals (factors that are currently not known). Headstarting programs should, at this point, still be considered experimental. Other possible to use techniques of protection of the European pond turtle are also ineffective (clutch protection), or data about ecology of the species are insufficient to use them (restitutions, building of artificial nesting places). Headstarting is useful only when used in tandem with a strategy that will reduce mortality of adult turtles. I recommend the initiation of headstarting program of the European pond turtle only when a population is in real danger of extinction, and only if it is impossible to reduce adult and subadult mortality. As morphological and genetic variations of the turtle in Europe are high, and only few information in the subjects from Poland area are available, translocations of individuals between populations should be present forbidden.

1408: +.113

Gibbons, like orangutans, are a group of threatened Asian apes, so that genetic monitoring of each species or subspecies is a pressing need for conservation programmes. We conducted a project to take, as far as possible, samples of known origin from wild-born animals from Sumatra and Borneo (Central Kalimantan) for genetic monitoring of agile gibbons. As a result, we found a whole arm translocation between chromosomes 8 and 9 (WAT8/9) specific to Sumatran agile gibbons. Furthermore, population surveys suggested that the form with the WAT8/9 seems to be incompatible with an ancestral form, suggesting that the former might have extinguished the latter from Sumatran populations by competition. In any case, this translocation is a useful chromosomal marker for identifying Sumatran agile gibbons. Population genetic analyses with DNA showed that the molecular genetic distance between Sumatran and Bornean agile gibbons is the smallest, although the chromosomal difference is the largest. Thus, it is postulated that WAT8/9 occurred and fixed in a small population of Sumatra after migration and geographical isolation at the last glacial period, and afterwards dispersed rapidly to other populations in Sumatra as a result of the bottleneck effect and a chromosomal isolating mechanism.

1410: +.047

With only two known wild populations, the Florida semaphore cactus [*Consolea corallicola* (Cactaceae)] is one of the rarest plant species endemic to South Florida. The species is known to occur in two populations in the Lower Florida Keys (currently seven individuals) and in the Upper Florida Keys at Biscayne National Park (approximately 570 plants). We used ISSR molecular markers to assess the levels of genetic variation of these two populations. We found no genetic diversity within these two populations and only four of the 64 ISSR loci showed differences between them. A single individual from an extirpated population of Big Pine Key is currently maintained in the ex situ collection of Fairchild Tropical Botanic Garden; this individual was also included in our ISSR study and it was genetically different from the ones in the wild, lacking six alleles found in the two wild populations. Therefore the species is currently comprised of three ISSR genotypes. These results are consistent with previous reproductive biology studies that suggested that *C. corallicola* does not propagate sexually and that asexual reproduction is the main life-history strategy of this species.

1411: +.464

The European network CRAYNET "European crayfish as keystone species-linking science, management and economics with sustainable environmental quality" emphasises knowledge-based management strategies. The CRAYNET meetings concentrate on certain topics: monitoring in conservation and management of natives; interaction between natives and aliens; control of aliens; habitat restoration; reintroduction and restocking; legislation; education. The Irish meeting (Kilkenny, 2003) "The endangered native crayfish *Austropotamobius pallipes*: bioindicator and heritage species" initiated debates about (1) what is a bioindicator, a flagship species or a heritage species?; (2) the problem of species complexes and the need to clarify and resolve taxonomy before management; and (3) what is meant by biodiversity in the context of European crayfish? The Norwegian meeting (Halden, 2003) "European native, crayfish with a special focus on *Astacus astacus*: linking socioeconomics and conservation" involved roundtables about (1) threats to indigenous population of crayfish at a landscape level; (2) exploitation, conservation, legislation; (3) reintroduction of indigenous crayfish, habitat restoration and monitoring; and (4) the urgent need for joint research about pathology. The present meeting (Innsbruck, 2004) "European native crayfish in relation to land-use and habitat deterioration with a special focus on *Austropotamobius torrentim*" aims to identify the species protection programs, to examine if legislation is working well in protecting vulnerable species, the state of advances about conservation genetics and how to make progress in education of the public. A permanent connection between the 12 core members provides opportunities to check the needed lines of research, to prepare recommendations, and to gather information for an atlas on the distribution of crayfish species in Europe as well as to prepare leaflets for the public.

1412: **-.083**

The fish hosts of *Margaritifera auricularia*, the critically endangered Giant Pearlmussel, have been identified. Natural infestations were searched for in the lower Ebro river (Catalonia, Spain), where the last viable population of *M. auricularia* survives. No encysted glochidia were found on wild fish. In addition, artificial infections were performed on 8 native and 8 exotic fish species. Encystment and growth was observed on the gill filaments of three species: *Acipenser baeri*, an introduced fish (showing that our early hypothesis involving sturgeons cannot be rejected, although it is not sufficient nor necessary); *Gambusia holbrooki*, a widespread exotic that may be useful in captive breeding; and *Salapia fluviatilis*, which is highly susceptible to infection, was the only species where full development was observed, shares the bivalve's habitat, and is also endangered. The dramatic reduction of the Giant Pearlmussel's range can now be explained as due to a combination of habitat destruction and disruption of its life cycle. This knowledge can now be used in a recovery program centered on the rearing of juvenile pearl mussels in captivity for reintroduction to the wild.

1413: **-.008**

Allozyme electrophoresis was used to determine the extent of clonality in four naturally occurring populations of *Acanthocladium dockeri* F. Muell. from the mid-north of South Australia. A total of 33 loci was scored for at least 16 plants from each population. The four known populations of *A. dockeri* represent four quite distinct genetic clones. Each natural population consists of a single genet, and no indication of any correlation between geographical proximity and genetic similarity was found. Seed set in flowers was very low (0.6% of florets), probably owing to low pollen germinability. Seedlings raised from *A. dockeri* seed collected at Hart displayed obvious genetic affinities to their parent, but were nevertheless genetically distinct. Differences were consistent with the derivation of this seed by selfing of the Hart genet. *A. dockeri* is considered at high risk of extinction because of its low genetic diversity, poor seed production, lack of seedling recruitment

and population growth by clonal reproduction alone. On the basis of the outcomes of this research, the following recommendations for conservation management of *A. dockeri* are made: (1) all four extant genets should be preserved in their respective habitats; (2) at least one ex situ collection of all four extant genets should be maintained at a secure site as an insurance against population loss; (3) further surveys are required to potentially locate new populations with superior fertility; and (4) mixing of clones or seed provenances into a single population should be avoided until appropriately designed experimental translocations have evaluated the possible consequences of such mixing on competitive, reproductive and genetic responses of populations.

1414: +.171

We examined the role of the grass-tree *Xanthorrhoea semiplana* F. Muell. canopy in the survival of the nationally endangered orchid *Caladenia* (syn. *Arachnorchis*) *behrii* Schldl. at three sites in the northern Adelaide region. We compared grazing and pollination of the flowering orchids within and away from the grass-tree canopy. Grass-trees generally provided significant protection from grazing, but orchids protected by grass-trees experienced reduced pollination for 2 out of 5 years. The net effect of these interactions, as measured by seed set, varied across years. When grazing pressure is high, orchids may benefit from grass-tree protection (facilitation), but under low grazing pressure, it is more probable that orchids set seeds away from grass-trees than under their canopy. Grazing pressure probably does not decrease in view of habitat fragmentation the importance of fragments as wildlife refuges. Therefore, factors affecting the survival of grass-trees, such as *Phytophthora cinnamomi*, may also affect orchid survival. Kangaroos which are often assumed to be responsible for most grazing in the Adelaide Hills are not the only predators of orchids, and a culling program has so far not resulted in a decrease of grazing pressure for the orchids. Translocation and fencing programs should examine the role of facilitative plants and grazers before spending precious conservation resources.

1415: +.066

The study is part of the surveys carried out within the framework of the European Community Life Project "Econet - corridors for life", aiming, to create, in the Emilia-Romagna region (Northern Italy), an ecological network in the plain of the Modena and Bologna provinces. The regional status of two fish species of conservational interest (the panzarolo goby *Knipowitschia punctatissima* and the three-spined stickleback *Gasterosteus aculeatus*) has been investigated and the possibility of restoring some of their populations analysed. 29 sites in the regional territory were surveyed, in 16 of which the fish and in 13 the benthic macroinvertebrates communities were recorded. Both the fish species are confirmed as critically endangered oil a regional level and virtually extinct in the province of Modena, where a reintroduction could be tried in two water systems of the Tiepido stream alluvial fan (Castelnuovo Rangone and Modena districts).

1416: +.389

After complete eradication, Eagle Owl *Bubo bubo* (L.) was re-introduced in the north-western hillside areas of Germany. Scientific research including diet-analyses were part of the re-introduction program to clarify, if food availability and prey choice limit reproduction and population development of the re-introduced *Bubo bubo* population. Here I compare prey choice of eagle owl and climatic- / habitat factors in the Eifel area and the population development of eagle owl and rabbit *Oryctolagus cuniculus* (L.), an important prey in many parts of Europe. Several and very different species, namely hedgehog, rabbit, hare, pigeons brown rat and common vole provide the basis of nutrition. This is presumably the reason for a stable and high

reproductive success and still increasing population of eagle owl in the Eifel, despite the dramatic decrease of rabbit due to the diseases RI-ID and Myxomatosis. Climatic conditions and suitable nest sites seem at present to be more important limiting factors for *Bubo bubo* in the Eifel area with its relatively cool temperate climate than the abundance of single prey species. However, landscapes change fast and therefore abundance of prey species can reach critical values soon, therefore an adequate food supply is a key-factor for eagle owl. Thus, eagle owl protection always has to consider adequate hunting areas, especially in Special Protection Areas of the European Birds Directive.

1417: +.113

One of the conservation precautionary measures applicable to overexploited species is to implement protected population through translocation of exogenous individuals. The European lobster (*Homarus gammarus* L. 1758) and the brown meagre (*Sciaena umbra* L. 1758) are species under strong fishing pressure. In summers 2001 and 2002 we released four translocated lobsters and two translocated brown meagres inside the Natural Marine Reserve of Miramare, where the species are naturally present. The spatial behaviour of the released animals was monitored using two different acoustic tracking systems (Track28 and VR1 receivers; Vemco Ltd). On the base both of bibliography and of our preliminary experimental outcomes, the lobsters were tagged by gluing the pinger to the dorsal surface of the cephalothorax and the brown meagres were tagged by implanting the pinger in the peritoneal cavity. All the animals, both lobsters and brown meagres, disappeared from the detection range of the hydrophones after a variable number of days (2-16 days of continuous monitoring). We suppose that they did not colonize the site, leaving the protected area. From the methodological point of view, VR1 mode proved to be a suitable tool to evaluate the colonisation of an area by transferred animals.

1418: +.124

The West Indian manatee (*Trichechus manatus*) is an exclusively herbivorous aquatic mammal. Recently, the stranding of live-orphaned calves has been the main threat to the species in northeastern Brazil. Since 1989, the Brazilian Manatee Project (PPB) has recovered 52 calf carcasses, of which 44 were alive. In 1994, "Lua" and "Astro" were the first manatees released from captivity in Brazil, and they have been tracked using radio telemetry methods. During daily tracking bouts, Lua's behavior and movement patterns were recorded, including reproductive behavior. On 17 December 2003, while she was in the Maracaípe Estuary, Lua gave birth to her first calf. Beginning on 18 December 2003, the mother/calf pair began repeated, tidally determined moves from the estuary used during high tides to the sandstone reefs used during low tides. Four days after the birth, an increase in motorized boat traffic in Maracaípe Estuary was observed. On 22 December, Lua and her calf moved to Serrambi Beach and remained outside the estuary in the reef area. On 25 December, the ninth day after the birth, Lua was sighted alone. On 26 December, the calf was found dead at Serrambi Beach. The place of birth supports the hypothesis that estuaries are birthing areas for manatees. The fact that Lua established her main fidelity site and gave birth in an area where manatees had previously been extirpated indicates a potential for reestablishing the species in its historical range via the rescue, rehabilitation, and reintroduction program developed by PPB. The calf's death confirms the fragility of the species' conservation. The last 44 live-orphaned calves seem to have been caused by habitat destruction and/or human disturbances within their habitat. The lack of effective coastal management programs, despite being mandated within the federal Environmental Protection Areas established in the region, are factors that severely impair conservation of the Antillean manatee in Brazil.

1419: +.195

Leiopelma hamiltoni from Maud Island, Marlborough Sounds, New Zealand is confined to two populations totalling approximately 19,000 individuals. In May 1997, 300 *L. hamiltoni* from Maud Island were translocated to nearby Motuara Island in an effort to expand their distribution and lower the risk of extinction for the species. By August 2002, 155 of the translocated frogs had been recaptured and the population contained a range of young to old frogs. Population estimates indicated the population on Motuara Island had stabilised with losses of the translocated frogs offset by new recruits. The first juvenile frog was found in January 1998, only 10 months after the translocation and 42 recruits were captured by August 2002. Although initial survival was low for the translocated frogs, survival following the initial 2-month settling-in period was high (71-100%). New recruits produced on Motuara Island had survival rates of 29-88%. Capture-recapture analyses support the view that the survival estimates include a large dispersal component. The a priori criteria for a successful translocation were met; the appropriateness of the Motuara Island habitat for breeding and adult survival was demonstrated.

1420: +.192

In the preservation of plant biodiversity, there are fundamental genetic and ecological similarities involved it]: (1) predicting the fate of small, isolated populations, (2) ensuring the successful reintroduction of endangered species back into natural habitats, and (3) understanding the establishment of species beyond their native ranges. In all three cases, populations small in size only experience high levels, of inbreeding and subsequently the expression of inbreeding depression. The ability of these populations to persist will depend, in part on the magnitude of inbreeding depression and the ability of selection to remove (or purge) the genetic load that causes inbreeding depression. The loss of genetic variation caused by inbreeding or drift in these small populations will restrict their evolutionary potential, placing a high premium on the ability of plants to respond plastically to environmental variation. When plants make appropriate phenotypic adjustments in truly novel environments while maintaining high fitness, we suggest the use of a new term, "opportunistic plasticity," for this attribute. Opportunistic plasticity may be particularly critical and advantageous in the case of plant introductions in ecological restoration where habitats resemble but are not identical to seed collection sites, or in the initial establishment phase of exotic species in non-native locations where many aspects of the environment differ from the native range. Overall phenotypic plasticity may also be an important means of dealing with environmental heterogeneity in many small populations, but unfortunately we have limited data on the interaction between inbreeding and plasticity in plants. The science and practice of conservation biology has generally appreciated the importance of inbreeding, but we feel that it will benefit greatly by considering the potential interactions between inbreeding and phenotypic plasticity and their effects in the establishment and persistence of small populations.

1422: +.018

The Red River of the North basin (RRNB) has an area of about 287,000 square kilometers of the upper Midwestern United States and south-central Canada. The river forms the North Dakota-Minnesota boundary and flows into Lake Winnipeg, Manitoba, and then, via the Nelson River, into Hudson Bay. While the Red River main stem remains a sinuous stream similar to early descriptions, the river's watershed has been altered dramatically by intensive agriculture, wetland drainage, channelization of tributary streams, and dam construction. Early land surveys described a landscape largely covered by prairie and wetlands. However, thousands of kilometers of ditches have been excavated to drain wetlands for agriculture in the United States in the late 1800s to the

1920s, and continuing, in Canada, to the present. Over 500 dams have blocked access to critical spawning habitat in the basin starting in the late 1800s. Also, during the mid-1900s, many of the tributaries were channelized, causing the loss of several thousand stream kilometers. While much of RRNBs fish assemblage remains similar to earliest historical records, the loss of the lake sturgeon *Acipenser fulvescens* is a notable change resulting from habitat loss and fragmentation, and overfishing. Additional localized extirpations of channel catfish *Ictalurus punctatus*, several redhorse *Moxostoma* species, sauger *Sander canadensis*, and other migratory fishes have occurred upstream of dams on several tributaries. Presently, efforts are underway to restore migratory pathways through dam removal, conversion of dams to rapids, and construction of nature-like fishways. Concurrently, lake sturgeon is being reintroduced in the hope that restored access to historic spawning areas will allow reestablishment of the species. Proposed construction of new flood control dams may undermine these efforts.

1423: +.240

Three Pacific salmonid species *Onchorynchus* spp. have replaced the extirpated Atlantic salmon *Salmo salar* as the main migratory salmonid in the Lake Ontario drainage. One of those species, the nonnative rainbow trout *O. mykiss*, has become widely distributed within the historical Atlantic salmon habitat, occupying an ecological niche similar to that of juvenile Atlantic salmon. Consequently, both a tributary's carrying capacity for Atlantic salmon and competition from established normative species are important when considering the feasibility of Atlantic salmon restoration. Estimation of juvenile rainbow trout production will help evaluate the capacity of tributaries to produce salmonids that occupy similar niches. Geostatistical methods were applied to standardized and efficiency-corrected electrofishing data from three of New York's best salmonid-producing streams to precisely estimate juvenile rainbow trout populations. Results indicated that each study stream could produce 20,000-40,000 age-0 and 4,000-10,000 age-1 and older rainbow trout per year. Statistical interpolation indicated areas of significantly different production potential and points of significant changes in productivity. Closer examination of the niche similarity and competitive potential of these two species is needed to properly interpret these estimates with regard to Atlantic salmon restoration.

1424: +.185

Stream temperature is an important factor influencing habitat suitability for cutthroat trout *Oncorhynchus clarkii*, but temperature data from headwater habitats are difficult to obtain. We tested the ability of easily obtained landscape and meteorological data to predict the mean daily temperature measured at 79 sites in tributaries to the Madison River, Montana. We also evaluated stream habitat suitability by using temperature predictions to estimate growth potential for age-0 westslope cutthroat trout *O. c. lewisi*. A model using mean daily air temperature, elevation, and channel gradient explained approximately 75% of the observed variation in mean daily stream temperatures. Classifications of habitat suitability based on predicted fish growth indicated that the majority (78%) of stream habitat in Madison River tributaries provides suitable or highly suitable habitat for westslope cutthroat trout. However, these higher-quality habitats occur primarily in lower-elevation reaches where westslope cutthroat trout have been displaced by normative salmonids. Linking potential fish growth to stream temperature predictions will help managers prioritize conservation efforts for this declining subspecies by predicting habitat suitability at potential reintroduction or population expansion sites.

1425: +.206

Because most reintroduced species are rare, data on their dynamics are scarce. Consequently, reintroduction programs often rely on data from other species or captive populations to project the performance of the reintroduced population in the wild. We compared the reproductive success and survival of a Persian fallow deer (*Dama mesopotamica*) population reintroduced in Israel over the first 5 years of the project with the survival and reproduction parameters estimated while planning the reintroduction. In addition, we compared the actual growth of the wild population with the growth originally projected by a computer model in the original reintroduction program. We monitored 74 radio-collared individuals (57 females and 17 males) released semiannually 1996-2001. Survival during the first year after release was lower than later years (0.90 and 0.82 versus 0.95 and 0.88, for females and males, respectively). Such an impact was not anticipated in the original plan, but overall survival was higher than originally projected. As assumed in the reintroduction program, reproductive success improved significantly with time since release and overall, was higher than expected. The mean number of animals released annually was lower than planned. Overall, the growth of the reintroduced population was slower than projected, but the deviation was close to confidence limits and the pattern similar. After 5 years it appears that the original time frame of 8-10 years for project completion can be met or at worst will cause a 1-year delay. Over the short term of 5 years, projection models in reintroduction programs are useful tools for assessing the sustained use of the breeding core, depicting the dynamics of the population in the wild, providing a relatively accurate time frame for the successful completion of the project, and assessing project success.

1426: +.155

Reintroduction or re-enforcement programmes are major tools in species conservation, but there is a need for more studies that assess the influence of different husbandry and release methods on the survival of released animals. We investigated the survival of globally threatened Marbled Teal (*Marmaronetta angustirostris*) taken into captivity as ducklings when they became trapped in an irrigation channel, then released again after fledging. We used wing tags and mark-recapture models to estimate the survival of released teal. Ducklings rescued in 1996 ($n = 53$) were released soon after fledging in September and their survival was modelled for seven months until April 1997. Their apparent monthly survival rate (lower than true survival owing to loss of wing tags) was 0.85 ± 0.12 (\pm -s.e.). Ducklings rescued in 1997 ($n = 44$) were released together in February 1998 over five months after fledging, and their survival was modelled for six months from February until August. Their apparent monthly survival rate was 0.54 ± 0.06 . Ducklings rescued in 1998 ($n = 159$) were released in August-September soon after fledging and their survival was modelled for 10 months from August until June. Their apparent monthly survival rate was 0.83 ± 0.07 . Monthly survival was significantly higher for the 1996 and 1998 cohort, suggesting that retaining birds in captivity after fledging had a negative impact on post-release survival. When birds were released in February, a lower proportion survived until the breeding season three months later than when they were released five months earlier in September. (C) 2004 Elsevier Ltd. 1427: +.200

This study reports on three scarlet macaw (*Ara macao*) reintroduction projects using hand-raised birds in Peru and Costa Rica. The habitats at the release sites ranged from pristine tropical forest to forest fragments in an agricultural matrix. The combined first-year survival was 74% and the annual post first-year survival was 96%. Survival rates were very high despite a wide range in predator communities. Number of birds released explained 70% of the variation in survival with birds from larger releases having higher survival rates. Behavioral evidence suggests that birds

established at the site facilitated survival of later releases. Breeding attempts were recorded at all three sites and hand-raised birds with wild mates successfully fledged young in Peru. Supplemental feeding post-release played an important role in keeping the birds near the release site and facilitating social interactions. This work shows that properly socialized hand-raised macaws can survive and breed in the wild but that ex-pets are not good release candidates. (C) 2004 Elsevier Ltd. All rights reserved.

1428: +.272

Insight regarding the genetic origin and composition of the studied population of the red-legged partridge (*Alectoris rufa*) is likely to provide general and critical information for the appropriate management and possible conservation of the species. The reintroduced population of red-legged partridges living in Pianosa Island (National Park Tuscany Archipelago) has proven to be sustainable: captive-bred individuals, morphologically assigned to the taxon *A. rufa*, were released to the island approximately 20 years ago, establishing an apparently well-adapted population. We have investigated this population by means of 10 microsatellite loci in order to shed light on its genetic structure. Considering that *A. rufa* is known to crossbreed with *A. chukar*, the Pianosa Island population was compared at the molecular level with a red-legged partridge breeding stock (Aulla, MS) as well as with a population of pure *A. chukar*. Our results indicate that the red-legged partridge population from Pianosa, morphologically identified as *A. rufa*, is actually partly introgressed with *A. chukar*, questioning its genetic purity and the possible use of this population as a starting stock for future reintroductions elsewhere.

1429: +.090

The little bustard (*Tetrax tetrax*) has declined rapidly across European farmland landscapes due to agricultural intensification. In France, the number of breeding males in agricultural habitats has been reduced by 92% over the last 20 years as a result of decreases in insect abundance and nest destruction during harvesting. An age- and sex-structured stochastic metapopulation model was formulated for the remaining little bustard population in south-west France and, using actual estimates of demographic rates obtained after 1997, its extinction risk over the next 30 years was estimated to be ca. 0.48. Limited population reinforcement has thus appeared as a potential conservation strategy for this species in agricultural habitats, while agro-environmental actions have begun to have an effect on habitat quality at the landscape level. Different strategies for the reinforcement of fledglings, including the number and frequency of releases and the number of release localities in relation to four criteria for choosing the release points, were evaluated in terms of their effect in reducing the extinction risk of local populations and of the metapopulation. The reinforcement of 100 fledglings per year for 5 years and choosing the actual release points using the current abundance were found to be the optimal choices for reducing the estimated extinction risk of the remaining little bustard population in south-west France.

1430: +.095

Relocation of endangered species can be an effective conservation tool if it does not mix populations that represent significant intraspecific variation. The threatened Italian agile frog, *Rana latastei*, has small populations with low genetic diversity: translocation has been proposed to improve the likelihood of survival of populations. Using a common environment experiment and field surveys, we investigated whether there were differences in larval growth and developmental rate between foothill and lowland *R. latastei* populations, to evaluate if they are evolutionarily significant units. In nature, the colder climate of the foothills causes delayed metamorphosis.

Conversely, in a common environment, larvae from foothill populations show faster growth and development. We did not find a significant egg-size related maternal effect or any differences in size at metamorphosis. We hypothesise that counter-gradient selection promoted fast growing phenotypes in a cold environment, where low temperatures slow down larval development. Foothill populations, despite being only a small geographical distance away from lowland populations, seem to be adapted to a colder climate and represent an evolutionarily significant unit. Different populations should, therefore, be managed independently, avoiding translocation. We suggest that evolutionary divergence between populations should be verified prior to planning relocation programmes, to prevent the risk of genetic homogenisation.

1431: +.225

Translocation of primates is still a rare event. The translocation in 1984 of two research groups of wild baboons that had been studied for 12 years prior to translocation and observed for 18 years afterwards offers a comprehensive set of data with which to evaluate success. A comparison with indigenous baboon troops at the release site provides an independent control for assessing performance in the release area. Two success criteria are developed with the use of indicator measures that include birth rate, death rate, patterns of mortality and survivorship, body condition, intestinal parasites, and group size. The baboon translocation succeeded according to both criteria: the two troops were saved by the translocation, and they did as well or better than could be expected in their new home. Their performance matched or exceeded that of translocated groups of other primate species. (C) 2005 Wiley-Liss, Inc.

1432: +.211

We used landmark-based geometric morphometric methods to describe patterns of body shape variation and shape covariation with size among populations of the threatened White Sands Pupfish (*Cyprinodon tularosa*), a species that occurs in dissimilar aquatic habitats. White Sands Pupfish populations include two genetically distinct, native populations that have been historically isolated in Salt Creek, a saline river, and Malpais Spring, a brackish spring. In addition, two populations were established approximately 30 years before this study by translocation of fish from Salt Creek to Lost River (a saline river) and Mound Spring (a brackish spring). We found significant body shape variation among populations and between males and females. Body shapes were more slender for females than for males and more slender for saline river populations than brackish spring populations. Introductions of pupfish to new habitats resulted in significant departures in body shape and shape allometry from the native Salt Creek population. Shape divergence was more pronounced for the Mound Spring population, which is consistent with a greater change in abiotic conditions. Although Mound Spring pupfish, like Malpais Spring pupfish, were more deep-bodied than saline river pupfish, differences in body shape and the level of sexual dimorphism were significant between the two brackish spring populations, indicating that deep-bodied shapes may be achieved from different anatomical configurations. The significant shape divergence of introduced populations warrants consideration for the conservation of this rare species, as creation of refuge populations for native stocks is a current management strategy.

1433: +.081

Perhaps no species elicits more polarized opinions in the United States than the gray wolf (*Canis lupus*). Both proponents and opponents of wolf recovery use symbolic language in an attempt to persuade others to change their attitudes and values. We used structured phone interviews with 1,300 registered voters to examine the attitudes of people living in Arizona, Colorado, and New

Mexico toward a proposed restoration of the gray wolf to the southern Rocky Mountains, and to examine the ability of persuasive arguments to change these attitudes. We found a high level of support for wolf restoration by residents of all 3 states; 64% of respondents favored reestablishing wolves in the southern Rockies, whereas 33% expressed opposition. Support was general across almost all demographic and other groups sampled, the exception being ranchers (44% in favor, 53% opposed). Persuasive arguments had little impact on respondents' attitudes toward wolves and their proposed restoration. Overall support for wolf reestablishment remained high and increased slightly after respondents heard persuasive arguments for and against wolf restoration. Yet most respondents (63.3%) did not change their level of support or opposition to the idea of reestablishing wolves after hearing persuasive arguments. Most people who did change their opinion increased the extremity of their responses, supporting attitudinal theory that predicts that people with strongly held attitudes will increase the extremity of their opinions after receiving more information. The attitudes people hold are critically important to the success of wolf restoration efforts. Although most of the public supports wolf restoration, polarization of the issue remains strong. This polarization poses a significant challenge to wildlife managers. If management agencies decide to pursue wolf restoration in the southern Rockies, efforts to mitigate strongly polarized positions should be given a high priority. Alternatively, if those agencies choose not to restore wolves, they likely will face significant controversy as unsatisfied wolf proponents make their feelings known.

1434: -.040

The peninsular pronghorn (*Antilocapra americana peninsularis*) in the Baja California peninsula is an endangered subspecies. We constructed captive breeding facilities in the Vizcaino Desert within the current range of peninsular pronghorn to assist in population recovery. The captive breeding facilities included fences, shade, feeders, an irrigation system, observation towers, housing for caretakers, and a visitor center. We document the initial 6-year cycle of the captive management, 1 step of the recovery effort, from the first capture of 5 fawns in 1998 to 90 captive peninsular pronghorns by the end of 2003. We identified problems with the captive breeding facility (e.g., identification of animals and movements into, and accidents with, fences), but overall the facility has been a success. We projected the first potential translocation of animals into the wild in 2004. If the translocation of captive animals is successful, peninsular pronghorn may begin the recovery process in the wild.

1435: -.016

Human-induced erosion regularly delivers massive quantities of fine sediments into streams and rivers forming large static bodies of sediment known as sand slugs, which smother in-stream habitat, alter community structure, and decrease biodiversity. Sand slugs are widespread in parts of southeastern Australia as well as in many other parts of the world, and there is now considerable interest in restoring such affected streams. The reintroduction of large timber is widely suggested as a strategy for restoring habitat complexity, but this has rarely been tested in sand slug-affected streams. We examined the response of fish populations to wood addition to two streams in southeastern Australia that have been impacted by sand slugs. Manipulated sites (three per treatment) had either one or four timber structures added, and these sites were compared with (three) unmanipulated (control) sites before and after the manipulation occurred. Despite a suprased seasonal drought during the study, we observed short-term increases in the abundance of Mountain galaxias (*Galaxias olidus*) at the four-structure sites, while both the four-structure and the one-structure treatments appeared to buffer against drought-induced declines in two other species, River blackfish (*Gadopsis marmoratus*) and Southern pygmy perch (*Nannoperca*

australis), relative to controls. However, drought eventually caused the complete loss of surface water from these streams and the loss of fish from both manipulated and unmanipulated sites. Thus, although the study supports the use of timber structures as a means of increasing local fish abundances, these beneficial effects were, in these streams, contingent upon permanency of flow. Because sedimentation has depleted the number of permanent refuge pools in these creeks, recovery rates of the fauna (i.e., resilience) are likely to be slow. We therefore conclude that in streams subjected to frequent disturbance, restoring refugia may be as, if not more, important as restoring what we term residential habitat.

1436: -.020

Salvaging from premining areas and translocation of succulent plants has been investigated for the revegetation of gypsiferous mine spoil in an arid region of South Africa. Given that facilitation effects are thought to outweigh competition effects in harsh environments, we hypothesized that the survival of translocated succulents would be higher when planted in multispecies clumps than alone and that the growth rate (measured as stem extension) and fruit-set would be greater for plants in clumps than for those planted alone. Two leaf-succulent species (*Aridaria noctiflora* ssp. *noctiflora* and *Drosanthemum deciduum*) and one stem-succulent species (*Psilocaulon dinteri*) were salvaged from the area destined for mining and translocated onto the mine spoil. These plants were planted either in a multispecies clump of the three species together or alone. One year after translocation, 67% of the plants survived. It was also found that the succulents used in these experiments survived in higher numbers when planted alone. Due to the similar root morphology of *D. deciduum* and *P. dinteri*, they competed for resources instead of facilitating each other's establishment. The results were variable for each of the species used, and neither growth nor seed-set was improved by clumping. These findings would also possibly vary from year to year with different abiotic conditions.

1437: +.105

Breeding biology of the endangered Mauritius Olive White-eye *Zosterops chloronothos*, the least known extant species of the endemic Mauritian avifauna, was studied for three consecutive breeding seasons between 1998 and 2001. Fifteen territories were monitored each year. Six nests were found and closely monitored. Prior to this study, only two nesting episodes had been documented. Nest observations revealed that both male and female were involved in incubation, brooding and feeding of the young at both the nestling and fledgling stage. One nest was successful (this being the first observation of a successful nest for this species) with fledging and juvenile dependency periods of 14 and 61 days, respectively. The remaining five nests were depredated, with evidence suggesting predation by the introduced Ship Rat *Rattus rattus*. Five breeding pairs each produced a single fledgling during the three-year period and no pair produced more than one fledgling. Targetted poisoning and trapping of nest predators on the main island of Mauritius and translocation of Olive White-eyes to predator-free islands should be implemented as conservation measures. Further ecological studies of the Mauritius Olive White-eye are sorely needed to direct conservation management of this declining species.

1438: +.072

The western barred bandicoot (*Perameles bougainville*) is an endangered species, free ranging on only two islands off the coast of Western Australia (Dorre and Bernier Islands). Conservation efforts are currently directed at reintroducing these marsupials into predator-proof enclosures and habitats in historical distribution ranges on the mainland in the southwest of Western Australia and

in South Australia. In September 2000, 19 western barred bandicoots were captured on Bernier Island for translocation, and 11 of these had evidence of at least one of the following eye conditions: corneal opacity, conjunctivitis, ocular discharge, and blepharitis. Five bandicoots were examined, and conjunctival and cloacal swabs were collected. Polymerase chain reaction for Chlamydiales was positive in four bandicoots. Four Chlamydiales types were identified by gene sequencing, including a strain of Chlamydia pecorum different from strains previously found in koalas and several new Chlamydiales genotypes. The bandicoots responded excellently to treatment with oxytetracycline weekly for 6 wk, and topical oxytetracycline and neomycin were administered topically to both eyes s.i.d. for 4 mo.

1439: -.014

Mbuna, the dominant fishes on the rocky shores of Lake Malawi, have become a major 'model system' for the study of rapid speciation and adaptive radiation. At least 295 putative species are known, of which more than 200 remain undescribed. There is no good evidence for monophyly in the mbuna, rather mitochondrial DNA phylogenies indicate that they are polyphyletic with respect to benthic feeding cichlids of the genera Aulonocara, Alticorpus and some species of Lethrinops. Male mbuna hold territories for 18 months or more and breed year-round. All species are maternal mouthbrooders, but females do not guard free-swimming young. Mbuna are polygamous (both sexes). There is sexual dimorphism in size, colour and fin length, and many species show within-population colour polymorphism. Mbuna genera are largely differentiated on the basis of head, jaw and tooth morphology, but congeneric species are generally distinguished by male colour. Many morphologically specialized forms have broad diets and often feed on common easily obtainable resources. While it is likely that dietary and habitat niche partitioning contributes to species coexistence, this has never clearly been demonstrated under experimental conditions. Populations on spatially separated habitat patches are often genetically differentiated, probably because most species are specialized for life on rocky shores, and lack a dispersal phase in their life histories. Males seem to disperse more than females, but are able to home several kilometres back to their territories. Some closely related ecologically equivalent allopatric populations are differentiated in male colour. Those tested have been shown to mate at least partially assortatively. Sexual selection acting on male colour seems the most plausible mechanism for initial species divergence. The same colour forms seem to have arisen several times, suggesting frequent parallel evolution. The main conservation threat to mbuna at present seems to be translocation of species within the lake as a result of the aquarium trade. However, deleterious effects on indigenous populations are not documented. In the long run, sedimentation, pollution, introduction of alien species and the development of targeted food fisheries could be more serious threats.

1441: +.172

Dispersal is universally considered important for biodiversity conservation. However, the significance of long- as opposed to short-distance dispersal is insufficiently recognized in the conservation context. Long-distance dispersal (LDD) events, although typically rare, are crucial to population spread and to maintenance of genetic connectivity. The main threats to global biodiversity involve excessive LDD of elements alien to ecosystems and insufficient dispersal of native species, for example, because of habitat fragmentation. In this paper, we attempt to bridge the gap in the treatment of LDD by reviewing the conservation issues for which LDD is most important. We then demonstrate how taking LDD into consideration can improve conservation management decisions.

1442: +.048

The southern brown bandicoot (*Isodon obesulus*) has undergone significant range contractions since European settlement, and it is now considered "Endangered" throughout south-eastern mainland Australia. This species currently has a highly fragmented distribution inhabiting a mosaic of habitats. This project uses mitochondrial DNA (mtDNA) and microsatellite data to determine levels of genetic diversity, population structure and evolutionary history, which can aid wildlife managers in setting priorities and determining management strategies. Analyses of genetic diversity revealed low levels of mtDNA variability (mean $h = 50.42\%$, $\pi = 0.76\%$) and divergence (mean $d(A) = 0.29\%$) across all regions investigated, and was among the lowest recorded for marsupials. These data indicate a relatively small female effective population size, which is most likely a consequence of a large-scale population contraction and subsequent expansion occurring in pre-history (mismatch distribution analysis, SSD P-value = 0.12). Individuals from the Sydney region experienced significant reductions in microsatellite diversity ($A = 3.8$, $H-E = 0.565$), with the Garigal National Park (NP) population exhibiting "genetic reduction signatures" indicating a recent population bottleneck. Population differentiation analysis revealed significant genetic division amongst *I. obesulus* individuals from Sydney, East Gippsland and Mt Gambier regions ($\theta = 0.176 - 0.271$), but could not separate the two Sydney populations (Ku-ring-gai NP and Garigal NP). Based on these data and habitat type, translocations could readily be made between the two Sydney populations, but not between the others. Phylogenetic comparisons between *I. obesulus* and *I. auratus* show little support for current *Isodon* taxonomy, consistent with the findings of Pope et al. 2001. We therefore recommend the recognition of only three *I. obesulus* sub-species and suggest that these comprise a single morphologically diverse species that once was widespread across Australia.

1443: **-.047**

Lake minnow is a cyprinid fish species, which is critically endangered in Poland and protected by law, and also included in the Polish Red Data Book of Animals. This species is an inhabitant of small and shallow, isolated water bodies, vulnerable to the total destruction mainly due to swamp draining and amelioration. In recent decades, the rapid disappearance of Polish lake minnow populations has been observed, from about 80 described in literature ever to as little as 19 at present; most of them (13) known from Kaszuby region in northern Poland (Fig. 1). It is therefore considered necessary to urgently begin the active protection of this species, including either protection in situ or ex situ. The latter is now possible due to good knowledge of the techniques of lake minnow captive breeding and production of stocking material under controlled conditions. The strictly limited, local translocations of this species, based on the results of preliminary studies on genetic variability of Polish populations, are planned to be performed in the Mazowsze region (central Poland) in the nearest future, in order to increase there the number of existing populations from 2 to 4. Long-term monitoring will enable to evaluate efficiency of such activities as concerns the most endangered lake minnow populations in other regions in Poland.

1444: **+.156**

The aim of the work was to illustrate characteristics of the natural resources and the evaluation of the small mesotrophic Wiejki Lake situated in Grodecko-Michalowska Basin (Polnocnopolaska Lowland, north-eastern Poland). The lake is one of only four such objects located in this part of the Polish Lowland. In this article, influence of lowering of groundwater levels and anthropogenic use on the lake vegetation in the period between 1953 and 2003 are also presented. Changes in natural environment surrounding the Wiejki Lake are described on the basis of aerial photographs and phytosociological records. In the past the lake occupied a considerably larger area, what is reflected in a mineral and organic gyttja layer a few metres thick occurring in the bottom of

organic deposits (Fig. 2). Low birch-willow thickets (*Betula humilis*-*Salix rosmarinifolia* community) and moss-sedge associations mostly determined the earlier vegetation of the lake. At present in the surroundings of the Wiejki Lake, seven plant communities are distinguished: *Equisetum fluviatilis*, *Caricetum rostratae*, *Caricetum diandrae*, *Salicetum pentandro-cinereae*, *Thelypterido-Betuletum*, *Ribeso nigri-Alnetum* and dominant *Festuca rubra* communities. They create distinct zones around the water level mark (Fig. 4). Sites of shrubby birch *Betula humilis* listed in Polish Red Data Book of Plants and additionally three plant species strictly protected in Poland (*Drosera rotundifolia*, *Dactylorhiza maculata*, *Dactylorhiza incarnata*) were found in vicinity of the lake. In the natural environment of the Wiejki Lake, significant changes of vegetation were affirmed in the course of last 50 years. They are: forming of reed-mace *Typha latifolia* concentrations in littoral zone, narrowing of sedge and moss-sedge communities zones as well as encroaching of grey willow *Salix cinerea* to rush and sedge phytocoenoses (Fig. 3, 4). Birch-willow tickets were replaced by birch-alder forests *Thelypterido-Betuletum* and cultivated wet meadows. The overall water surface area has not changed in this period, however deepness of the lake has decreased to about 1,5 m. These changes are directly connected with thorough drainage made in the middle of the 1980s. The outcome of the work is to define a protection plan of the Wiejki Lake in which indispensable methods of nature conservation were specified. It provides for: rising of ground water level, elimination of drainage ditches, reintroduction of Lapland willow (*Salix lapponum*) and the removal of shrubs and trees in order to preserve sites of *Betula humilis* (Fig. 3). Finally, a change of the protection status of the object from ecological area to nature reserve is suggested.

1445: -.006

Reintroduction projects may fail because captive-reared animals do not possess the behavioural skills required for survival in the wild. Rearing captive-bred animals in semi-natural enclosures prior to release has been used to improve the survival of reintroduced endangered species, but it is unclear how rearing environment influences the development of behaviour. This study examined the effect of rearing conditions on the behaviour of the goodeid *Skiffia multipunctata*, an endangered species of Mexican fish. Under standard laboratory conditions, the courtship, aggression, boldness and foraging behaviour of fish raised in aquaria was compared to that of fish reared in outdoor ponds. We present initial behavioural descriptions for this species and show that laboratory-reared fish displayed increased courtship, aggression and curiosity towards a novel predator in comparison to their pond-reared counterparts. Laboratory-reared fish also commenced foraging on a novel food item (*Artemia*) more rapidly than fish reared outdoors. These findings suggest that captive rearing environments promote the development of behavioural tendencies, such as boldness and aggression, which could be detrimental to the survival of reintroduced individuals. 1446: +.128

The small Cape mountain zebra population in Gamka Mountain Nature Reserve represents a third of the entire gene pool of this endangered species and is thus vital for its conservation. Presently, management of this population is largely hands off, with the belief that it will grow to levels which will allow it to form a source for the mixing of mountain zebra stocks in the future. The growth of this population however, has been slow and we investigated the influence of habitat and fire on this growth. Firstly, we used a diffusion model to perform a population viability analysis. This analysis indicated that the population had a low probability of attaining quasi-extinction in the next 50 years ($G = 0.0032$). However, our findings indicated that less than 30% of the reserve was suitable for mountain zebra and that the preferred habitat would have to be burnt at unnaturally short

intervals to sustain the present growth. We therefore argue that the risk of quasi-extinction to this population is greater than predicted and suggest that management options need to be implemented to reduce this risk. These options include; translocation to another protected area; acquisition of adjacent land; burning preferred habitat at unnaturally short intervals; forming a conservancy with adjacent landowners; leasing cultivated land for pasture. We suggest that only the latter two options are likely to stimulate mountain zebra population growth in the short term and that these should receive immediate attention. (C) 2004 Elsevier Ltd. All rights reserved.

1447: +.058

Little is known about the reproduction of the Iberian lynx (*Lynx pardinus*) even though it is the most endangered felid in the world. We studied during 9 years several reproductive parameters of the Iberian lynx in one of the subpopulations situated in Donana National Park (south-western Spain), by means of radio-tracking, direct observations and photo-trapping. The potential breeding subpopulation was usually composed of 3 adult females, which bred 83% of the total possible 29 female-reproductive year. The minimum total number of cubs born during the study was 64 (7.7 +/- 0.69 per year). There was no correlation between the number of cubs born or number of breeding females and population size of European rabbit (*Oryctolagus cuniculus*, the main prey of the lynx). All known births (n = 16) occurred in March except one in April and another in June. Mean litter size was 3.0 +/- 0.16 (n = 16, range = 2-4). Sex-ratio (n = 59 cubs) was 1.03:1.00 (females: males). Nevertheless, the commonest picture was a female with 2 cubs older than 3 months. Altogether, at age of 3 months, 75% of cubs survived. Number of lynx alive at 10 months old and before dispersing was 69% and 57%, respectively. Sex did not affect survival for any age. Normally, it was not possible to know the causes of the death of cubs younger than 3 months. Survival at this age was not related with mother, mother age, or rabbit abundance. All females that bred were older than 3 years. The age of last reproduction was 9 years. For 3 females that were tracked during almost their complete reproductive a life, the life time reproductive output was between 11 and 19 cubs. Iberian lynx reproductive parameters did not respond to wide changes in prey abundance during the study. Conservation plans considering the extraction of cubs with a low survival probability should be considered by managers, for instance, in translocation campaigns. (C) 2004 Elsevier Ltd. All rights reserved.

1448: +.095

Great crested newts (*Triturus cristatus*) are protected under European and UK legislation, but are frequently the subject of conflict between development and conservation in England. When this occurs, the developer is legally obliged to instigate a mitigation plan to reduce the impacts on the newts. This usually involves the translocation of newts coupled with habitat enhancement and creation. We reviewed mitigation projects carried out in England between 1990 and 2001 by (1) analysing licensing information collected by the governmental licensing authorities; and (2) a questionnaire survey of a sample of mitigation projects. Over half of the licensed projects on file contained no report of the work undertaken. There was an increase in the number of new translocation projects from less than 10 a year in the early 1990s to over 80 a year by 2000. This translates into about 1.5 million per year currently being spent on great crested newt mitigation projects. Most of these projects involved in situ translocations of newts to areas within or adjacent to the development site. The number of newts translocated per project declined over the same period, and was related to the total area of habitat destroyed and work effort. About 27% of great crested newt terrestrial habitat was destroyed during the developments along with about half of all ponds. Although the number of new ponds created compensated for the number of known great crested newt ponds lost, there was a net loss in terms of overall area of aquatic habitat. Where

follow-up monitoring of translocations was conducted, there was evidence of breeding at most sites one-year post-development, but it is unclear whether these populations were sustainable in the long-term. (C) 2004 Elsevier Ltd. All rights reserved.

1449: +.234

Kaka (*Nestor meridionalis*), red-crowned parakeet (*Cyanoramphus novaezelandiae*), whitehead (*Mohoua albicilla*), tomtit (*Petroica macrocephala*), and bellbird (*Anthornis melanura*) have all recently been reintroduced to sites in or near Wellington city. Prior to or concurrent with these translocations, unmarked individuals of all five species were detected in forested reserves on Wellington peninsula. Based on the number of birds seen, and frequency of sightings, we suggest that red-crowned parakeets, whiteheads and bellbirds have established resident populations in some reserves independent of translocations. We attribute these successful re-establishments to the effective control of possums (*Trichosurus vulpecula*) and rats (*Rattus* sp.) undertaken by Greater Wellington Regional Council and the Department of Conservation.

1450: +.102

A trial translocation to establish a new fluttering shearwater (*Puffinus gavia*) colony is reported. From 1991 to 1996, 334 fluttering shearwater chicks were transferred from Long Island to Maud Island, Marlborough Sounds, New Zealand. Chicks were artificially housed and hand-fed until fledging. Overall fledging success was 82%, 32 of the 273 chicks that fledged returned to Maud Island, and 30 have bred. Mean age of first breeding was 6.8 years (range 5-10 years). Returning chicks were heavier at fledging and spent longer on Maud Island than chicks that did not return. Transferred chicks showed typical post-fledging behaviour by dispersing to southeast Australian waters. The new colony has gradually increased, and 15 pairs bred in 2003/04. Methods developed have application to endangered species management.

1452: +.060

The Przewalski's horse was extinct in the wild in the late 1960s of the last century. But it survived in captivity, in zoos and animal parks. The successful breeding between 1950 and 1980 allowed the reintroduction to the wild after 1990. Different sites were checked in Mongolia, and the Gobi B-strictly protected area turned out to be the most suitable habitat. Between 1992 and 2004 89 Przewalski's horses were transported to the Gobi and 93 foals were born. 91 animals survived until now. Especially during winter 2000/2001 severe losses were registered. By 2004 four harem-groups and one stallion-group were established in the wild. Since 1998 a substantial scientific program was established, which was helpful for the monitoring of the Przewalski-population and different habitat factors. Since 2002 the focus has changed; the Przewalski's horse is not the first goal of the project anymore, but the umbrella species for the development of the Gobi B-strictly protected area into a biosphere reserve.

1453: +.250

Understanding the mechanisms by which climate and predation patterns by top predators co-vary to affect community structure accrues added importance as humans exert growing influence over both climate and regional predator assemblages. In Yellowstone National Park, winter conditions and reintroduced gray wolves (*Canis lupus*) together determine the availability of winter carrion on which numerous scavenger species depend for survival and reproduction. As climate changes in Yellowstone, therefore, scavenger species may experience a dramatic reshuffling of food

resources. As such, we analyzed 55 y of weather data from Yellowstone in order to determine trends in winter conditions. We found that winters are getting shorter, as measured by the number of days with snow on the ground, due to decreased snowfall and increased number of days with temperatures above freezing. To investigate synergistic effects of human and climatic alterations of species interactions, we used an empirically derived model to show that in the absence of wolves, early snow thaw leads to a substantial reduction in late-winter carrion, causing potential food bottlenecks for scavengers. In addition, by narrowing the window of time over which carrion is available and thereby creating a resource pulse, climate change likely favors scavengers that can quickly track food sources over great distances. Wolves, however, largely mitigate late-winter reduction in carrion due to earlier snow thaws. By buffering the effects of climate change on carrion availability, wolves allow scavengers to adapt to a changing environment over a longer time scale more commensurate with natural processes. This study illustrates the importance of restoring and maintaining intact food chains in the face of large-scale environmental perturbations such as climate change.

1454: -.029

Morangaya pensilis is an endemic monotypic cactus genus from the southern part of the Baja California Peninsula, Mexico. Previously known only as scattered individuals occurring at a very low density in the highest areas of Sierra de La Laguna, the occurrence of a relatively more dense population (4-7 plants per 250 m²) is reported on Sierra Cacachilas, c. 40 km to the north. Disturbance to the species' habitat includes fragmentation, illegal collection and trade, and land use changes, especially to farming and cattle ranching. Seeds collected from Sierra Cacachilas had a relatively high viability (92%) but recruitment (of 2-month old seedlings) in the area was relatively low, despite above average rainfall in the year of measurement. *M. pensilis* is eligible for inclusion in Mexico's list of threatened species and fulfils the requirements for categorization as Vulnerable on the IUCN Red List. Management activities that are already taking place in this area include restrictions on cattle and goat grazing and consideration of areas suitable for translocation of the species.

1455: +.149

The distribution and abundance of the greater sage-grouse (*Centrocercus urophasianus*) have declined dramatically, and as a result the species has become the focus of conservation efforts. We conducted a range-wide genetic survey of the species which included 46 populations and over 1000 individuals using both mitochondrial sequence data and data from seven nuclear microsatellites. Nested clade and STRUCTURE analyses revealed that, in general, the greater sage-grouse populations follow an isolation-by-distance model of restricted gene flow. This suggests that movements of the greater sage-grouse are typically among neighbouring populations and not across the species' range. This may have important implications if management is considering translocations as they should involve neighbouring rather than distant populations to preserve any effects of local adaptation. We identified two populations in Washington with low levels of genetic variation that reflect severe habitat loss and dramatic population decline. Managers of these populations may consider augmentation from geographically close populations. One population (Lyon/Mono) on the southwestern edge of the species' range appears to have been isolated from all other greater sage-grouse populations. This population is sufficiently genetically distinct that it warrants protection and management as a separate unit. The genetic data presented here, in conjunction with large-scale demographic and habitat data, will provide an integrated approach to conservation efforts for the greater sage-grouse.

1456: +.032

The newly described Gunnison sage-grouse (*Centrocercus minimus*) is a species of concern for management because of marked declines in distribution and abundance due to the loss and fragmentation of sagebrush habitat. This has caused remaining populations to be unusually small and isolated. We utilized mitochondrial DNA sequence data and data from 8 nuclear microsatellites to assess the extent of population subdivision among Gunnison sage-grouse populations in southwestern Colorado and southeastern Utah, USA. We found a high degree of population structure and low amounts of gene flow among all pairs of populations except the geographically adjacent Gunnison and Curecanti populations. Population structure for Gunnison sage-grouse was significantly higher than has been reported for greater sage-grouse (*C. urophasianus*). Further, we documented low levels of genetic diversity in some populations (particularly Dove Creek/Monticello and Pinon Mesa with an average of only 3.00 and 2.13 alleles per locus respectively) indicating that translocations from larger, more genetically diverse populations may be warranted. Bayesian analysis identified 3 potential migrants (involving San Miguel, Dove Creek/Monticello, Crawford, and Curecanti). Further, this analysis showed that 4 individuals from Cerro/Cimarron were more closely related to birds from San Miguel than to its geographically closer neighbors Gunnison and Curecanti. This suggests the Cerro/Cimarron area may act as a stepping stone for gene flow between San Miguel and Gunnison and that habitat restoration and protection in areas between these 2 basins should be a priority in an attempt to facilitate natural movement among these populations. Conservation plans should include monitoring and maintaining genetic diversity, preventing future habitat loss and fragmentation, enhancing existing habitat, and restoring converted sagebrush communities.

1457: +.106

1. Large carnivores are currently recolonizing areas where they have been extinct for decades. This poses considerable challenges for wildlife managers, partly because the optimal harvesting strategies of prey populations may be affected. If the carnivores in such areas are under strict management control (as in Scandinavia), the predator will not show a numerical response to changes in prey density. Consequently, the density of prey is mainly determined by the vital rates of the prey population and the predation pressure. In this study we modelled the optimal harvesting strategy for a prey population in which there was no numerical response by the predator.
2. Our model is an age-structured deterministic matrix model system. Optimal harvesting strategies are determined, measuring yield either as number of animals harvested or as mass of meat.
3. First, using a moose population in Hedmark in south-eastern Norway as a case study, we demonstrate that continuing to harvest at the rates used prior to wolf recolonization will lead to a decline in the moose population.
4. Secondly, harvesting quotas are specified by age and sex, usually with a high proportion of calves. Although wolves mainly kill juvenile moose (calves and yearlings), the relationship between harvest composition and yield is not affected by predation. Both in the presence and absence of predation, a high proportion of calves in the harvest gives the highest yield measured as the number of animals harvested, whereas a high proportion of adults maximizes the yield measured in terms of meat. Furthermore, a female-biased sex structure in the population gives a higher yield in both the presence and absence of the predator.
5. Synthesis and applications. We have shown that managers facing the new challenges presented by recolonizing populations of large predators such as wolves should reduce the size of harvest quotas in order to avoid decreases in prey populations. However, the general relationship between the harvesting strategy and yield maximization is not affected by wolf predation. The harvest yield from cervid populations is often important to local economies, and moose is the single most important game species in Scandinavia. It is therefore important to implement optimal harvesting strategies under

these new conditions in order to prevent an unnecessary loss of yield, and success in this task may in turn affect local attitudes towards large carnivores.

1458: *-.070*

The European minnow, *Phoxinus phoxinus* (L.), constitutes a serious threat to natural brown trout, *Salmo trutta* L., stocks in Norway following its introduction and translocation. In the present study, the leaping capabilities of the European minnow (50-110 mm total length) and brown trout (64-255 mm total length) were investigated with the aim of constructing suitable waterfall barriers to prevent further unwanted dispersal of the minnow, but still allow passage of larger brown trout. No successful leap of minnows was recorded at 4.9-6.5 degreesC, even at height intervals as low as 3 cm. At 14.0-16.5 degreesC, minnows were able to force waterfall barriers up to 27 cm high. At 4.9-6.5 degreesC brown trout forced waterfall barriers up to 40 cm. Thus, building of such barriers in brooks and rivers can help prevent the dispersal of minnows, and still allow larger brown trout to pass during feeding and spawning migrations.

1459: *+.172*

To minimise the risks of unintentional translocation and further spread of the non-native cyprinid, *Pseudorasbora parva* (Temminck & Schlegel) in the UK, various morphological and meristic characters of this species were measured, with a view to isolating the characters which allow reliable identification of this species during the early stages of development. The combination of myomere numbers, the nature of the internal pigmentation associated with the notochord and the lack of a single row of external melanophores along the route of the lateral line organ reliably facilitate the ability to distinguish this species from the native fauna of the British Isles. Thus, for the first time, fishery managers and environmental agencies have a much needed tool to screen for the presence young-of-the-year of this species when authorising movements of other fish species.

1460: *+.049*

Here I present a detailed analysis of individual inbreeding coefficient effects on some reproductive parameters and longevity in three species of gazelles under different conservation status: vulnerable dorcas gazelle, endangered Cuvier's gazelle, and extinct in the wild mhorr gazelle. The novelty of this study stems from the inclusion of both males and females in analyses including a large database of information collected during two decades of periodical studbook inventories for these species. Translocations to different zoo locations of the extinct subspecies mhorr gazelle do not apparently affect reproductive performance (population sex ratio) or individual longevity. In agreement with previous works, the average inbreeding coefficients vary inter-specifically, being higher in Cuvier's, followed by mhorr and dorcas gazelles. This reflects the different population size of the founding individuals of each species captive population. Sexual maturity and age at first birth follow an allometric pattern, occurring at an earlier age in the smallest species (dorcas), followed by Cuvier's and then the mhorr gazelle. Twinning in Cuvier's gazelle depends on maternal experience, as it is less frequent in primiparous females. Inbreeding affects neither twinning nor sex ratio. Mhorr gazelles' studbook shows several causes of death and it emerges that a higher proportion of non-inbred females die due to pathologies than males, although both sexes show similar proportion of mortal pathologies when inbred. Multifactor ANOVA shows that longevity decreases with inbreeding level and that females live longer than males in the three species of gazelles studied, as expected in polygynous mamma Mhorr and dorcas non-inbred females show higher juvenile survival than males, whereas inbred individuals show a similar declining juvenile survival, particularly in mhorr and Cuvier's gazelles. Finally, it is discussed the

apparent inbreeding tolerance in Cuvier's species, and the great value keeping and studying long term data of well-monitored captive populations may prove to the conservation of threatened species. (C) 2004 Elsevier Ltd. All rights reserved.

1461: +.043

The escalating threats to ecosystems worldwide have lead to a need for efficient methods to breed animals in captivity and to prepare captive-born animals for release back to the wild. However, life in captivity may lead to modifications in the animals behaviour mainly by genetic changes, including behavioural adaptations such as reduced predator responses. Such modifications may seriously affect survival after a reintroduction. The present study was a first screening of behavioural and morphological variation between different captive populations in standardized test situations using red junglefowl as a model species. The birds were tested in three different test situations in order to measure anti-predatory behaviour, social behaviour and exploratory behaviour. The results of this study clearly show that there are behavioural differences between the captive populations which potentially can be crucial for the animals in a reintroduction situation. However, the extent to which these differences are due to genetic changes caused by small breeding populations or adaptations to the different captive environments is not yet known. Although morphological differences found suggest that genetic variation may cause some of the behavioural differences as well. The differences found imply that life in captivity can affect an animal's behaviour and even though the red junglefowl is merely used as a model here, this suggests that these aspects may be important to consider also in other species where reintroduction is a more central motive for keeping the animals in captivity. 1462: +.012

We assessed the effects of range disjunction, migratory habit, coloniality, and habitat structure on the genetic differentiation of North American Burrowing Owl (*Athene cunicularia*) populations. Burrowing Owls in North America comprise two forms or subspecies: *A. c. floridana* in Florida, separated by ~1,500 km from the western form, *A. c. hypugaea*, which ranges from Texas to California and north to southern Canada. Burrowing Owls tend to be loosely colonial, and both the Florida populations and southerly populations of *A. c. hypugaea* from California to Texas are nonmigratory. To assess genetic structure, we examined 201 individuals from nine western and six Florida populations at seven highly variable microsatellite DNA loci. Mean gene diversity (H_{exp}) was higher in the west than in Florida (0.539 and 0.341, respectively; $P < 0.05$). Populations within subspecies were essentially panmictic (*A. c. floridana*: $\theta = 0.038$, $\rho = 0.014$; *A. c. hypugaea*: $\theta = 0.014$, $\rho = 0.009$) and even genetic differentiation across subspecies was modest ($\theta = 0.051$, $\rho = 0.014$). Nevertheless, the western and Florida forms were easily distinguished by any of several criteria, such as allelic absences in Florida, assignment tests, and well-supported branches on the inferred phylogenetic tree. Genetic differentiation was at least twice as great in resident Florida ($\theta = 0.038$) and California ($\theta = 0.021$) populations as in migratory western populations ($\theta = 0.012$), though 95% confidence intervals of theta estimates overlapped. We found no evidence of a genetic bottleneck that would result in evolutionary disequilibrium within subspecies. In the west, high observed heterozygosity values and evidence of gene flow suggest that population declines and patchy habitat, which currently imperil this species throughout much of its range, have not led to inbreeding or biologically meaningful genetic differentiation among the sampled populations.

1463: +.146

Experimental translocations of three endangered plants undertaken in South Australia confirmed the impact of specific factors thought to affect the survival and establishment of seedlings of each species. A trial involving *Prostanthera eurybioides* planted into several different microsites, found microsite to be a critical determinant of survival and growth. Herbivore grazing and weed competition adversely affected survival and growth of *Acacia cretacea* and *Acacia whibleyana* translocants, respectively. While these findings may not necessarily extrapolate to all species, common sense suggests that these three factors should be important considerations when planning other plant translocations. For example, attention needs to be given to the exact placement of individuals in relation to suitable edaphic, biotic and climatic factors around the receptor site. Where weeds threaten the population, they need to be controlled either before or at the time of planting. Furthermore, protection of new plantings from herbivores is likely to be crucial, particularly during the first few months after planting.

1464: +.047

Temperate grassy ecosystems are amongst Australia's most endangered ecosystems. Most remnants are small, fragmented and highly degraded. Practical methods for restoring native understorey species are urgently required. Dominant native grasses such as Kangaroo Grass (*Themeda triandra* Forssk.) and Tussock-grasses (*Poa* species) have been eliminated from many remnants by heavy grazing in the past. The reintroduction of these grasses is a critical step for understorey restoration. This paper (i) reviews the literature on *Themeda* seed biology and seedling establishment; (ii) summarizes the lessons learnt from three major attempts to establish *Themeda* stands in south-east Australia; and (iii) identifies the research needed to enhance *Themeda* restoration. Considerable information is available on *Themeda* seed and establishment biology, and restoration exercises have shown that *Themeda* stands can be readily established by surface-spreading awned seeds in seed-bearing hay. However, many practical challenges remain, including the need to identify optimal sowing periods, create better seedbed conditions, develop practical mulching techniques, and improve weed control. The use of seed-bearing hay has constrained restoration to relatively small areas in the past. Future trials may benefit by using more concentrated seed products such as seed-bearing florets and pure seeds which permit larger areas to be restored at one time.

1465: -.012

The island fox (*Urocyon littoralis*) on Santa Catalina Island is among the most imperiled species on the Channel Islands due to a recent outbreak of canine distemper virus (CDV). The western subpopulation, which was not exposed to CDV, is a crucial element in the recovery of foxes by providing a source of animals for translocation and captive breeding. Using the program VORTEX, we developed a population viability analysis for the Santa Catalina Island fox to (1) address the likelihood of population persistence, (2) estimate the current susceptibility of the population to catastrophic events, and (3) evaluate the efficacy of current restoration strategies of releasing captive bred foxes and transplanting wild animals. Overall, we found the population to be susceptible to catastrophic events; a 50% increase in mortality every 20 years was sufficient to elevate the extinction risk above 5%. Current management activities entail the transplanting of 12 juvenile foxes annually, which may reduce the viability of the western subpopulation. A minimum population size of at least 150 foxes should be maintained in each subpopulation to reduce the risk of extinction due to demographic stochasticity. Releases of translocated and captive bred animals affect the speed of recovery on the eastern half of Catalina Island, but not the probability of extinction, which is near zero under current conditions. We conducted a sensitivity analysis for demographic parameters by incrementally varying survival, fecundity and density-dependence

parameters, while holding all other parameters constant. Sensitivity analyses identified mortality and mean litter size as the most sensitive parameters, while the implementation of density-dependence and environmental variation of model parameters did not seem to affect population performance. We conclude that the population of island foxes on Santa Catalina is currently at a critically low population level, but recovery of the species appears possible. (c) 2004 Elsevier B.V. All rights reserved.

1467: +.175

This report provides guidelines for the captive management of mudfish (*Neochanna*) species in New Zealand. This includes the requirements for captive rearing, breeding, stock maintenance, and the establishment of new *Neochanna* populations. The reproductive and developmental biology of *Neochanna* species has been an infrequently studied topic, with the exception of Canterbury mudfish (*N. burrowsius*). Further, spawning in captivity has been documented only once in the cases of black (*N. diversus*) and brown (*N. apoda*) mudfish, and never for the Chatham (*N. rekohua*) or Northland (*N. heleios*) mudfishes. As each species has differing characteristics that are likely to influence its requirements, and much is still to be learnt, the aim of this report is to collate information and provide preliminary guidelines. Improving the survival rate of eggs and fry through successful captive breeding and rearing may provide a pool of recruits for the establishment of further populations. Translocation is an important method of safeguarding against species extinction by spreading the risk among a greater number of populations. However, captive management and translocation are not without risk, and should be contemplated thoroughly. *Neochanna* species have proved a challenge to breed in captivity, and many translocation attempts have failed to establish populations. These disappointments illustrate that a greater understanding is required to direct future conservation efforts. Thus, this report provides practical guidance to encourage further research into the biology of *Neochanna* species based on observations from both successful and unsuccessful experiences of breeding *Neochanna* species in captivity.

1468: +.113

At least five species and six taxa of kiwi (*Apteryx* spp.) are recognised at present. All taxa are currently listed as threatened. Since the 1890s, translocation of kiwi populations to the offshore islands of New Zealand has been used in the conservation of the genus. This report identifies and reviews offshore (and lake-bound) islands where kiwi occur naturally, together with islands to which kiwi have been translocated. Brief, descriptive histories of populations and translocations are provided. At least 28 offshore islands (excluding Stewart Island) currently support populations of kiwi. A number of islands, nominated by DOC conservancies, which might be suitable for future translocations, are also listed. The criteria for this list of potential islands include: lack of predators; sufficient size (at least 100 ha); presence of suitable habitat; legal protection; and absence of conflicting conservation values. Before recommendations as to which species should be translocated (and to which islands) can be made, consultation with other interested parties and detailed investigations of the islands. suitability will be required.

1469: +.201

Throughout the latter half of the twentieth century, wildlife habitat destruction and species extinctions have greatly increased. As the number of endangered species grows, the use of reintroduction as a conservation tool against species extinction increases. This study focuses on a 16-month study on marsh deer reintroduced in the Jatai Ecological Station. The animals were radio tagged and tracked daily between December 1998 and April 2000. Displacement activity and

spatial preferences were monitored by triangulation. The animals wandered the floodplains inside the protected area and also a floodplain that is part of privately owned property on the western edge of the Jatai Ecological Station. During the study, most of the reintroduced marsh deer preferred the private floodplain area more than the floodplains inside the protected area. This preference revealed the ecological importance of the area and the necessity of its incorporation into the Jatai Ecological Station.

1470: +.160

In this work, in vitro clonal propagation of *Drosophyllum lusitanicum* (Dewy pine) was obtained from seedlings germinated in vitro. Seeds were collected in various populations identified in the Algarve region and germinated in vitro on MS medium supplemented with 0.5 mg l⁻¹ BA (6-benzyladenine) and 0.1 mg l⁻¹ GA(3) (gibberellic acid). The obtained shoots were used in several multiplication assays. The best results were observed in MS medium supplemented with 0.2 or 0.5 mg l⁻¹ zeatin. The highest rooting frequency (83%) was observed on 1/4MS medium supplemented with 0.2 mg l⁻¹ IBA (indole-3-butyric acid). Fifty percent of the plantlets were successfully acclimatized to ex vitro conditions, exhibiting normal development. Plans are underway to reintroduce the in vitro produced plants from this study in selected locations in their natural habitat.

1471: +.254

1. *Najas flexilis* (Willd.) Rostk. & Schmidt is a submerged annual macrophyte, rare in Europe, which is protected under the EC Habitats Directive. 2. *N. flexilis* grows in deep, often coloured or turbid water in mesotrophic lakes. Because of this habitat preference it is difficult to locate and assess the ecological state of populations of the species for conservation monitoring purposes. 3. A method is described based on plant community information that can be used to determine the baseline probability that conditions in a lake are suitable for supporting *N. flexilis* growth. This can be applied to conservation management decisions, such as whether a detailed underwater survey is justified for monitoring the integrity of existing populations of *N. flexilis*, or whether the lake may be a suitable site for introduction, or reintroduction, of populations of the plant. 4. Two methods of plant community description are compared: a quantitative micro-habitat scale approach and a whole-lake-scale qualitative approach. Plant community data collected using each method were grouped using TWINSpan, and environmental descriptors of the sites comprising each plant community group were compared statistically. 5. Micro-habitat-scale community groups differed significantly only in the light extinction coefficient, indicating the zone within the lake in which *N. flexilis* occurred. 6. The whole-lake-scale community groups differed in a number of environmental variables indicative of eutrophication and acidification, two major environmental threats to *N. flexilis* survival. 7. This study suggests that a lake-scale qualitative plant community description would be a better indicator of site suitability for *N. flexilis* growth than a quantitative micro-habitat plant community description. This is because the whole-lake-scale approach could detect a difference in the environmental factors that affect *N. flexilis* growth, which the micro-habitat scale approach could not. 1473: -.060

In Brazil, few efforts have been made to reintroduce the species seized from the illegal traffic of animals, so they are frequently released in habitats different from their own and without any type of identification. The introduction of such species in such habitats can cause great disturbance, at times irreparable. The present study addresses the breeding of a group reintroduction of *Aratinga*

aurucapilla specimens seized from the illegal traffic of sylvan animals and recuperated and medicated in a Selection Center. All the specimens were banded with adequate steel bands before being released. Soon after their reintroduction, the birds started nesting in artificial nests made of PVC tubes, having generated several offsprings. The birds and their offsprings are being monitored for the last seven years.

1474: -.255

The Przewalski's horse (*Equus caballus przewalskii*) was extinct in the wild by the mid 1960s. The species has survived because of captive breeding only. The Takhin Tal reintroduction project is run by the International Takhi Group; it is one of two projects reintroducing horses to the wild in Mongolia. In 1997 the first harem group was released. The first foals were successfully raised in the wild in 1999. Currently, 63 Przewalski's horses live in Takhin Tal. Little information exists on causes of mortality before the implementation of a disease-monitoring program in 1998. Since 1999, all dead horses recovered ($n = 28$) have been examined and samples collected and submitted for further investigation. Equine piroplasmiasis, a tick-transmitted disease caused by *Babesia caballi* or *Theileria equi*, is endemic in Takhin Tal and was identified as the cause of death of four stallions and one stillborn foal. In December 2000, wolf predation was implicated in the loss of several Przewalski's horses. However, thorough clinical, pathologic, and bacteriologic investigations performed on dead and surviving horses of this group revealed lesions compatible with stranglers. The extreme Mongolian winter of 2000-2001 is thought to have most probably weakened the horses, making them more susceptible to opportunistic infection and subsequent wolf predation. Other occasional causes of death since 1999 were trauma, exhaustion, wasting, urolithiasis, pneumonia, abortion, and stillbirth. The pathologic examination of the Przewalski's horses did not result in a definitive diagnosis in each case. Several disease factors were found to be important in the initial phase of the reintroduction, which could potentially jeopardize the establishment of a self-sustaining population.

1476: +.182

Conservation of mammal species often requires the application of predictive habitat models. While empirical models can indicate the potential suitability and distribution of recent habitat, they may fail to depict native habitat and distribution. Therefore, we advocate validating such models with archaeozoological data. To demonstrate the power of archaeozoological data in investigating native distribution patterns, we use the alpine chamois (*Rupicapra rupicapra*) as a model species. After experiencing a severe historical population bottleneck due to overexploitation, chamois populations recovered markedly during the last century. Fostered by humans and having profited from translocations, this alpine ungulate greatly expanded its range and began to invade forested areas both within and outside the Alps, where damage to vegetation was soon obvious. Consequently, a controversy arose concerning the natural distribution and habitat of chamois. To study the native habitat and distribution of alpine chamois in Switzerland, we focus on the Late Mesolithic and Neolithic period (6000-2200 BC). This period best suits our purpose because pristine forests then dominated the landscape and human influence was as yet minimal. We describe two opposing habitat models: the alpine model assumes that chamois had survived only in alpine areas, whereas the forest model assumes that they also roamed in steep, entirely forested areas. We validate these models with archaeozoological data. Because the probability of chamois bone occurrence in prehistoric settlements is expected to decrease with increasing distance from chamois habitat, the models differ in their geographical predictions of chamois bone records. Applying logistic regression models, only settlement proximity to chamois forest habitat explains recoveries of fossil chamois bones. The resulting function of catchment

distances (i.e., the likelihood of hunting chamois depending on the distance between a settlement and the nearest chamois habitat) matches the spatial behavior of extant hunters within pristine forests. We conclude that Holocene chamois range in Switzerland naturally included steep and entirely forested regions, like the Jura Mountains. The recent invasion of these areas by chamois thus constitutes repatriation of native habitat. Accordingly, we propose a shift in perspective toward landscape integration of chamois.

1477: -.035

Endemic to the islands of Guam and Rota in the Mariana islands, Mariana Crow *Corvus kubaryi* is the only corvid in Micronesia. Currently, it survives on Guam only because of translocation of individuals from Rota (1999-2003). island-wide surveys in 1982 and 1995 on Rota yielded population estimates of 1,348 and 592 respectively, indicating a 56% decrease in only 13 years. A sharp decline in the only viable Mariana Crow Population has serious implications for conservation efforts on Rota and for efforts to re-establish the Guam population. However, the validity of the apparent decline has been debated among scientists and government management agencies. We augmented the 1982 and 1995 island-wide VCP surveys with (1) an additional island-wide survey conducted in 1998, and (2) roadside surveys conducted during 1991-1993 and again during 1999-2002. We also outline historical changes in Rota's limestone forest based on aerial photographs and historical information. Data from all surveys indicate a significant decline in the Mariana Crow population. Declines occurred especially along the north-central coast and in the area east of the airport known as As Dodo in the 1990s, but the data indicate an island-wide decline over the entire span of the surveys. Introduced predators, human persecution, and habitat loss and degradation by anthropogenic and natural causes have all contributed to the decline. Long-term preservation of this species will require effective brown treesnake *Boiga irregularis* control, habitat protection, continued monitoring and research, and increased public education and awareness of Rota's rare and endangered species.

1478: +.044

We report the results of eight years of post-release monitoring of 37 wild-born, captive chimpanzees released into the Conkouati-Douli National Park, Republic of Congo. Overall survival was high, with 23 (62%) individuals remaining in the release zone, and only 5 (14%) confirmed dead. Released females regularly interacted with wild chimpanzees. Several females appeared to have integrated into wild groups for extended periods of time, and four released females gave birth to a total of five offspring. However, encounters with wild chimpanzees were a major cause of mortality in released males, and 40-50% of released males would have died without veterinary intervention. These sex differences are in accordance with knowledge of chimpanzee behavioural ecology. Our results demonstrate that wild-born, captive chimpanzees can be released into the wild successfully, under certain specific conditions. Most importantly, careful planning and preparation is critical at all stages; a suitable release area must be identified; potential risks to existing wild populations, including the possibility of disease transmission, must be minimised; and post-release monitoring is essential. Adolescent females are the most suitable candidates for release, as they appear to be able to integrate successfully into wild communities. However, males should not be released where wild chimpanzees occur, as they are likely to be attacked and killed. Release into the wild addresses the welfare of certain individual animals, although it clearly cannot address the fate of all captive, wild-born chimpanzees. Knowledge of how to successfully release chimpanzees into the wild also has both current and potential future benefits for the conservation of wild chimpanzee populations. (c) 2005 Elsevier Ltd. All rights reserved.

1479: +.240

African wild dogs are endangered, and in South Africa as elsewhere, they inhabit a fraction of their former range. In this study, we assessed the potential for economic benefits derived from ecotourism to offset the costs of three wild dog conservation options using a contingent valuation study of the willingness of visitors to four protected areas to pay to see wild dogs at the den - within a viable population in a large protected area (Kruger National Park), through reintroduction into nature reserves, and through the conservation of wild dogs occurring on ranchland in situ. Results indicated that tourism revenue from wild dogs in large protected areas is more than sufficient to offset the costs and could potentially be used to subsidise wild dog reintroductions or the conservation of wild dogs in situ on ranchland. On ranchland and for reintroductions, tourism revenue was generally predicted to offset most of the costs of conserving wild dogs where predation costs are low, and to exceed the costs where willingness to pay is high, and/or where the costs of predation by wild dogs are zero. Conservation efforts should facilitate the derivation of eco-tourism-related benefits from wild dogs on ranchland and in private reserves to create incentives for wild dog conservation. Ecotourism should be part of a multifaceted approach to wild dog conservation which also includes education and awareness campaigns, and efforts to encourage landowners to cooperate to form conservancies. 1480: +.213

Translocation is an important tool for the conservation of species that have suffered severe range reductions. The success of a translocation should be measured not only by the survival of released animals, but by the reproductive output of individuals and hence the establishment of a self-sustaining population. The bridled nailtail wallaby is an endangered Australian macropod that suffered an extensive range contraction to a single remaining wild population. A translocated population was established and subsequently monitored over a four year period. The aim of this study was to measure the reproductive success of released males using genetic tools and to determine the factors that predicted reproductive success. Captive-bred and wild-caught animals were released and we found significant variation in male reproductive success among release groups. Variation in reproductive success was best explained by individual male weight, survival and release location rather than origin. Only 26% of candidate males were observed to sire an offspring during the study. The bridled nailtail wallaby is a sexually dimorphic, polygynous macropod and reproductive success is skewed toward large males. Males over 5800 g were six times more likely to sire an offspring than males below this weight. This study highlights the importance of considering mating system when choosing animals for translocation. Translocation programs for polygynous species should release a greater proportion of females, and only release males of high breeding potential. By maximizing the reproductive output of released animals, conservation managers will reduce the costs of translocation and increase the chance of successfully establishing a self-sustaining population. 1481: -.028

The wild grapevine, *Vitis vinifera* L. subsp. *silvestris* (Gmelin) Hegi, is considered to be an endangered taxon in Europe, mainly as a consequence of the introduction of pathogens from North America and of the destruction of its habitat. In the Rhine Valley, nearly all populations disappeared due to river management, the intensification of forestry, and the introduction of phylloxera. After a growing awareness of the need to preserve endangered forest ecosystems, attempts to reintroduce wild grapevine in the Rhine Valley were performed, particularly in the

French nature reserves Erstein and Offendorf since 1992. However, regular surveys of the plants indicate the rapid decline of the populations. In 2002, we proposed to summarise the knowledge accumulated after 10 years of experiments. Results indicate that from the initial 91 individuals planted in 1992, only 14 survived in 2002 (2 in Erstein, 12 in Offendorf). The failure of the experiment may be explained by several factors: unsuitable sites (too shady, absence of support for the young plants), absence of monitoring, vandalism or predation. According to these results and recent knowledge of the ecology of the plant and of vines in general, new transplantation experiments are proposed in which the plants will be monitored during their establishment in the forests. The success of this second transplant (50 plants per reserve) will be enhanced by restoration projects of the Rhine River dynamics, with partial re-flooding. Floods should help to avoid, or at least to reduce, pest and disease expansion on future adult plants.

1482: +.067

Populations of harlequin frogs *Atelopus* are declining throughout their geographical range. In Peru six of the 11 nominally described species are Critically Endangered, and there are at least 17 undescribed additional forms (all representing apparently distinct species), the conservation status of which is unknown. Most *Atelopus* taxa in Peru have relatively small geographical ranges, some known only from single populations, and have only a limited chance of survival. Conservation will require: (1) improvement of the faunistic and taxonomic knowledge of the genus, (2) field surveys, including in remote areas, (3) assessment of all species and populations for chytridiomycosis and research on the agent's biology, (4) ex situ conservation measures to facilitate later reintroduction, and (5) involvement of national and international conservationists and local people.

1483: +.028

In species of great conservation concern, special attention must be paid to their phylogeography, in particular the origin of animals for captive breeding and reintroduction. The endangered European mink lives now in at least three well-separated populations in northeast, southeast and west Europe. Our aim is to assess the genetic structure of these populations to identify 'distinct population segments' (DPS) and advise captive breeding programmes. First, the mtDNA control region was completely sequenced in 176 minks and 10 polecats. The analysis revealed that the western population is characterized by a single mtDNA haplotype that is closely related to those in eastern regions but nevertheless, not found there to date. The northeast European animals are much more variable ($\pi = 0.012$, $h = 0.939$), with the southeast samples intermediate ($\pi = 0.0012$, $h = 0.469$). Second, 155 European mink were genotyped using six microsatellites. The latter display the same trends of genetic diversity among regions as mtDNA [gene diversity and allelic richness highest in northeast Europe ($H-E = 0.539$, $R-S = 3.76$), lowest in west Europe ($H-E = 0.379$, $R-S = 2.12$)], and provide evidences that the southeast and possibly the west populations have undergone a recent bottleneck. Our results indicate that the western population derives from a few animals which recently colonized this region, possibly after a human introduction. Microsatellite data also reveal that isolation by distance occurs in the western population, causing some inbreeding because related individuals mate. As genetic data indicate that the three populations have not undergone independent evolutionary histories for long (no phylogeographical structure), they should not be considered as distinct DPS. In conclusion, the captive breeding programme should use animals from different parts of the species' present distribution area.

1484: +.318

1. The genus *Castor* comprises two species: the Eurasian beaver *Castor fiber*, and the North American beaver *Castor canadensis*. Both species suffered from overexploitation, but have seen a revival since the 1920s due to increased protection and reintroduction programmes. Increases in the populations and distributions of species that are able to modify ecosystems have generated much scientific interest. Here we review the available literature concerning the possible ecological impact of beaver species in the Old and New World. 2. Beavers, being ecosystem engineers, are among the few species besides humans that can significantly change the geomorphology, and consequently the hydrological characteristics and biotic properties of the landscape. In so doing, beavers increase heterogeneity, and habitat and species diversity at the landscape scale. Beaver foraging also has a considerable impact on the course of ecological succession, species composition and structure of plant communities, making them a good example of ecologically dominant species (e.g. keystone species). 3. Nevertheless, the strength of beavers' impact varies from site to site, depending on the geographical location, relief and the impounded habitat type. Consequently, they may not be significant controlling agents of the ecosystem in all parts of their distribution, but have strong interactions only under certain circumstances. We suggest that beavers can create important management opportunities in the Holarctic, and this review will help land managers determine the likely outcome of beaver activity.

1485: +.018

1. The effects of captivity on the behaviour of wild and domestic animals have been relatively well studied, but little has been published on morphological changes in wild animals in captivity. We review the evidence for changes in a wide variety of mammalian taxa, with non-mammalian examples where relevant. 2. We consider the morphological effects of the process of domestication, and compare changes in both hard and soft tissues in captive and domestic animals with those in their wild counterparts. These include skull shape differences, brain size reduction, postcranial adaptations and digestive tract changes. 3. We also summarize studies that have looked at morphological change in feral animals in comparison with their wild and domestic ancestors, and consider their use as an analogue for morphological change in captive-bred animals that have been released into the wild. 4. We then discuss the importance of this work for the wider aims of conservation of endangered species and captive breeding over many generations, and emphasize the importance of studying these changes now, while for many species, the process is just beginning rather than many generations down the line, or immediately prior to release, where survival of captive-bred animals may be severely compromised.

1486: +.061

In this study we determined the complete sequence of the mitochondrial DNA (mtDNA) control region of the Eurasian otter (*Lutra lutra*). We then compared these new sequences with orthologues of nine carnivores belonging to six families (Mustelidae, Mephitidae, Canidae, Hyaenidae, Ursidae, and Felidae). The comparative analyses identified all the conserved regions previously found in mammals. The Eurasian otter and seven other species have a single location with tandem repeats in the right domain, while the spotted hyena (Hyaenidae) and the tiger (Felidae) have repeated sequences in both the right and left domains. To assess the degree of genetic heterogeneity of the Eurasian otter in Italy we sequenced two fragments of the gene and analyzed length polymorphisms of repeated sequences and heteroplasmy in 32 specimens. The study includes 23 museum specimens collected in northern, central, and southern Italy; most of these specimens are from extinct populations, while the southern Italian samples belong to the sole extant Italian population of the Eurasian otter. The study also includes all the captive-reared animals living in the colony "Centro Lontra, Caramanico Terme" (Pescara, central Italy). The

colony is maintained for reintroduction of the species. We found a low level of genetic polymorphism; a single haplotype is dominant, but our data indicate the presence in central and southern Italy of two slightly divergent haplotypes. One haplotype belongs to an extinct population, the other is present in the single extant Italian population. Analyses of length polymorphisms and heteroplasmy indicate that the autochthonous Italian samples are characterized by a distinct array of repeated sequences from captive-reared animals.

1487: +.162

Aim We examine patterns of temporal turnover of common species in avian assemblages in North America to test the hypothesis that changes in avian diversity structure observed in these assemblages were associated with the colonization of common species. **Location** The contiguous United States and southern Canada. **Methods** We measured temporal turnover from 1968 to 2003 for 547 avian species at 1673 North American Breeding Bird Survey (BBS) routes. We used the Euclidian distance between expected and observed presence/absence vectors and randomization tests to place species into two categories, common and not-common, and into three categories for common species: (1) always common, (2) common and colonizing, and (3) common and extirpated. We used these categories to identify species experiencing extreme colonization and extirpation events and to examine changes in species composition at BBS routes. We also determined how these patterns were associated with changes in species richness and changes in similarity in species composition. **Results** Nine of the 547 species represented outliers, where the number of BBS routes colonized greatly exceeded the number extirpated; no species showed extreme values for extirpation. The nine species colonized BBS routes primarily in the upper Midwest and north-eastern United States. Presence of the nine species at BBS routes was correlated with increasing net gain in common species (difference between common colonized and common extirpated), higher levels of species richness and increasing species richness over time, more similar species compositions and increasing similarity over time, and a greater prevalence of common species over not-common species. The literature indicates that all nine species experienced some form of geographical range expansion during the time of the survey involving four elements: (1) introduction and invasion; (2) the ability to use human-altered environments, including habitats associated with agricultural, suburban, or urban areas; (3) intensive management activities, including habitat improvements and reintroductions and (4) the ability to use habitats formed through forest regeneration. These factors in combination point to anthropogenic activities and related land use histories as the primary drivers of change. One of the nine species colonized regions well outside its historic geographical range and the remaining eight species were native within the regions they colonized. **Main conclusions** Our results suggest that a combination of anthropogenic activities promoted, within certain regions of North America, the geographical expansion of a limited number of common species that were native to those regions. These colonization events were correlated with changes in diversity structure, implying that large-scale diversity patterns were being influenced by anthropogenic activities. These changes can be characterized primarily by gains in species richness, an increased prevalence of common species, and more similar species compositions. Thus, using simple large-scale measures of diversity could be problematic if recent biogeographical patterns of species diversity are not considered. Specifically, using species richness or an indicator species to assess diversity could bias assessments towards common species whose populations have recently benefited through anthropogenic activities.

1488: +.092

The progressive decline in red squirrel (*Sciurus vulgaris*) numbers in Wales has led to

conservation and reintroduction projects being established on the island of Anglesey. The recovery of the island's remnant wild population was initially successful, however concern remained over potential loss of genetic diversity resulting from an observed demographic bottleneck. We used mitochondrial DNA (mtDNA) control region sequences and six microsatellite loci to assess current levels of genetic variation in the population. Samples were monomorphic for control region sequences and a historic specimen from the same area carrying a different haplotype demonstrated a loss of mtDNA diversity during the last 20 years. Inclusion of other Welsh haplotypes indicated phylogeographic structure in the region, in contrast to previous UK studies. Genotyping results showed allelic diversity and heterozygosity to be less than 50% of that recorded in other UK populations, with strong evidence for a recent genetic bottleneck. A parallel reintroduction programme on Anglesey included genetic analysis of individuals during the selection of captive breeding pairs. We present analysis of sequence and microsatellite data, and subsequent management decisions taken to maximise diversity in the founder and F1 generations. Population and Habitat Viability Analysis applied to both populations modelled future levels of heterozygosity and allelic diversity. Supplementation of the remnant and reintroduced populations with translocated squirrels was simulated as a potential management tool; results support use of this strategy to reduce loss of diversity and increase survival. The limitations of applying conservation genetic theory within small-scale management projects are discussed.

1489: +.085

Populations of the endangered giant kangaroo rat, *Dipodomys ingens* (Heteromyidae), have suffered increasing fragmentation and isolation over the recent past, and the distribution of this unique rodent has become restricted to 3% of its historical range. Such changes in population structure can significantly affect effective population size and dispersal, and ultimately increase the risk of extinction for endangered species. To assess the fine-scale population structure, gene flow, and genetic diversity of remnant populations of *Dipodomys ingens*, we examined variation at six microsatellite DNA loci in 95 animals from six populations. Genetic subdivision was significant for both the northern and southern part of the kangaroo rat's range although there was considerable gene flow among southern populations. While regional gene diversity was relatively high for this endangered species, hierarchical F-statistics of northern populations in Fresno and San Benito counties suggested non-random mating and genetic drift within subpopulations. We conclude that effective dispersal, and therefore genetic distances between populations, is better predicted by ecological conditions and topography of the environment than linear geographic distance between populations. Our results are consistent with and complimentary to previous findings based on mtDNA variation of giant kangaroo rats. We suggest that management plans for this endangered rodent focus on protection of suitable habitat, maintenance of connectivity, and enhancement of effective dispersal between populations either through suitable dispersal corridors or translocations.

1491: +.237

The successful introduction of captive bred takhi or Przewalski's horse, *Equus ferus przewalskii*, into Mongolia in the 1990s is a good example of the benefits of ex situ conservation and one of the few examples of the recovery of an animal after it became extinct in the wild. This is also particularly interesting because virtually nothing was known about how takhi lived before they died out, and the introductions have enabled us to study how they have settled, and their ecology and behaviour within their former natural range. In this paper, we describe the movement, home range size and shape, and habitat use of takhi at one of the release areas, the 570 km² Hustai National Park in Mongolia. Harem home ranges varied between 129 and 2399 ha, with 80% core

areas of between 61 and 1196 ha. There was no relationship between range size and harem size, or length of time since release. Initially, harems stayed near their release enclosures, but over time they established home ranges further away. There was little overlap between home ranges of different harems, but neither was there evidence of exclusive range use. The more nutritious vegetation at lower elevations was preferentially selected. Thus the present situation looks good, but, as the population continues to grow, we anticipate that there will be potential problems related to intraspecific competition for water and vegetation resources, and the potential for hybridisation with domestic horses belonging to the local people. We consider the time it may take for takhi to reach carrying capacity within Hustai National Park and emphasise that continual monitoring of the population is essential because interventional management is likely to be required in the future. 1492: -.045

We evaluated the effectiveness of supplemental stockings being proposed in the recovery of the federally endangered Key Largo woodrat (KLWR, *Neotoma floridana smalli*) using a stage-based, stochastic model. Supplemental stockings were evaluated with a population model using current trapping and telemetry data along with published and unpublished KLWR data. Model simulations predicted the KLWR had > 70% probability of terminal extinction over the next 10 years even with the use of supplemental annual stockings. Supplemental stockings of KLWRs (≤ 20 females) appear to delay the extinction of the species, but negative population trajectories accelerated after stockings cease. Model results illustrated the importance of determining limiting factors on the population prior to the use of supplemental stockings as a recovery option for this endangered woodrat population. 1493: +.271

Management policies to save threatened species are not always successful, often due to the lack of a scientific basis and evaluation of the species response. We describe the ecological studies and the conservation actions taken between 1985 and 1992 on Cousin Island (29 ha, Seychelles) to safeguard the future of the highly threatened Seychelles warbler (*Acrocephalus sechellensis*), which until 1988 only occurred on this island. A detailed field study was designed to (1) identify the key processes influencing warbler demography, (2) identify appropriate management techniques to increase the warbler population, and (3), assess the influence of the resulting habitat management. Since 1980 the island has been saturated with c. 115 territories and c. 320 birds. The warbler is purely insectivorous. *Morinda* (*Morinda citrifolia*), the most insect rich tree, is preferred for foraging. The higher the insect abundance (and *Morinda* cover) in territories the higher the reproductive success and survival of warblers. Insect numbers were highest in the central part of Cousin and decreased towards the coast. Coastal territories protected by a salt tolerant hedge of *Scaevola* (*Scaevola taccada*) had more insects and higher reproductive success than unprotected territories. Between 1990 and 1992 *Morinda* trees were planted on the island and *Scaevola* along the coast. Although these habitat restoration measures have not resulted in higher numbers of adult warblers and territories due to habitat saturation, they have been successful in terms of improving the quality of existing breeding territories and with that the reproductive success of breeding birds (including the number of territories producing recruits), and the exchange of individuals (genetic material) between territories. We provide evidence that the high reproductive potential of this species is likely to improve the resilience of the species to catastrophic events. (c) 2005 Elsevier Ltd. All rights reserved.

1494: +.328

The Australian freshwater crayfish, *Cherax destructor* is cultured commercially and has been translocated throughout much of Australia. Previous investigation on *C. destructor* using 16S rRNA sequences of samples collected from natural environments has revealed a significant phylogeographic structure in this species with three well supported geographically non-overlapping clades, namely 'northern' *C. d. destructor*, 'southern' *C. d. destructor* and *C. d. albidus*. Movement of individuals beyond their natural range of distribution may have adverse effects on genetic integrity of the species. In the present study, aspects of translocations of the species were genetically investigated. Sequences of the 16S rRNA gene region of the mitochondrial DNA (mtDNA) were obtained from samples collected in nine quasi-natural waterbodies, supplemented with sequences of samples obtained from 31 natural waterbodies examined in a previous study. Results of phylogeographic analysis provide evidence that certain haplotypes from major clades of *C. destructor* have been translocated. The findings of this study have important implications for the conservation and management of genetic diversity within *C. destructor*.

1495: +.039

The two key objectives of the recovery plan for the Federally threatened tiger beetle *Cicindela dorsalis dorsalis* Say are to protect populations within the Chesapeake Bay and to establish by reintroductions new populations in the U.S. northeast (New Jersey to Massachusetts). This article reports on the development and implementation of translocation work to establish a population of *C. d. dorsalis* at Gateway National Recreation Area, Sandy Hook, NJ, by using larvae from Chesapeake Bay populations. Previous experimental translocation trials in Virginia by using adults were unsuccessful because the adults dispersed from the translocation sites within 1-2 wk. Experimental translocations were conducted to test methods with larvae from several Virginia sites to Sandy Hook in September 1994 and 1995. The translocated larvae readily dug burrows, many survived the winter, and some emerged as adults the following summer. Additional translocations of > 475 larvae each year were conducted in early May 1997, 1999, and 2000. Peak numbers of emerging adults counted each year in July increased from 178 in 1997 to 749 in 2001. Adults exhibited normal behaviors in the field (foraging, thermoregulation, and mating) and recruited larvae each year. A population seemed to be successfully established, but adult numbers declined sharply after the 2001 peak to 142 in 2002, 43 in 2003, and six in 2004. We have little evidence for the cause of this sharp decline in adult numbers, but it may have resulted from predation by gulls, dispersal triggered by the high gull densities where beetles occurred, or perhaps from coastal storm impacts causing a progressive decline in survival and recruitment of the beetle population. The initial success of this translocation suggests that efforts using these methods should be continued, but closer monitoring at the translocation site is needed to determine the fate of the population. These methods also may be applicable to the recovery of other threatened or endangered tiger beetles.

1496: -.045

Captive-reproduced stocks of some species of ungulates (Artiodactyla), and particularly the red deer (*Cervus elaphus*), fallow deer (*Dama dama*), roe deer (*Capreolus capreolus*) and the wildboar (*Sus scrofa*) are more or less extensively translocated in Italy, mainly for local reintroductions or restocking of exploited wild populations. However, captive breeding often involves the reproduction of non-indigenous individuals or the production of artificial hybrids. Consequently, translocations of captive-reproduced ungulates are of concern for the conservation of indigenous populations and gene pools. The impact of translocations should be evaluated within the background of the growing knowledge on population genetic and phylogeographic structure of ungulates. Molecular genetic markers are being used to map geographic genetic diversity, and

reconstruct the phylogeographic history of natural populations (i.e., in the roe deer). Molecular markers are also used to detect the consequences of domestication and identify hybrids between wild and domesticated populations (i.e., in the wildboar), or to detect inter-specific hybridisation (i.e., between the red deer and wapiti). Hybridisation of wild and domestic pigs, and diffusion of hybrids in nature is widespread in Italy. Admixture of indigenous and non-indigenous roe deer stocks is also widespread. Therefore, conservation and management of indigenous ungulates calls for careful evaluation of captive-reproduced stocks.

1497: +.114

Common wild rice (*Oryza rufipogon* Griff.), known as the ancestor of Asian cultivated rice (*Oryza sativa* L.), is the most important germplasm for rice improvement. The first male sterility gene was found in the wild rice, and introduced to the cultivated rice, which launched the fast development of the high-yielding hybrid rice. Other agronomically beneficial traits in the wild rice, such as rice tungro virus resistance, bacterial leaf blight (Xa21 gene) resistance and acid sulfate soil tolerance, have played important roles in rice breeding. China has the northernmost distribution area of wild rice possessing great genetic diversity. However, most of the populations of this species have disappeared in China over the last three decades, mainly caused by habitat loss, fragmentation and other human disturbances. Unfortunately, the decline of existing populations still continues. In the present study, we reviewed studies on genetic diversity and conservation of this wild rice in China, concentrating on population structure, pollen competition, pollen/gene flow from cultivated rice to wild rice, and ecological restoration in relation to in situ conservation. The relatively high genetic diversity of populations of *O. rufipogon* in China suggests that there is great value for conservation. Considerable gene flow from cultivated rice to wild rice may alter the genetic structure of natural populations of *O. rufipogon* and eventually lead to its genetic erosion. Pollen competition between wild and cultivated rice has caused a low rate of crop-to-wild gene flow, but it does not completely prevent gene flow from the crop. Effective isolation measures should be undertaken in the regions where in situ conservation of *O. rufipogon* is carried out. Reintroduction is an important alternative for the in situ conservation of wild rice species. As wild rice is an important genetic resource, both in situ and ex situ conservation strategies are needed.

1498: +.077

1. The distribution of dispersal distances (the dispersal kernel) is a major determinant of spatial population dynamics, yet little is known about the shape of the dispersal kernel for most species. This is partly because of the relative difficulty of measuring dispersal, exacerbated by a lack of standardized protocols. We suggest that this problem can be addressed by using modelling approaches to aid the design of studies to quantify dispersal. 2. In this study we present such an approach by optimizing seed trap sampling design using stochastic simulations. A number of alternative sampling designs (random placements, grid arrays, transects, sectors and annuli arrangements) for a point source were tested against a common kernel to assess the best methods for estimating the dispersal kernel. 3. For a given source strength and total trap area, transects and sectors of traps usually provided better data for kernel estimation than random placement, grid arrays and annuli. Kernel estimation was improved by increasing the source strength (the number of dispersing propagules) and the trap area, as expected. 4. When the 'true' kernel was unknown, transects were slightly better for identifying the thin-tailed exponential distribution, whereas sectors were better for detecting the fat-tailed half-Cauchy. 5. In the case of anisotropic dispersal (here, dispersal biased in one direction), annuli and grid arrays performed better than transects and sectors when the anisotropy was unknown. However, when the anisotropy was anticipated, and the trap arrangements were adjusted accordingly, transects and sectors were better. This was true

regardless of source strength and total trap area.6. Synthesis and applications. This study presents a simulation approach to the design of dispersal experiments. While the general results of our simulations can be used by those designing field studies for plant point sources, the simulation approach itself can be modified for a wide range of organisms, dispersal mechanisms and dispersal measurement approaches. Thus, the approach presented here facilitates improvements of dispersal study designs, which in turn will increase the precision of dispersal kernel estimates and predictions of spatial population dynamics, including modelling of rates of spread or metapopulations. This is invaluable in a range of ecological applications, such as the management of rare or invasive species, predicting species' response to climate change, or planning species reintroductions.

1499: +.146

The effect of habitat destruction on the likelihood of species survival is often estimated based on the assumption that colonization and extinctions are in balance. This assumption is not sustainable in species where the dynamics of colonization and extinctions is slow in relation to landscape changes, such as in most plants. Here we use an alternative approach, a realistic, dynamic landscape-level model that does not rely on this assumption. It enables estimation of the effect of habitat destruction using field data on the biology of a species and on real landscape structure. Because our approach relies on direct comparisons of changes in population size and survival probability due to habitat changes, it can be easily extended to other conservation questions, such as assessing the effects of events causing the extinction of populations but allowing for recolonization, or identifying optimal reintroduction strategies. We applied this method to a perennial herb, *Succisa pratensis*, that is a typical grassland species. We combined detailed demographic data with information on the spatial distribution of suitable habitats to model species dynamics in the landscape under different scenarios. The results show that habitat destruction alone has little effect on regional survival. However, the effect of habitat destruction increases when combined with factors causing extinctions of the existing populations that are expected to play a significant role in the study system. Our results further show that an optimal reintroduction strategy at the landscape level depends on the number of available seeds. The approach presented here was designed for studying systems where species colonization-extinction dynamics is slow compared with landscape changes. Such time lags and nonequilibrium dynamics have been suggested to be important features of many ecosystems and life forms, and this approach is thus likely to be useful for a wide range of future studies. The approach also allows the estimation of short-term effects of habitat destruction, i.e., situations that are nonequilibrium by definition. This is never possible with equilibrium models, giving the model a wide applicability for all types of organisms.

1500: +.115

Aside from Kruger National Park, no other suitable reserves of sufficient size exist in South Africa that will hold a viable population of wild dogs (*Lycaon pictus*). Consequently, conservation efforts have been focused on creating a metapopulation through a series of wild dog reintroductions into isolated fenced reserves. Additional potential exists for conserving wild dogs on private ranch land. Establishing the metapopulation was an expensive process, accounting for approximately 75% of the US\$380,000 spent on wild dog conservation in South Africa during 1997-2001. The principal goal of the metapopulation project was to reduce the risk of catastrophic population decline. Now that this has been achieved, we developed a uniform cost-efficiency index to estimate the cost efficiency of current and potential future conservation strategies in South Africa. Conserving wild dogs in large protected areas was predicted to be the most cost-efficient

conservation strategy (449 packs/\$100,000 expenditure). Establishing the metapopulation has been less cost efficient (23 packs/\$100,000), and expansion of the metapopulation was predicted to be even less cost efficient if predation by wild dogs results in additional costs, as is to be expected if private reserves are used for reintroductions (3-13 packs/\$100,000). Because of low logistical costs, conserving wild dogs in situ on private ranch land was potentially more cost efficient than reintroducing wild dogs (14-27 packs/\$100,000). We recommend that donor funding be used to reintroduce wild dogs into transfrontier parks, when they are established, to maintain the existing metapopulation and to establish conservation programs involving wild dogs on private ranch land. Investing in the expansion of the metapopulation should be limited to state-owned nature reserves willing to carry predation costs without compensation.

1501: +.071

Conservation efforts involving introductions, reintroductions, and translocations of populations have an inherent and inescapable problem of small initial populations. Small founding populations are likely to have a small proportion of the genetic variability carried by the original population. This may manifest phenotypically through changes in individual morphology, such as decreased body size, increased degree of fluctuating asymmetry, or changing susceptibility to environmental stressors. I investigated the effects of population and landscape variables on the morphology and fluctuating asymmetry in individual bush-crickets by examining 584 individual Roesel's bush-crickets (*Metrioptera roeseli*) from 29 established populations from different propagule sizes that were introduced in areas previously unoccupied by the species. The introduction sites were in landscapes similar to where the species occurs naturally, but sites differed in connectivity and amount of surrounding suitable habitat. Individuals were caught up to 9 years after the initial introduction, and five different morphological traits were measured. All introduced individuals originated from the same population and individuals from this source population were also collected for comparison in the analyses. Male body weight and female body length were positively affected by initial population size and degree of connectivity of the introduction patch. Isolation also affected fluctuating asymmetry in male tibias, with a higher degree of asymmetry in males that came from more isolated populations. In a relatively short time period, I was able to detect the effect of isolation and small population sizes on morphology and asymmetry. Small propagule sizes and habitat isolation are both likely to have resulted in decreased genetic diversity, the latter by reducing population sizes through decreased survival. These results show the importance of both large propagule sizes and good connectivity of habitats when introducing populations. The differences between the sexes in response to the variables examined also indicate that studies on morphology and fluctuating asymmetry need to consider males and females separately to avoid inaccurate generalizations of the state of the population.

1502: +.357

We analysed the spatial distribution of home-ranges and the habitat use of re-introduced grey partridges *Perdix perdix* in relation to newly established ecologically enhanced areas, i.e. wild-flower strips and hedges, within an intensively cultivated area in Switzerland from which the species had become extinct. All birds settled within the ca. 30% of the study area where the proportion of enhanced areas was highest (5.8%). At the level of the individual family group, we found a significant over-proportional use of enhanced areas throughout the year. Furthermore, when the birds used the agricultural fields, the use densities strongly declined with distance from the nearest enhanced area. Thus, the availability and spatial distribution of ecologically enhanced areas were the main determinants of the partridges' range use. These results indicate that a framework of ecologically enhanced areas is a key habitat structure for grey partridges, and that

these enhancements, even if small in proportion, were the crucial first measure to restore the research area to an appropriate grey partridge habitat and, thus, the basis for successful re-introduction in this intensively cultivated area. © 2005 Elsevier Ltd. All rights reserved.

1503: +.122

We report natural abundance of (15)N content in a suite of plants and lichens from a sloping open peatland in coastal northern British Columbia, Canada. A wide range of delta(15)N values varying between -11 and +3 parts per thousand were observed in the studied species. Herbs, mosses, and shrubs generally grouped individually along the delta(15)N gradient from enriched to more depleted values. This grouping probably reflects similar nitrogen acquiring strategies within the group, but some species with different strategies showed deviated delta(15)N values from the cluster. Hummock-lawn gradient, which is illustrated as depth to water table, explains the variation in delta(15)N signature of cryptogams: the deeper the groundwater table, the more depleted is the (15)N. This trend might be explained by differences in nitrogen sources and/or differences in internal fractionation during nitrogen translocation processes. (c) 2005 Elsevier B.V. All rights reserved.

1504: +.053

For selected species, conservation breeding has become integrated into recovery plans, most often through the production of offspring for reintroduction into nature. As these programs increase in size and scope, it is imperative that conservation managers retain the biological integrity of the species. This study investigated the causes of morphological changes that are known to occur in black-footed ferrets (*Mustela nigripes*) maintained ex situ. In a previous study, ferrets maintained in captivity were 5-10% smaller in body size than pre-captive, in situ animals. In the present study, the authors compared nine morphological characters among ex situ animals and their in situ descendants. Within the ex situ population, cage types were compared to determine whether housing influenced morphometry. Black-footed ferrets born to reintroduced individuals quickly returned to their pre-captive size suggesting that a diminutive morphology ex situ did not have a genetic basis. Furthermore, cage type affected overall body size and shape; ulnas and tibias were as much as 9% shorter for ex situ animals. The authors hypothesise that small cage size and environmental homogeneity inhibit the mechanical stimuli necessary for long bone development. These findings have ramifications for ex situ managers who need to create artificial captive settings that promote natural physical development. In the absence of such an environment, 'unnatural' morphologies can result that may contribute to poor fitness or perhaps even domestication.

1506: +.257

The anthropogenic introduction of exotic species is one of the greatest modern threats to marine biodiversity. Yet exotic species introductions remain difficult to predict and are easily misunderstood because knowledge of natural dispersal patterns, species diversity, and biogeography is often insufficient to distinguish between a broadly dispersed natural population and an exotic one. Here we compare a global molecular phylogeny of a representative marine meroplanktonic taxon, the moon-jellyfish *Aurelia*, with natural dispersion patterns predicted by a global biophysical ocean model. Despite assumed high dispersal ability, the phylogeny reveals many cryptic species and predominantly regional structure with one notable exception: the globally distributed *Aurelia* sp.1, which, molecular data suggest, may occasionally traverse the Pacific unaided. This possibility is refuted by the ocean model, which shows much more limited

dispersion and patterns of distribution broadly consistent with modern biogeographic zones, thus identifying multiple introductions worldwide of this cryptogenic species. This approach also supports existing evidence that (i) the occurrence in Hawaii of *Aurelia* sp. 4 and other native Indo-West Pacific species with similar life histories is most likely due to anthropogenic translocation, and (ii) there may be a route for rare natural colonization of northeast North America by the European marine snail *Littorina littorea*, whose status as endemic or exotic is unclear.

1507: +.253

This chapter presents a vision of the involvement of zoos and aquariums, as centres of expertise in small population management, in regional or global cooperative breeding programmes. To maximize value to conservation, ex situ populations need to be demographically stable, well-maintained and capable of self-sustaining reproduction. They should be distributed among several institutions and of sufficient size to maintain high levels of genetic diversity. However, many programmes have too few founders and participating institutions, depleted genetic diversity and/or poor breeding success. Strategies to enhance viability include: increasing breeding spaces, expanding from regional to global programmes, increasing the intensity of genetic management, improving husbandry practices through research, and importing founders from the wild or other regions. Population management includes demographic and genetic management, veterinary care and husbandry. The first involves monitoring numbers, and age, social and sex structure. Genetic management involves verifying taxonomic identity, and avoiding deleterious effects of inbreeding and loss of genetic diversity. Management decisions are developed through studbooks. Population data are held on a database system at the International Species Information System (ISIS), supported by registration and analysis software. Other management aspects discussed include confiscated and abandoned animals, ownership, and the impact of regulations on animal transfers. The chapter emphasizes that a primary goal of ex situ programmes is support (including demographic and genetic reservoirs) for in situ conservation. Metapopulation management involves managing a set of interacting populations under a common conservation goal. Its components may include ex situ populations, in-country breeding programmes, wild populations and genome banks. Transfer between populations may involve reintroduction. The chapter ends by stating that many wild populations are like ex situ ones - of small size with limited gene flow between them. The science of small population management developed primarily for managing ex situ populations is thus of direct relevance to field conservation. This expertise is a major contribution that zoos and aquariums can offer conservation.

1508: +.135

We assessed whether behavioral markers could be used to evaluate pair compatibility and predict pair bond success of captive-reared San Clemente loggerhead shrikes (*Lanius ludovicianus mearnsi*) released into the wild. Potential breeding pairs of shrikes were introduced at the Zoological Society of San Diego's captive-breeding facility and then moved to release cages located in suitable but unoccupied habitat. Courting pairs were affected negatively by the disturbance of translocation to a new location and generally needed a few days to reinitiate pair bonding in the release enclosures. We separated and returned pairs to captivity when intra-pair aggression or cessation of all courtship behavior occurred; all other pairs were released into the wild. The rate of nest approaches was the best marker to predict a successful release into the wild (i.e., pairs that remained near the release site and attempted to breed). Additionally, all experienced breeding pairs (i.e., pairs with males and females with prior captive breeding experience) exhibiting nesting behavior were successful, although previous experience alone does not ensure post-release breeding. Results from this study indicate the importance of assessing

behaviors of individuals paired for population augmentation. In using behavioral cues, identifying pairs with a low probability of success is possible, and replacing these pairs with individuals that have a higher likelihood of post-release success can occur. This strategy will be important to

1509: +.039

We evaluated translocation as a method to promote recovery of black-tailed prairie dogs (*Cynomys ludovicianus*) after plague-induced population declines in colonies at the Charles M. Russell National Wildlife Refuge, Montana. We translocated prairie dogs in June of 1999 and evaluated the effects of translocation on colony area 1 year and 4 years later. We also assessed effects of release group size and estimated rates of population growth and survival. Initial size of experimental colonies was categorized as inactive (0 ha), small (0.1-2.0 ha), or large (2.0-6.6 ha); numbers of prairie dogs translocated to each colony size class were 0 (control), 60, and 120. Among inactive colonies, the control remained inactive and the colony receiving 60 prairie dogs grew to 1.5 ha by 2000 and after a second release in 2002 was 1.9 ha in 2003. The colony receiving 120 grew to 3.3 ha by 2000 and decreased to 2.6 ha by 2003. Patterns on small and large colonies after 1 year were less dramatic, but in each case the proportional increase in colony area was lowest on the control and highest on the colony receiving 120 prairie dogs. Patterns were more difficult to discern 4 years after translocations. It appears that as large colonies approach historic size, area growth decreases and is slower than on small colonies. Experimental colonies grew 24.6 ha (315%) by 2000 and 72.1 ha (924%) in 4 years compared to non-experimental colonies of similar size that grew 6.5 ha (23%) in 1 year and 26.5 ha (93%) by 2003. Monthly survival rates of prairie dogs during the first 3 months following translocation were higher on large colonies (0.79, 95% CI=0.75-0.82) than on small (0.67, 95% CI=0.62-0.72) or inactive colonies, (0.63, 95% CI=0.57-0.68). Monthly survival rates were relatively high (0.88-1.0) during subsequent intervals and did not vary among initial colony size classes. Recapture rates for all colonies were higher during the fall trapping session (0.83, 95% CI=0.76-0.90) than in the winter (0.59, 95% CI=0.49-0.69). Translocation was effective for restoration of prairie dog populations, particularly on inactive colonies.

1510: -.004

Large mammals such as Asiatic elephant (*Elephas maximus*), rhino (*Rhinoceros* sp.), golden monkey (*Rhinopithecus roxellana*), gibbon (*Hylobates* sp.), giant panda (*Ailuropoda melanoleuca*), Pere David's deer (*Elaphurus davidianus*), sika deer (*Cervus nippon*), and brown bear (*Ursus arctos*) once lived in the Dongting Lake drainage area of the middle-lower reaches of Yangtze River. However, due to climate change change, geomorphological change and human disturbance, these large mammals were extirpated from the area. After humans settled in the Dongting Lake drainage area, human activity was the major cause of the extinction of local mammalian fauna, especially human hunting, habitat loss to human settlements and land reclamation. Rhino and Asiatic elephant were extirpated or emigrated from the area during the late period of the Northern Song Dynasty while Pere David's deer, golden monkey, gibbon, giant panda, sika deer and brown bear became extinct in the Dongting Lake Drainage Area in the late 19th century. According to our investigations during past years, such a process of species extinction is still escalating. We recorded 21 national key protected mammals in the 30 nature reserves or forest parks in the Dongting Lake drainage area. Among those species, five species are critically endangered, six species are endangered and ten species are vulnerable. Primary causes that threaten the survival of mammals are habitat loss, environmental pollution, hunting, and competition for food or habitat among wild animals. Impacts of human activities on survival of presently endangered mammalian species are much greater than ever before. These threats should

be considered when reintroducing Pere David's deer to the Dongting Lake region. A suitable habitat with enough foods and space and no human disturbance, a healthy founder population under close monitoring, and active conservation measures based on community co-management will be prerequisites for successful re-establishment of the extinct Pere David's deer in the Dongting Lake drainage area.

1511: +.047

Black rhinoceros (*Diceros bicornis*) are one of the most endangered mammal species in Africa, with a population decline of more than 96% by the end of the last century. Habitat destruction and encroachment has resulted in fragmentation of the remaining populations. To assist in conservation management, baseline information is provided here on relative genetic diversity and population differentiation among the four remaining recognized subspecies. Using microsatellite data from nine loci and 121 black rhinoceros individuals, and comparing the results with those of other African species affected in similar ways, *Diceros bicornis michaeli* retained the most genetic diversity (heterozygosity 0.675) compared with *Diceros bicornis minor* (0.459) and *Diceros bicornis bicornis* (0.505), suggesting that the duration of the known bottlenecks in these populations has only had a limited impact on diversity. Comparable and moderate degrees of population differentiation were found between *D. b. minor*, *D. b. bicornis* and *D. b. michaeli*. Results from the single sample available of the most endangered subspecies, *Diceros bicornis longipes*, showed the least diversity of all individuals examined. This information should assist conservation management decisions, especially those affecting population viability assessments and selection of individuals for translocations, and will also facilitate subspecies identification for ex situ individuals of uncertain origin.

1512: +.069

In 2000-2001 a national distribution survey of the badger (*Meles meles*) was undertaken. The survey was to contribute to the interim evaluation of the badger protection plan of the Ministry of Agriculture, Nature Management and Fisheries of the Netherlands. The execution of this protection plan started in 1984. The outcomes of this survey are presented in this article. The following aspects are described: (1) the historic development in the distribution, (2) the occupation rate of suitable badger habitat, (3) the development of settlement types, (4) the merger of subpopulations, (5) the continuity of occupation, (6) the output of translocations, and (7) the number of disappeared setts and the disturbances registered. In addition, a comparison is made with the results from the surveys of 1960, 1970, 1980, 1990 and 1995. The collected data originated mainly from fieldwork. For every 1-km square, the more than incidental use of badger setts was recorded. Earlier research (1995) on the habitat of the badger qualified 15% of the research area (about 25,000 km²) as suitable. In 2001, badgers occupy about 25% of the suitable habitats available to them. The northern and eastern parts of the study area had a relatively low occupation-rate, i.e. 4 to 5 times lower than the rate for the middle and south, where the three largest populations are located. The increase of distribution in the north and east, however, was twice as much as in the middle and the south. In the Netherlands 4,400 badger setts have been recorded since 1960. During the survey more than 2,500 locations (57%) were visited. In the period 1995-2001, the distribution area of the badger increased with almost 30%. The distribution area of the nine splinter populations even increased by 48%. A decrease of 17% was recorded for the 25 dispersed populations. The average distance between the core populations existing from 1980 onwards decreased from 28 to 21 kilometres. For the period 1995-2001, in the regions of Gelderland-Veluwe and Zuid-Limburg the 18% increase in distribution area remained below the national average (29%). The large population in Gelderland-Veluwe even hardly grew (1%). The

much smaller population in the Reest valley, at the border of the provinces of Drenthe and of Overijssel, did not grow at all. In the region of Gelderland-Achterhoek, the growth was minimal if the contribution from translocations is excluded. The continuity in occupation increased. Since 1960, of the 1-km squares remained occupied in the following year of survey (n=2,536). 1,402 1-km squares were at least occupied once by badgers. Of these, 257 were new in 2001, whereas 253 1-km squares remained vacant after initial occupation. Continuous occupation since 1960 occurred in 115 1-km squares. The remaining 892 1-km squares were occupied more than once, but not continuously. The three main distribution areas, Gelderland-Veluwe, Maasvallei and Zuid-Limburg, showed an increase of occupied 1-km squares of 36%. This is well above the national average of 29%. These large populations cover 84% of the badger distribution in the Netherlands. The increase must be credited almost entirely to the growth of the Meuse valley population. In the period 1990-1995, the increase of 1-km squares occupied by the three largest populations was 4% below the national average, i.e. 12%. In this period, the growth is concentrated in Zuid-Limburg. In the period 1987-2001, the translocation of badgers contributed at least 4% (37 km²) to the total distribution of 2001. In this period, 210 badgers were translocated from enclosed release sites at 26 locations in seven provinces. At least 202 setts disappeared between 1995 and 2001, representing about 8% of the locations visited. One in five was occupied in 1995. The amount of destroyed setts decreased with almost 40% in comparison with the period of 1990-1995.

1513: +.131

This work presents new data from 48 maned sloths *Bradypus torquatus* captured between November 2002 and November 2003 in three regions of the Atlantic forest where the largest remnant populations of this species are found. Data from another long-term study, carried out from 1994 to 1996 and from 1999 to the present (n = 14), were also used, making a total sample of 62 sloths. Average adult body weight is 6594 +/- 236 g and average headbody length is 66.5 +/- 0.8 cm (n = 35), indicating that *Bradypus torquatus* is the heaviest of all four *Bradypus* species. Individuals from lower-montane forests (600-1000 in a.s.l.) are significantly larger (head-body length; t-test; P = 0.001) than individuals from the lowlands (< 350 m a.s.l.), suggesting altitudinal differentiation between populations. Sexual dimorphism, here reported for the first time, was found in body length (females are significantly larger than males) and in other external characters, such as mane size and form (darker and larger in males), and size and shape of the external genitalia. Most differences between sexes are, however, only discernible in reproductively active individuals. Breeding is slightly seasonal; minimum observed interbirth interval was 1 year and litter size was always one. Infants stayed with their mothers until 8-11 months old; started feeding on solid food as early as 2 weeks old but continued suckling until c. 4 months of age. Age of sexual maturity was estimated at 2-3 years and the oldest captured maned sloth was a healthy male who was at least 12 years of age. Overall, results indicated that maned sloths are similar in these aspects to congeneric species. Information presented here significantly improves the current knowledge on this endangered sloth species and is useful for the proper planning and implementation of in situ conservation strategies such as translocations and reintroductions.

1514: +.096

Rapid propagation of *I. malabarica* (Reichb.f.) J D Hook, an endemic and endangered orchid of the Western Ghats of Kerala, India through conversion of axillary buds to protocorm-like bodies (PLBs), and Subsequent plant regeneration was achieved. Growth regulators and sugar displayed significant influence in the induction of PLBs. In vitro derived shoots from field grown rhizomes of *Ipea* cultured on Murashige and Skoog (MS) medium with 13.3 μ M N-6-benzyladenine (BA) containing 2% commercial grade sugar turned the axillary buds to PLBs within 25 days, and

developed a mean of 33.1 PLBs within 50 days. Kinetin (KIN) did not induce PLBs, but facilitated axillary bud proliferation. Transfer of PLBs on medium having same concentration of BA and sugar facilitated rapid multiplication, and developed a mean of 47.5 PLBs. No decline of PLB proliferation was observed up to 10(th) subculture. Half strength MS medium with 6.97 μ M KIN facilitated conversion of 98% PLBs to plantlets. On this media, a mean of 5.8 roots were also developed per shoot. Shoots developed bulbs during culture were grown to rhizomes. Increase of sugar to 6 or 8% hastened the development of bulbs/rhizomes. Reintroduction of PLB-derived plantlets in the natural habitat i.e. at Vellarimala (at 1300 m height) of the Western Ghats of Kerala was attempted as a means to assist in situ conservation. This is the first report of conversion of axillary buds to PLBs. The protocol enables to surmount the threat of extinction of this endemic and endangered orchid.

1515: +.263

In 1886 William T. Hornaday, the Chief Taxidermist of the US National Museum, led the 'Smithsonian Institution Buffalo Outfit' to Montana. The American bison was fast heading toward extinction and the mission of the expedition was to locate those of the elusive animals that remained and obtain specimens for the scientific collection at the museum. The successful expedition produced the most complete scientific series, and the finest artistic grouping of taxidermied specimens of the American bison anywhere in the world. Haunted by the scattered skeletal remains of the millions of slaughtered bison that peppered the Eastern Montana Plains, Hornaday fought to establish the National Zoological Park, which would provide sanctuary for bison and other endangered species, and a captive breeding program, which would result in the eventual reintroduction of the American bison to the wild.

1516: +.002

The Idaho ground squirrel, which consists of a northern (*Spermophilus brunneus brunneus*) and a southern subspecies (*S. b. endemicus*), has suffered from habitat loss and fragmentation, resulting in a reduction in both numbers and geographic range of the species. The northern Idaho ground squirrel (NIDGS) is listed as a threatened subspecies under the Endangered Species Act, and the southern Idaho ground squirrel (SIDGS) is a candidate. Because Idaho ground squirrel populations are small and often isolated, they are susceptible to inbreeding and loss of genetic diversity through drift. This research evaluates levels of genetic diversity and patterns of population divergence in both subspecies of Idaho ground squirrels. We hypothesized that NIDGS would exhibit lower genetic diversity and greater population divergence due to a longer period of population isolation relative to most SIDGS populations. Genetic diversity and divergence were quantified using 8 microsatellite loci. Contrary to expectations, SIDGS populations exhibited consistently lower levels of microsatellite diversity. Additionally, NIDGS exhibited only modest divergence among populations, while divergence levels among SIDGS populations were highly varied. Preliminary evaluations of mitochondrial DNA diversity and structure revealed lower diversity in NIDGS and some differences in gene flow that warrant further study. Based on our results, we suggest different management strategies for the two subspecies. Habitat restoration appears to be the most desirable conservation strategy for NIDGS populations. In contrast, low genetic diversity observed in SIDGS may warrant supplementation of isolated populations through translocations or captive breeding to mitigate further loss of genetic variability.

1517: +.218

Eurasian lynx are slowly recovering in Germany after an absence of about 100 years, and

additional reintroduction programs have been launched. However, suitable habitat is patchily distributed in Germany, and whether patches could host a viable population or contribute to the potential spread of lynx is uncertain. We combined demographic scenarios with a spatially explicit population simulation model to evaluate the viability and colonization success of lynx in the different patches, the aim being to conclude guidelines for reintroductions. The spatial basis of our model is a validated habitat model for the lynx in Germany. The dispersal module stems from a calibrated dispersal model, while the demographic module uses plausible published information on the lynx' life history. The results indicate that (1) a viable population is possible, but that (2) source patches are not interconnected except along the German-Czech border, and that (3) from a demographic viewpoint at least 10 females and 5 males are required for a start that will develop into a viable population with an extinction probability of less than 5% in 50 years. The survival rate of resident adults was the most sensitive parameter, and the best management strategy for the success of reintroduction would be to reduce the mortality of residents in the source patches. Nevertheless, the extremely low probability of connectivity between suitable patches makes most of the reintroduction plans isolated efforts, and they are therefore questionable in the long run. With such a model, the suitability of the single habitat patches can be assessed and the most appropriate management scheme applied. This study shows that simulation models are useful tools for establishing the comparative effectiveness of reintroduction plans aimed at increasing the viability of the species. 1518: +.146

In South Africa, wild dogs are limited to a single viable population in Kruger National Park. Current conservation efforts aim to develop a meta-population through the reintroduction of wild dogs into fenced reserves. However, significant potential also exists for conserving naturally occurring wild dogs in situ on ranchland. This study represents an assessment of the attitudes of southern African landowners towards wild dogs to determine the scope for conserving them on private land, and to identify the conditions under which conservation efforts might succeed. Over half of ranchers interviewed indicated that they would like to have wild dogs on their property. Younger ranchers were more positive than older ranchers, suggesting that traditional prejudices against wild dogs are fading. Attitudes were generally negative where ranches are game-fenced, and where cattle or consumptive wildlife utilisation dominate land use. Negative attitudes were typically related to economic costs associated with wild dogs, and conservation initiatives aimed at reducing costs or creating benefits from the species represent the most direct way to improve attitudes. Many ranchers recognised the potential ecotourism value of wild dogs, and attitudes were most positive where ranches belong to conservancies, and where ecotourism-based land uses predominate. Similar relationships were found between ranch/rancher characteristics and attitudes towards most large carnivores. Thus, our findings have general relevance for large carnivore conservation on private land in southern Africa. Encouraging the formation of conservancies should be a priority for carnivore conservation efforts on ranchland, to reduce conflict and promote coexistence between people and predators. 1519: +.287

For species whose decline preceded the modern era and whose distribution is in the developing world, it is difficult to map suitable habitat across its former range. Eld's deer (*Cervus eldi*) is an endangered cervid whose range across Southeast Asia was reduced during the last century to disjoint populations in Myanmar and Cambodia. We used ecological data from the present populations to determine landscape and habitat parameters that would help us predict the occurrence of the species in forests not yet surveyed. The suitable-forest GIs model was created

using four readily available datasets for elevation, forest type, canopy closure, and human density. Comparison of the GIs model with 24 verified sightings of Eld's deer during recent large mammal surveys in Cambodia, found 22 sightings (92%) within predicted suitable forest. Use the suitable-forest GIs model to survey a province in southern Lao People's Democratic Republic, located a single, previously unreported population from 9 patches surveyed. In a separate analysis, a logistic regression model to predict Eld's deer habitat in Northern Cambodia found percent tree cover, presence of wetlands, and distance to villages as the best predictors of deer, similar to variables used in the GIs model, with the exception of the importance of wetlands. Using mean annual rainfall to rank suitable-forest patches identified in the GIs model indicated dry dipterocarp forests in Northeastern Cambodia and Northern Myanmar have the highest potential to conserve Eld's deer. Examination of the suitable forest GIs map and current protected areas indicated only Cambodia, with 11% suitable forest protected, has placed sufficient dry dipterocarp forest under protected status. Other Southeast Asia countries have not recognized dry dipterocarp forest as a significant ecotype worthy of conservation status. (c) 2005 Elsevier Ltd. All rights reserved.

1520: +.026

Thirteen Cuvier's gazelles were relocated to a 6-ha acclimatization enclosure in Boukornine National Park (Boukornine NP) in Tunisia, where they are part of a reintroduction project. To determine the degree of adaptation and habitat use under the new conditions, the acclimatization enclosure was divided into 6 sections according to topography, plant cover and plant species in the area. Signs of gazelle activity were coded as feeding site, paths, passages, feces and resting places. Sampling was done in spring, summer and autumn from September 2000 to July 2001. Multivariate analysis using PATN analysis and chi(2) distribution tests were used to analyze the data. Multivariate analysis yielded 5 groups of biotopes according to the above variables. The chi(2) distribution test showed the significant effect of each variable on the presence of signs of gazelles. Cuvier's gazelles prefer areas with low and west to north facing slopes and scant plant cover; animals are attracted to the proximity of the fence as the limit of their territory and even though the presence of humans does not represent a disturbance, gazelles select areas far (> 50 m) from the supplementary feeding and water supply for their activities.

1521: +.105

The current distribution and status of five macaque species, *Macaca fascicularis*, *M. mulatta*, *M. arctoides*, *M. assamensis* and *M. nemestrina*, in Thailand were determined by questionnaire survey in the sub-district level and by field surveys. Among these 5 species of macaques, long-tailed macaques are the most successful species adapted to a wide range of ecological habitats in Thailand. We found this species at 68 localities during our survey, but in contrast at only 5- 10 localities for each of the other four species. In those troops where it was practically feasible, monkeys were temporarily caught, and data and samples were collected for morphological, physiological, and genetic analyses. Based on our analyses, long-tailed macaques have a wide geographical range in Thailand (from ca. 6[degree] N to 16[degree] N), and they can be lumped into either Indochinese or Sundaic groups separated by the boundary at the Isthmus of Kra. Two troops of *M. fascicularis aurea* were found on islands just below the Isthmus of Kra. The probable hybrid monkeys between long-tailed and rhesus macaques were found at the postulated hybrid zone (15-20[degree] N). The severe threats to Thai macaque populations are habitat deterioration and the artificial genetic pollution caused by pet release and monkey translocation.

1522: +.151

1. Climate change is recognized as a major threat to the survival of species and integrity of ecosystems world-wide. Although considerable research has focused on climate impacts, relatively little work to date has been conducted on the practical application of strategies for adapting to climate change. Adaptation strategies should aim to increase the flexibility in management of vulnerable ecosystems, enhance the inherent adaptability of species and ecosystem processes, and reduce trends in environmental and social pressures that increase vulnerability to climate variability. 2. Knowledge of the specific attributes of climate change likely to impact on species or habitats is central to any adaptive management strategy. Temperature is not the only climate variable likely to change as a result of anthropogenic increases in greenhouse gases. In some regions changes in precipitation, relative humidity, radiation, wind speed and/or potential evapotranspiration may be more marked than for temperature. 3. Uncertainty exists in the response of species and ecosystems to a given climate scenario. While climate will have a direct impact on the performance of many species, for others impacts will be indirect and result from changes in the spatiotemporal availability of natural resources. In addition, mutualistic and antagonistic interactions among species will mediate both the indirect and direct effects of climate change. 4. Approaches to predict species' responses to climate change have tended to address either changes in abundance with time or in spatial distribution. While correlative models may provide a good indication of climate change impacts on abundance, greater understanding is generated by models incorporating aspects of life history, intra- and interspecific competition and predation. Models are especially sensitive to the uncertainty inherent in future climate predictions, the complexity of species' interactions and the difficulties in parameterizing dispersal functions. Model outputs that have not been appropriately validated with real data should be treated with caution. 5. Synthesis and applications. While climate impacts may be severe, they are often exacerbated by current management practices, such as the construction of sea defences, flood management and fire exclusion. In many cases adaptation approaches geared to safeguard economic interests run contrary to options for biodiversity conservation. Increased environmental variability implies lower sustainable harvest rates and increased risks of population collapse. Climate change may significantly reduce habitat suitability and may threaten species with limited dispersal ability. In these cases, well-planned species translocations may prove a better option than management attempts to increase landscape connectivity. Mathematical models, long-term population studies, natural experiments and the exploitation of natural environmental gradients provide a sound basis for further understanding the consequences of climate change.

1523: +.326

The realms of rare species conservation and metapopulation biology theory are often interrelated, and hence share several basic challenges. Two of the most important are the critical and frequently difficult tasks of distinguishing a priori between habitat and nonhabitat, and then delimiting suitable habitat patches in a study area. We combined classification tree analysis, a subset of classification and regression tree (CART) modeling, with digital data layers of environmental variables in a geographic information system (GIS) to predict suitable habitat and potential new population occurrences for turkeybeard (*Xerophyllum asphodeloides*), a rare liliaceous understory herb associated with southern Appalachian pine-oak (*Pinus-Quercus*) forests, in northwestern Virginia. Sample values from eight environmental data layers and population survey data were used in the modeling process to produce a cross-validated classification tree that predicted suitable habitat in the study area. Elevation, slope, forest type, and fire frequency were the four main explanatory variables in the model. Approximately 4% of the study area was classified into five suitable habitat classes, with a misclassification error rate of 4.74%. The final 13-leaf tree correctly classified 74% of the known presence areas and 90% of the known absence areas, and ground-truthing surveys resulted in the discovery of eight new occupied habitat patches. Results of this

study are important for conservation and management of *X. asphodeloides*, as well as for the applicability of the habitat modeling techniques to enhancing the study of metapopulations and disturbance regimes in Appalachian forests. In addition, they confirm the potential and value of CART and GIS-based modeling approaches to species distribution problems. Our model was successful at defining suitable habitat and discovering new populations of a rare species at the landscape scale. Similar application to other rare species could prove very useful for addressing these and other ecological and conservation issues, such as planning translocation or reintroduction experiments, identifying metapopulation fragmentation thresholds, and formulating conservation strategies.

1524: +.100

Securing natural habitats into which reintroduced species are released and those into which they will radiate is essential for the long-term establishment and viability of reintroduced populations. Consequently, the ability to project future range expansion is critical in reintroduction programs. We evaluated whether numerical growth and spatial expansion of a reintroduced population can be projected based on short-term monitoring of a newly reintroduced population, by studying a Persian fallow deer (*Dania mesopotamica*) population reintroduced to Israel. Over a five-year period, five to six adult (>1 yr) females were released semi-annually, for a total of 53 over the research period. We developed an individual-based spatially explicit model that projected spatial expansion of the female population in the wild. Model parameters were derived from empirical studies on movement patterns, home range establishment, behavioral adjustments, and demographic dynamics of reintroduced females during the first three years of the reintroduction project. Significant factors that were found to affect home-range establishment and that were incorporated into the model were: occurrence of Mediterranean woodland; occurrence of moderate terrain; roads; built-up areas; and presence of conspecifics. We tested the model by comparing its projections with field observations at the end of the five-year period since the project's onset, i.e., two years beyond the time on which parameters were based. The model was able to predict the direction and rate of expansion of the population and the main activity areas in the wild during the last two years. By using the model for long-term projection, future potential activity centers and landscape connectivity, important for securing the lands required for the Persian fallow deer future radiation, can be identified.

1525: +.090

Successful nonlethal management of livestock predation is important for conserving rare or endangered carnivores. In the northwestern United States, wolves (*Canis lupus*) have been translocated away from livestock to mitigate conflicts while promoting wolf restoration. We assessed predation on livestock, pack establishment, survival, and homing behavior of 88 translocated wolves with radiotelemetry to determine the effectiveness of translocation in our region and consider how it may be improved. More than one-quarter of translocated wolves preyed on livestock after release. Most translocated wolves (67%) never established or joined a pack, although eight new packs resulted from translocations. Translocated wolves had lower annual survival (0.60) than other radio-collared wolves (0.73), with government removal the primary source of mortality. In northwestern Montana, where most wolves have settled in human-populated areas with livestock, survival of translocated wolves was lowest (0.41) and more wolves proportionally failed to establish packs (83%) after release. Annual survival of translocated wolves was highest in central Idaho (0.71) and more wolves proportionally established packs (44%) there than in the other two recovery areas. Translocated wolves showed a strong homing tendency; most of those that failed to home still showed directional movement toward capture

sites. Wolves that successfully returned to capture sites were more likely to be adults, hard (immediately) rather than soft (temporarily held in enclosure) released, and translocated shorter distances than other wolves that did not return home. Success of translocations varied and was most affected by the area in which wolves were released. We suggest managers translocating wolves or other large carnivores consider soft releasing individuals (in family groups, if social) when feasible because this may decrease homing behavior and increase release-site fidelity.

1526: +.282

Logistic regressions were used to study the relationship between habitat variables and the use of tropical watercourses by the West Indian manatee *Trichechus manatus* at Northeastern Costa Rica and Southern Nicaragua. Presence of manatees in watercourses was assessed through direct and reported sightings of individuals and feeding signs on aquatic vegetation. Indirect methods provided good approximations to the actual distribution that could not have been achieved through direct observations or aerial surveys. Best multivariate models showed that manatees were most present in watercourses that presented abundant aquatic vegetation, warm, and clear waters, high forest cover, and are wider than those where the species is absent. Although habitat variables that explain habitat use of manatees differed for the two sectors found within the study area, manatees preferred lagoons to other watercourses in both areas. These findings point to forest clearing on the shores as a threat for manatee conservation. Habitat variables are excellent predictors of manatee presence, and predictive models as those developed in this study can help assess potential distribution of manatees in areas where this information is lacking as well as to assist identify potential reintroduction areas. 1527: -.101

This paper describes the effect of a disease outbreak on the success of a translocation for conservation management in a critically endangered species. Three juvenile kakapo from a group of 19 translocated birds died within 72 h of transport between New Zealand offshore islands. Clinical findings, gross necropsy changes, cytology, histopathology and bacterial culture confirmed systemic disease caused by *Erysipelothrix rhusiopathiae*. On the island from which the kakapo were sourced, positive cultures of *E. rhusiopathiae* were obtained from the medulla of the ulna from 10 out of 15 seabird carcasses examined, suggesting that this could be the source of infection for the kakapo. Immediately after the diagnosis, all of the translocated birds were re-captured and treated with antibiotics. A vaccination programme has commenced using a commercial killed bacterin developed for turkeys. The disease outbreak has had costly implications for the population and conservation management of the species. This is the first report of erysipelas in wild parrots, and the first report of the management of erysipelas in a critically endangered wild population of birds.

1528: +.140

The northern pademelon (*Thylogale browni*) is a small to medium-sized macropodid that is native to northern and central New Guinea, but is also found on some of the islands of the Bismarck Archipelago, such as New Britain, New Ireland and Lavongai, where it appears to have been introduced. In New Ireland, archaeological evidence indicates that it may have been introduced by prehistoric human agency c. 7,000 years ago. In the chain of islands that constitutes New Ireland Province, historical evidence indicates that the species also recently occurred in the Tabar, Lihir, Tanga and Feni island groups prior to undergoing a series of local extinctions and range contractions during the first half of the 20(th) century. Furthermore *T. browni* also appears to have

declined on New Ireland and Lavongai, where it is now restricted to the remote mountainous interior. Much of the sudden range contraction coincided with the Pacific War (1942-1945), during which time blockaded Japanese troops confiscated local food produce. It is postulated that the privations of war led to an extended period of over-hunting which drove the species into local extinction in much of its former range. Furthermore, since the war, ongoing human pressures and a breakdown in the traditional ethnozoological translocation / re-stocking regimes which would normally have re-introduced this species to satellite islands, appears to have prevented *T browni* from regaining its former widespread distribution in the New Ireland Province Archipelago.

1529: +.123

This paper stated briefly about the current situation of the Giant Panda (*Ailuropoda melanoleuca*) including its population, density, habitat and the adjacent communities. It also analyzed the main problems facing to the protection of the Giant Panda, including: (1) serious disturbance resulted in the isolated situation of the Giant Panda population; (2) the florescence of bamboos threatening the survival of wild population; (3) the conflict between the development of communities and the protection of the Giant Panda. Then, this paper put forward the essential policy and four strategic objects for the Giant Panda conservation as follows: (1) forming several continuous conservation regions by establishing a series of natural reserves; (2) allaying the obstruct to the Giant Panda made by perpetual project; (3) making overall action plan for the development of the community economy and implementing management together with community; (4) implementing the project of reintroduction of the captive Giant Panda. In the end, it pointed out specially ways and measures to actualize these policy and objectives.

1530: +.044

We examined the physical habitat of nest sites chosen by hatchery Atlantic salmon, *Salmo salar*, in a recovery program for this extirpated species in Lake Ontario, Canada. We compared the sites used by these captive bred fish to a set of random locations in a wide range of available habitats. Compared to random locations in the stream, the nest sites chosen were lower in the relative abundance of sediment size classes that are detrimental to embryo and juvenile survival. In addition, the process of nest construction by these captive bred fish further reduced the proportions of these detrimental sediments. Although captive breeding may have changed some aspects of the nest site selection and construction behaviour, it has not caused a complete loss or major alteration of the trait and thus does not preclude hatchery fish from restoration or reintroduction programs.

1531: -.043

In this study samples of ten species of fish were analyzed for concentrations of organochlorine pesticides, PCBs and heavy metals (Pb, Cd, and Cu). Fish were captured using electric fishing on ten sites along the Drome river (Rhone-Alpes region). Quantitative determination of the organochlorine and PCBs compounds was performed by gas chromatography-electron-capture detection (GC-ECD). The concentrations of heavy metals were determined by atomic absorption spectrophotometry. Samples contained detectable concentrations of lindane, PCBs, and heavy metals but at concentrations below the maximum residue limit (MRL). Non-parametric statistical analysis was performed to distinguish groups of sites with different levels of contamination. PCBs concentrations increased along the river with four groups of sites significantly different from each other. Cadmium concentrations were below the MRL. Lead contamination showed two groups significantly different and a repartition similar to PCBs. Copper contamination was correlated with the localization of vineyards. We assessed the potential effects of contamination the otter (*Lutra*

lutra). The concentrations of all pollutants analyzed in fish sampled in this study are lower than the threshold values described in literature. The Drome river is relatively unpolluted river, and the establishment of otter populations should not be affected by pollution. (c) 2005 Elsevier Ltd. All rights reserved.

1532: +.122

We reintroduced 33 peregrine falcons (*Falco peregrinus*) at two release areas with contrasting habitat configurations to assess landscape influences on dispersal. One site (Daniel Boone National Forest) had non-forested corridors within a forest matrix, whereas the other site (Tom Dorman State Nature Preserve) had forested corridors within an agricultural matrix. We used aerial telemetry and ground observation to assess differences in dispersal between sites and we used multivariate statistical analyses to detect combinations of response variables depicting landscape influences. Non-forested corridors at Daniel Boone affected post-fledging movements and initiation of dispersal, whereas no discernable pattern in dispersal initiation was observed at Dorman Preserve. Results included significant ($p < 0.05$) differences between peregrines at Daniel Boone and Dorman Preserve in (x) over bar \pm SD post-fledging area (PFA) size (2643.5 \pm 2599.0 and 931.7 \pm 732.1 ha, respectively), maximum movement distances (12.9 \pm 13.9 and 6.1 \pm 4.6 km, respectively), orientation of movements (second-order (x) over bar angle \pm 95% confidence interval (CI) = 280.8 \pm 58.6 (non-random orientation) and 358.8 \pm 98.8 (random orientation), respectively), time spent on the PFA (16.0 \pm 12.2 and 31.0 \pm 3.3 days, respectively) and selection of agricultural habitats (Euclidean distance vectors $p = 0.66$ and $p = 2.50$, respectively). Selection of agriculture by peregrines released on Daniel Boone reflected selection of corridors as part of pre-dispersal movement. These results, coupled with generally unorientated movement behaviour by Dorman Preserve peregrines, provided evidence for an influence of functional landscape connectivity on dispersal in peregrines.

1533: +.209

Efforts to evaluate the efficacy of translocation as a conservation tool have mostly been inadequate, particularly for reptiles and amphibians, leading many biologists to discount translocation as a viable management option. Nevertheless, with two-thirds of the world's tortoise and freshwater turtle species at risk, translocation may be one of the few remaining options for re-establishing extirpated populations and reconnecting fragmented ones. We translocated 106 gopher tortoises (*Gopherus polyphemus*) to a protected area within the historical range but with no resident tortoises and tested the effects of penning on site fidelity and activity area size. We assigned 38 adults and subadults to one of three penning treatments (9 months, 12 months and no penning) and radio-tracked them for 2 years. Penning significantly increased site fidelity and resulted in smaller activity areas. Our data suggest that translocation coupled with penning will improve the likelihood of establishing self-sustaining tortoise populations.

1534: +.249

The successful eradication of introduced rodents from islets off the coast of Mauritius has led to local conservation bodies investigating the possibility of translocation as a measure of safeguarding endemic reptile populations. The present study was the first to determine the habitat and microhabitat requirements of Telfair's skinks (*Leiopisma telfairii*) on Round Island, Mauritius, with a view to aiding future translocation projects to islands within their historic range. Contrasting preferences found for Telfair's skink at macro- and micro-habitat levels underline the importance of sampling at multiple ecological scales in such investigations. Significantly fewer

sightings of *L. telfairii* were recorded in bare rock habitats compared to more vegetated habitats. Conversely, at a microhabitat scale principal component analysis indicated structural characteristics were the primary determinant of microhabitat choice. The first dietary analysis of Telfair's skinks confirmed their status as omnivores. Cockroaches (*Blattodea* spp.) appeared to be a primary food source. Four exotic plant species were also present in faecal samples and the potential for *L. telfairii* to aid their dispersal is discussed. Implications for the long-term management and proposed translocation of Telfair's skinks are discussed. (c) 2005 Elsevier SAS. All rights reserved.

1535: +.002

We used radiotelemetry and population modeling techniques to examine factors related to population establishment of black bears (*Ursus americanus*) reintroduced to Felsenthal National Wildlife Refuge (NWR), Arkansas. Our objectives were to determine whether settling (i.e., establishment of a home range at or near the release site), survival, recruitment, and population viability were related to age class of reintroduced bears, presence of cubs, time since release, or number of translocated animals. We removed 23 adult female black bears with 56 cubs from their winter dens at White River NWR and transported them 160 km to man-made den structures at Felsenthal NWR during spring 2000-2002. Total movement and average circuitry of adult females decreased from 1 month, 6 months, and 1 year post-emergence ($F_{2,14} = 19.7$, $P < 0.001$ and $F_{2,14} = 5.76$, $P = 0.015$, respectively). Mean first-year post-release survival of adult female bears was 0.624 (SE=0.110, SEinterannual = 0.144), and the survival rate of their Cubs was 0.750 (SE=0.088, SEinterannual=0.109). The homing rate (i.e., the proportion of bears that returned to White River NWR) was 13%. Annual survival for female bears that remained at the release site and survived > 1-year post-release increased to 0.909 (SE=0.097, SEinterannual=0.067; $Z=3.5$, $P < 0.001$). Based on stochastic population growth simulations, the average annual growth rate (λ) was 1.093 (SD=0.053) and the probability of extinction with no additional stockings ranged from 0.56-1.30%. The bear population at Felsenthal NWR is at or above the number after which extinction risk declines dramatically, although additional releases of bears could significantly decrease time to Population reestablishment. Poaching accounted for at least 3 of the 8 adult mortalities that we documented; illegal kills Could be a significant impediment to Population re-establishment at Felsenthal NWR should poaching rates escalate.

1536: +.186

Understanding how populations expand to recolonize former habitats is important to restoration efforts in wildlife management and conservation. Translocation of black bears (*Ursus americanus*) to Arkansas in the 1950s and 1960s has led to recolonization of former bear range in Oklahoma, with substantial increases in distribution and abundance of the species in Oklahoma over the last 15 years. We studied demographics of black bears in southeastern Oklahoma from May 2001 to November 2002 to provide insight into characteristics of recolonizing populations of large carnivores. We trapped 51 black bears (22 M, 29 F) 77 times and radiocollared 25 female bears. Sex ratios of adults and cubs were skewed toward females, and the age structure was younger than observed in other unharvested populations. Survival of adult females was estimated at 0.9 +/- 0.1, and fertility was estimated at 0.77 female young/female/year. Density on the study area was estimated at 0.21 bears/km² and the current finite growth rate (λ) of the study population was estimated to be 1.11/year. Demographic characteristics of the Oklahoma population of black bears were similar to those of other recolonizing populations of large carnivores.

1537: -.010

Although numerous authors are investigating indirect effects of wolf recovery, the most fundamental ecological impact of the Greater Yellowstone Area wolf reintroduction, the effects of wolf predation on ungulate populations, remains unclear. We report on a 5-year comparative study of wolf (*Canis lupus*)-elk (*Cervus elaphus*) dynamics on an elk herd in the headwaters of the Madison River within Yellowstone National Park and the lower Madison elk herd that winters 40 km downriver outside the Park. A resident pack became established on the Madison headwaters area in 1997 and grew to multiple packs totaling 30-40 animals by 2002. During winter 1999 emigrates from Yellowstone established a pack on the lower Madison area. However, poor recruitment and low adult survival limited wolf population growth, with the area supporting a single pack, never exceeding 5 animals. Wolf kill rates on the lower Madison area were approximately double that documented for the Madison headwaters area. Moderate kill rates in the Madison headwaters, combined with high wolf densities and modest elk densities, resulted in an estimated 20% of the elk population being killed during winter and projections for a declining elk population. In contrast, high kill rates on the lower Madison area, combined with low wolf densities and high elk densities, resulted in winter predation estimates not exceeding 40% of the elk population. We suspect this level of mortality will be of little biological significance with respect to elk population trajectory. These results suggest that the effects of wolf predation on elk populations differ substantially over relatively small spatial scales, depending on a complex suite of interacting factors. Thus, we caution against generalizing the effects of wolf restoration on elk dynamics from any single study and encourage collaborations to develop comparative predator-prey studies that improve our understanding of wolf-ungulate interactions and enhance conservation.

1538: +.039

Grasslands dominated by exotic annual grasses have replaced native perennial vegetation types in vast areas of California. Prescribed spring fires can cause a temporary replacement of exotic annual grasses by native and non-native forbs, but generally do not lead to recovery of native perennials, especially where these have been entirely displaced for many years. Successful reintroduction of perennial species after fire depends on establishment in the postfire environment. We studied the effects of vegetation changes after an April fire on competition for soil moisture, a key factor in exotic annual grass dominance. As an alternative to fire, solarization effectively kills seeds of most plant species but with a high labor investment per area. We compared the burn to solarization in a study of establishment and growth of seeds and transplants of the native perennial grass Purple needlegrass (*Nassella pulchra*) and coastal sage species California sagebrush (*Artemisia californica*). After the fire, initial seed bank and seedling densities and regular percent cover and soil moisture (0-20 cm) data were collected in burned and unburned areas. Burned areas had 96% fewer viable seeds of the dominant annual grass, Ripgut brome (*Bromus diandrus*), leading to replacement by forbs from the seed bank, especially non-native Black mustard (*Brassica nigra*). In the early growing season, *B. diandrus* dominating unburned areas consistently depleted soil moisture to a greater extent between rains than forbs in burned areas. However, *B. diandrus* senesced early, leaving more moisture available in unburned areas after late-season rains. *Nassella pulchra* and *A. californica* established better on plots treated with fire and/or solarization than on untreated plots. We conclude that both spring burns and solarization can produce conditions where native perennials can establish in annual grasslands. However, the relative contribution of these treatments to restoration appears to depend on the native species being reintroduced, and the long-term success of these initial restoration experiments remains to be determined.

1539: -.049

This paper summarises published research on Przewalski's horse, *Equus ferus przewalskii*. Biology of the species is described, as well as its history in the wild and in captivity. Reintroduction efforts at Takhiin Tal and Hustai National Park are discussed, with current population levels given, as well as some survivorship data. Ecology of the Przewalski horse at the different reintroduction sites is described, showing similarities and differences. Finally future conservation of Przewalski's horse is discussed, with particular reference to the change in status from Extinct in the Wild to Endangered, based on the IUCN Categories and Criteria.

1540: +.059

The Eurasian beaver, *Castor fiber* L., suffered extreme demographic reduction through overhunting until the end of the 19th century. However, active protection measures have led to a powerful recovery in range and population numbers. The vast majority of beavers (83%) now occur in the former Soviet Union. The present study investigates the geographic distribution of genetic variation of *C. fiber* in this eastern part of the species range (former Soviet Union and Mongolia), with special emphasis on small isolated populations of the Asian subspecies *C. fiber pohlei*, *C. fiber tuvinicus*, and *C. fiber birulai*. The analysis yielded 12 different haplotypes, all of which were population specific. Results indicate that *C. fiber* displays great population structuration ($F_{ST} = 0.985$), coupled with an overall low level of genetic divergence (mean number of pairwise differences 7.262 ± 3.435). In particular, the autochthonous populations in Mongolia or Siberia do not appear significantly different from samples from the European part of Russia, despite the great geographical distance. *C. f. birulai* appears as the most divergent member, a fact that could result from its longer genetic isolation in an enclosed watershed. Examination of our data suggests a single recent origin of the present beaver population in eastern Europe and Asia.

1541: +.057

Introduced rats depredate every life stage of island nesting seabirds, but the extent of predation is rarely quantified. Introduced black rat (*Rattus rattus*) and native deer mouse (*Peromyscus maniculatus anacapae*) predation on Xantus's murrelet (*Synthliboramphus hypoleucus scrippsi*) nests was experimentally quantified using artificial nests before and after rat eradication on Anacapa Island (California). The staged rat eradication programme provided experimental treatments: in 2002 rats were eradicated on one island (East Anacapa Islet) and remained on two islands (Middle and West Anacapa Islets), providing a control comparison, and, in 2003, rats were eradicated from the remaining islands (Middle and West Anacapa Islets). In 2002, 96% of artificial nests were depreciated on control islands (rats present) with rats accounting for most predation. Nest predation on the treatment island (rats eradicated) in 2002 was significantly lower: 8% of artificial nests were depredated, mostly by endemic deer mice. In 2003, following rat eradication on the remaining islands (Middle and West Anacapa Islets), nest predation was reduced from 96% in 2002 to 3% of total nests in 2003. Predation of nests on East Anacapa Islet (rats eradicated in 2002) increased significantly due to reintroduction and recovery of native deer mouse populations, with 23% of artificial nests depredated. The inference is that rat predation on real Xantus's murrelet nests was responsible for the historically low nesting success and small population sizes of breeding murrelets on Anacapa Island. With rats removed, the hatching success of Xantus's murrelet chicks and the number of individuals nesting on Anacapa Island will increase dramatically. Artificial nest studies are particularly well suited to quantifying introduced rat impacts on hole and crevice nesting seabirds and can simultaneously serve as an effective monitoring tool to detect the presence of rats and the recovery of native nest predators.

1542: +.121

Atlantic salmon (*Salmo salar*) was once native to Lake Ontario, however, its numbers rapidly declined following colonisation by Europeans and the species was extirpated by 1896. Government agencies surrounding Lake Ontario are currently undertaking a variety of studies to assess the feasibility of reintroducing Atlantic salmon. We released hatchery-reared adult Atlantic salmon into a Lake Ontario tributary to examine spawning interactions between this species and fall-spawning exotic salmonids found in the same stream. Chinook salmon, coho salmon and brown trout were observed interacting with spawning Atlantic salmon in nearly one-quarter of our observation bouts, with chinook salmon interacting most frequently. Whereas a previous investigation found that chinook salmon caused elevated agonistic behaviour and general activity by spawning Atlantic salmon, the present study found that interspecific courtship was the most common form of exotic interaction with spawning Atlantic salmon. In particular, we observed precocial male Chinook salmon courting female Atlantic salmon and defending the female against approach by male Atlantic salmon. We discuss the potential implications of these interactions on the Lake Ontario Atlantic salmon reintroduction programme.

1543: +.243

How does society influence the management of an introduced native mammal that is destroying its own habitat-especially when that animal is considered threatened on parts of the mainland, is aesthetically pleasing, and is important to the tourism industry? If control through sterilization and translocation is part of the answer, what lessons can be learned from this program?

1544: +.080
