ABSTRACT   Fusion of biological membranes, although mediated by divergent proteins, is believed to follow a common pathway. It proceeds through distinct steps, including docking, merger of proximal leaflets (stalk formation), and formation of a fusion pore. However, the structure of these intermediates is difficult to study because of their short lifetime. Previously, we observed a loosely and tightly docked state preceding leaflet merger using arresting point mutations in SNARE proteins, but the nature of these states remained elusive. Here, we used interferometric scattering (iSCAT) microscopy to monitor diffusion of single vesicles across the surface of giant unilamellar vesicles (GUVs). We observed that the diffusion coefficients of arrested vesicles decreased during progression through the intermediate states. Modeling allowed for predicting the number of tethering SNARE complexes upon loose docking and the size of the interacting membrane patches upon tight docking. These results shed new light on the nature of membrane-membrane interactions immediately before fusion.

SIGNIFICANCE   Membrane merger through fusion is essential in a myriad of processes, including neurotransmission and viral infection. Despite the importance of understanding the process of membrane fusion, there are still many open questions about the exact mechanism. Here, we present a new technique that allows imaging the small vesicles while they are attached during fusion to another membrane with unprecedented temporal and spatial resolution. This approach in combination with modeling allowed us to extract novel features of fusion intermediates, which, until now, have remained elusive. In particular, we were able to dynamically distinguish two states that occur before fusion: a loosely docked and a tightly docked state. Characterizing these dynamic differences can help us to better understand membrane-membrane interactions during fusion.

INTRODUCTION

Soluble *N*-ethylmaleimide-sensitive factor activating protein receptor (SNARE) proteins mediate membrane fusion in the secretory pathway of eukaryotic cells and are widely used as model for studying fusion. They are small, mostly membrane-anchored proteins characterized by a conserved motif (SNARE-motif) that is usually located adjacent to the C-terminal membrane anchor (1). Upon contact between

membranes destined to fuse, four complementary SNARE motifs assemble to form a *trans*-SNARE complex that cross-links the membranes. Assembly is initiated at the membrane-distal ends and then progresses toward the C-terminal membrane anchors ("zippering"), thus pulling the membranes tightly together (1–3). Zippering is highly exergonic and thus overcomes the energy barriers for membrane fusion (4–7). After membrane merger is completed, all SNAREs of the complex are aligned in parallel in the same membrane (*cis*-SNARE complex).

Despite major progress, the structural transitions along the fusion pathway are far from clear. Fusion commences with membrane contact and then leads via nonbilayer transition states to the final opening of an aqueous fusion pore. Experimental evidence complemented with both continuum- and particle-based models have suggested tentative pathways involving tight membrane contact brought about

by SNARE zippering, associated with local protrusions of high curvature in some models (8–10). This state may then lead to lipid tail splaying between the fusing bilayers (11), resulting in a merger of the proximal monolayers, yielding a structure that is also referred to as fusion stalk (see e.g., (12)). From the stalk intermediate, the system may progress to forming a hemifusion diaphragm (13) before the final opening of the fusion pore (8). For the transition from one intermediate to the next, energy barriers such as electrostatic repulsion or steric hydration forces need to be overcome (14–16).

Under physiological conditions, the lifetime of these intermediate states is very short. Indeed, only recently docking intermediates preceding hemifusion in SNARE-mediated fusion have been captured by cryoelectron microscopy (6,17,18). Deletion of a single amino acid in the SNARE synaptobrevin-2 (Δ84 syb) results in vesicles that are arrested in a tightly docked (but not hemifused) state in which the membranes are separated by less than 1 nm. In contrast, substitution of two amino acids more distal from the transmembrane domain (I45A, M46A; referred to as AA syb) uncovered a loosely docked state in which the membranes are separated by a larger gap only connected by reversible SNARE interactions (17). Finally, extended hemifusion diaphragms were observed when the wild-type (WT) syb protein was used (6).

In this study, we have used in vitro reconstitution to characterize the nature of the loose- and tight docking states. In particular, we have analyzed whether diffusion is affected by the nature of the docking intermediate. To this end, we have taken advantage of a previously established model system in which the SNARE-mediated docking and fusion of small vesicles with a single giant unilamellar vesicle (GUV) can be measured (19). In this work, we used the neuronal SNARE proteins syb, syntaxin-1, and SNAP-25 as models, with syb incorporated into small vesicles and an activated acceptor complex of syntaxin-1 and SNAP-25 (20) inserted into the GUV membrane. This system is ideally suited for studying particle diffusion on membranes because the membrane area is large but diffusion is not hindered by any type of surface contact as, for instance, in supported planar bilayers (21). We employed interferometric scattering (iSCAT) microscopy (22–24) to record three-dimensional (3D) trajectories of particle diffusion on the surface of GUVs. This technique has been shown to reach microsecond-temporal resolution and nanometer precision in detecting and tracking individual nanoparticles via the interference of their scattered light with a reference beam (see Materials and Methods). Using iSCAT, we could investigate the diffusion of unlabeled vesicles arrested at a loosely or tightly docked intermediate state using syb-point mutants as previously described (17). Modeling of the diffusion data allowed for approximating the number of SNARE complexes involved in vesicle docking (loose docking) as well as the size of the interaction interface (tight docking).

MATERIALS AND METHODS

Protein expression and purification

Rattus norvegicus-derived SNARE proteins (syntaxin-1A (183–288) (25)), SNAP-25 (cysteine-free) (26), synaptobrevin-2 (WT (27), Δ84 (28), I45A, and M46A (AA) (17,29)), 1–96 (30), and synaptobrevin-2 fragment (49–96) (20) were expressed and purified as described before (17,31). In short, proteins were expressed in *Escherichia coli* strain BL21 (DE3) and purified via nickel-nitrilotriacetic acid affinity chromatography (Qiagen, Hilden, Germany) followed by ion exchange chromatography on an Äkta system (GE Healthcare, Chicago, IL). The preassembled so called ΔN complex (20) was used to mimic plasma membrane SNARE acceptor complex. It consists of syntaxin, SNAP-25, and syb fragment 49–96. The complex was obtained by mixing the monomers overnight at 4°C, followed by purification of the complex using ion exchange chromatography (MonoQ column) in a buffer containing CHAPS as described before (20,31).

Liposome preparation

Lipids (brain-derived phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS) along with cholesterol (ovine wool)) were purchased from Avanti Polar Lipids (Alabaster, AL). For all liposome mixtures, lipids PC, PE, PS, and cholesterol were mixed in a ratio of 5:2:2:1, respectively. Liposomes were tested on regular basis for reconstitution efficiency of proteins as described before (6,31).

Large unilamellar vesicles (LUVs; diameter ∼100 nm) were prepared with a reverse phase evaporation method as previously described (6,19). Proteoliposomes were formed using a direct reconstitution method as previously described (6), with syb WT, Δ84, or AA reconstituted in a protein/lipid ratio of 1:500.

Small proteoliposomes (diameter ∼40 nm) were prepared as described before (19) by comicellization followed by size exclusion chromatography. During preparation, ΔN complex was added to yield a protein/lipid ratio of 1:1000.

GUV preparation

GUVs were prepared from small proteoliposomes containing ΔN complex by electroformation using in-house-built electroformation chambers containing platinum wires (32) using a protocol described previously (31).

iSCAT measurements

Liposomes were tracked using iSCAT microscopy (22–24). With iSCAT technology, we could reach microsecond-temporal resolution in 3D imaging by acquiring one image per time point instead of a z-stack from which data were extracted. Moreover, the interferometric nature of iSCAT provides a much higher axial resolution in comparison to confocal imaging (of the order of 1 nm) because the iSCAT contrast fully reverses within less than 100 nm of axial motion, providing a large gradient that reports on the axial location of the particle. The basic principle is schematically shown in Fig. 1 *a* (a more detailed description of the setup can be found in (33)). Briefly, the incoming light E_{inc} of a 532-nm laser (Verdi 2G; Coherent, Santa Clara, CA) is scattered from the GUV and the liposomes (E_{scat}) and partially reflected at the glass-sample interface (E_{ref}). E_{scat} and E_{ref} are collected via an oil-immersion 60× objective (ApoN, NA = 1.49; Olympus, Shinjuku City, Tokyo, Japan) and imaged onto a CMOS camera (MV-D1024E-CL; Photonfocus, Lachen, Switzerland). The intensity at the camera is given by

$$I_{det} = I_{ref} + I_{scat} + I_{int} = E_{ref}^2 + E_{scat}^2 + 2 \times E_{ref} \times E_{scat}$$
$$\times cos\varphi,$$

FIGURE 1   iSCAT detection of GUVs and liposomes. (*a*) Schematic illustration of the experimental optical setup allowing the observation of GUVs in bright field (on the CCD camera) and iSCAT (on the CMOS camera) as well as micropipette manipulation of GUVs (see *inset*). BS, beam splitter; λ/4, quarter wave plate; PBS, polarizing beam splitter; AOD, acousto-optical deflector. (*b*) iSCAT GUV image before (*upper image*) and after (*lower image*) background-correction procedure. In the background-corrected image, two docked LUVs become visible (marked with *yellow arrows*) with the PSF shape of the wide-field iSCAT microscope encoding the particular height of the particles. (*c*) A histogram of the average LUV size determined based on their contrast in iSCAT ($N_{LUV} = 56$).

and is thus dependent on the phase φ between the scatterer and the reflected light. Changes in the distance between the scatterer and the glass-sample interface result in a periodic modulation of the scatterer's contrast. Scattering at the GUV surface therefore creates a ring pattern, as shown in Fig. 1 *b*. In the same fashion, the point spread function (PSF) of a liposome changes its amplitude when it travels along the GUV surface and thus appears either bright or dark on the GUV background.

To hold the GUVs in place above the field of view, we used micropipette aspiration (34) using glass pipettes with an ∼5-μm opening connected to a height-adjustable water tank and a micromanipulator (Sensapex, Oulu, Finland). Using a 90:10 (T:R) beam splitter, a part of the collected light was sent onto a CCD camera (SensiCam; PCO, Kelheim, Germany) for monitoring the GUV aspiration process in bright field.

Videos of liposomes bound to GUVs were recorded typically for 5 s at a 1-kHz frame rate. For liposome tracking, we performed background correction based on image registration (details of the procedure can be found in the Supporting Materials and Methods). The iSCAT contrast of the liposomes typically amounts to 2–3%. In the background-corrected images, we fit a two-dimensional (2D) Gaussian function to each PSF for determining the 2D projected position. The particle height z_i in each frame is calculated based on the GUV center (x_{GUV}, y_{GUV}), the GUV radius r_{GUV}

(which we extract from the bright field image), and the 2D particle localization (x_i, y_i):

$$z_i = r_{GUV} - \sqrt{r_{GUV}^2 - (x_i - x_{GUV})^2 - (y_i - y_{GUV})^2}. \quad (2)$$

We determined the center of the GUV using two consecutive routines adopted from (35), which are described in the Supporting Materials and Methods.

The diffusion coefficient was calculated for each trajectory from the first two points of the mean-squared displacement (MSD(τ)) with time lag τ of Δt and $2\Delta t$ ($\Delta t = 1$ ms):

$$D = \frac{1}{4} \frac{MSD(\tau = 2\Delta t) - MSD(\tau = \Delta t)}{\Delta t}. \quad (3)$$

Modeling of loose docking

Liposomes loosely docked on the GUV surface were assumed to be tethered by different numbers of SNARE complexes. Their diffusion was simulated

using random walk (36) of individual SNARE complexes in a 2D membrane (similar to (37)). The constraining circular area (50 nm in radius) was introduced to reflect the maximal surface of the liposome-GUV-docking interface with the size resembling maximal LUV membrane deformation during docking as seen in (6,17,38). Other radii (5–100 nm) of constraint areas, including an adaptive one (constraint radius increasing with increasing number of tethering SNARE complexes), were also tested; however, they did not yield substantially different results (data not shown). The effect of solvent friction on vesicle's diffusion in this case was assumed to be negligible (see Fig. S6 and corresponding Supporting Materials and Methods). It also seems unlikely that membrane deformation generated here by diffusing SNARE complexes would result in major decrease of the diffusion coefficient. Therefore, we did not introduce such energy potential in our model.

Initially, a various number of tethering SNARE complexes are randomly distributed within the constraining area. Each SNARE complex displacement dx was determined in every time step dt (usually 100 μs):

$$dx = \sqrt{dt \times 2 \times D_{\text{SNARE}}}, \tag{4}$$

with D_{SNARE} being the diffusion coefficient of the assembled SNARE complex of 3.8 μm^2/s as determined by means of fluorescence correlation spectroscopy with fluorescently labeled versions of neuronal SNAREs incorporated into GUVs in (39). The absolute position of a vesicle after each displacement step was then calculated as center of mass of all simulated proteins. Each 5-s-long simulation was performed 20 times to determine average MSD and diffusion coefficient of the vesicle. Further, we have investigated how clustering of SNARE complexes influences diffusion of loosely docked vesicles, but we did not observe any large effects (Fig. S7). The source code used for simulations in Octave (40) and MATLAB (MathWorks, Natick, MA) are available at Zenodo (41).

Modeling of tight docking

The diffusion speed of tightly docked vesicles was modeled with the use of an analytical expression (42) for the model developed earlier by Hughes et al. (43) to predict diffusion of membrane-embedded objects (proteins) based on the hydrodynamic radius of the membrane-embedded part. The version of the approximation used in this study was presented by (44):

$$D = \frac{k_{\text{B}}T}{4\pi\mu_{\text{m}}h} \left(\frac{(2\varepsilon - 1)ln(\varepsilon) - \gamma + \frac{8\varepsilon}{\pi}}{1 + \frac{8\varepsilon^3 ln(\varepsilon)}{\pi} + \frac{a_1\varepsilon^{b_1}}{1+a_2\varepsilon^{b_2}}} \right), \tag{5}$$

with the parameter ε being dependent on the inclusion radius R:

$$\varepsilon = \frac{R\mu_{\text{s}}}{h\mu_{\text{m}}} \tag{6}$$

Explanation of used symbols can be found in Table 1. Values used in the model are given in Table 2.

Simulated example trajectories of tightly docked vesicles were generated as random walk (Eq. 4) of objects of a certain radius characterized by the diffusion coefficient obtained from Eq. 5.

RESULTS

To study loosely and tightly docked intermediates, a GUV containing SNARE acceptor complexes was immobilized with a micropipette (see Fig. 1 a) and brought in close proximity to the cover glass. Next, we added LUVs (80–100 nm

TABLE 1 Symbols used in Eqs. 5 and 6

in diameter) containing syb and used iSCAT microscopy to track LUVs on the lower hemisphere of individual GUVs from a single focus position (47). The LUVs readily bound to the GUV and either fused with it (as for WT syb (19)) or they remained docked on its surface and diffused (Videos S1, S2, and S3). Detection of the LUV-scattering signal was greatly improved with a background-correction procedure (compare *upper* and *lower image* in Fig. 1 b) described in more detail in Supporting Materials and Methods. The iSCAT contrast of a nano-object is directly proportional to its polarizability, which is, in turn, linked to the particle size (24). The size of the LUVs was estimated from the observed iSCAT contrast to be ~90 nm (see Fig. 1 c). Thus, an LUV appears as the iSCAT PSF of microscope, which consists of few lobes encoding the 3D position of the scatterer (48). This PSF could be fitted with a physical model to extract the third dimension (49); however, here, we fitted the main lobe for the lateral localization and used the change of the central lobe contrast (50,51) as well as the geometry of the GUVs (47) to extract the axial position of the vesicles (Fig. 1 b).

Lack of photobleaching in iSCAT allowed for monitoring the 3D motion of docked vesicles over prolonged periods (as shown exemplarily in Fig. 2 a; Fig. S2) while maintaining nanometer spatial precision (see Fig. S1 and

TABLE 2 Model parameter values used in Eqs. 5 and 6

FIGURE 2 Tracking of docked LUVs on a GUV surface. (*a*) 3D-reconstructed trajectory of a single liposome docked on the GUV surface tracked for 40 s. The color bar shows the time evolution. The sphere represents a GUV surface with a radius of 18 μm. (*b*) *xy* projection of the docked liposome's trajectory from (*a*). The point color depends on the LUV iSCAT signal intensity reflecting fluctuations in the LUV *z*-position relative to the GUV membrane. Regions marked in black and red correspond to the regions of dark and bright iSCAT particle contrasts, respectively (see *lower insets*). The gaps in the trajectory between regions with positive and negative contrast result from the fact that the vesicle is barely visible when undergoing a contrast switch. (*c*) Histograms presenting diffusion coefficients of LUVs docked on the GUV surface depending on the syb variant (AA, *Δ*84, or WT). Bin width is 0.2 μm^2/s. Blue lines represent a Gaussian fit. $N_{AA} = 32$, $N_{Δ84} = 17$, $N_{WT} = 32$. Illustrations above the graph depict possible docking states of the vesicles.

corresponding Supporting Materials and Methods). Docked vesicles closely follow the topography of the GUV surface, thus displaying a characteristic periodic ring-shaped contrast pattern (see Fig. 2 *b*), similar to the Newton rings encountered in Fig. 1 *b* (also see *inset* in Fig. 2 *b*). We then compared surface diffusion of docked vesicles containing either WT syb or the docking mutants *Δ*84 syb and AA syb (described above). As expected, all three vesicle populations dock to GUVs that contain acceptor SNARE complexes. However, when we determined their diffusion coefficients from the measured 3D trajectories (Fig. 2 *a*), significant differences were observed between the three populations (Fig. 2 *c*). Vesicles carrying the AA syb mutants showed the fastest diffusion, followed by those containing the *Δ*84 mutant, whereas vesicles with the WT protein were the slowest. These data show that the different states uncovered previously by electron microscopy (17) indeed represent physical differences in the nature of membrane attachment between the two vesicles.

As discussed above, the loosely docked state is probably governed exclusively by *trans* interactions between individual SNAREs whereas in the tightly docked state the membranes are firmly attached, forming a disk that is probably rigid (6,17). Using the experimentally obtained diffusion data, rather than extracting data directly from recorded trajectories (as it was demonstrated before for virion tracking in total internal reflection fluorescence microscopy (52)), we have therefore carried out random walk simulations to evaluate whether the data are compatible with these models. First, we modeled the diffusion of vesicles connected by multiple (1–20) SNARE complexes (Fig. 3 *a upper panel*). To gain insight into the diffusion of a liposome docked on the GUV surface while being tethered to different numbers of SNARE complexes we simulated random walks of individual SNARE complexes within the constraining circular area to reflect the maximal docking interface area (Fig. 3 *b*, for details see Materials and Methods). Vesicle position was repeatedly determined after each displacement step as the center of mass of all simulated proteins (Fig. 3 *b*) to
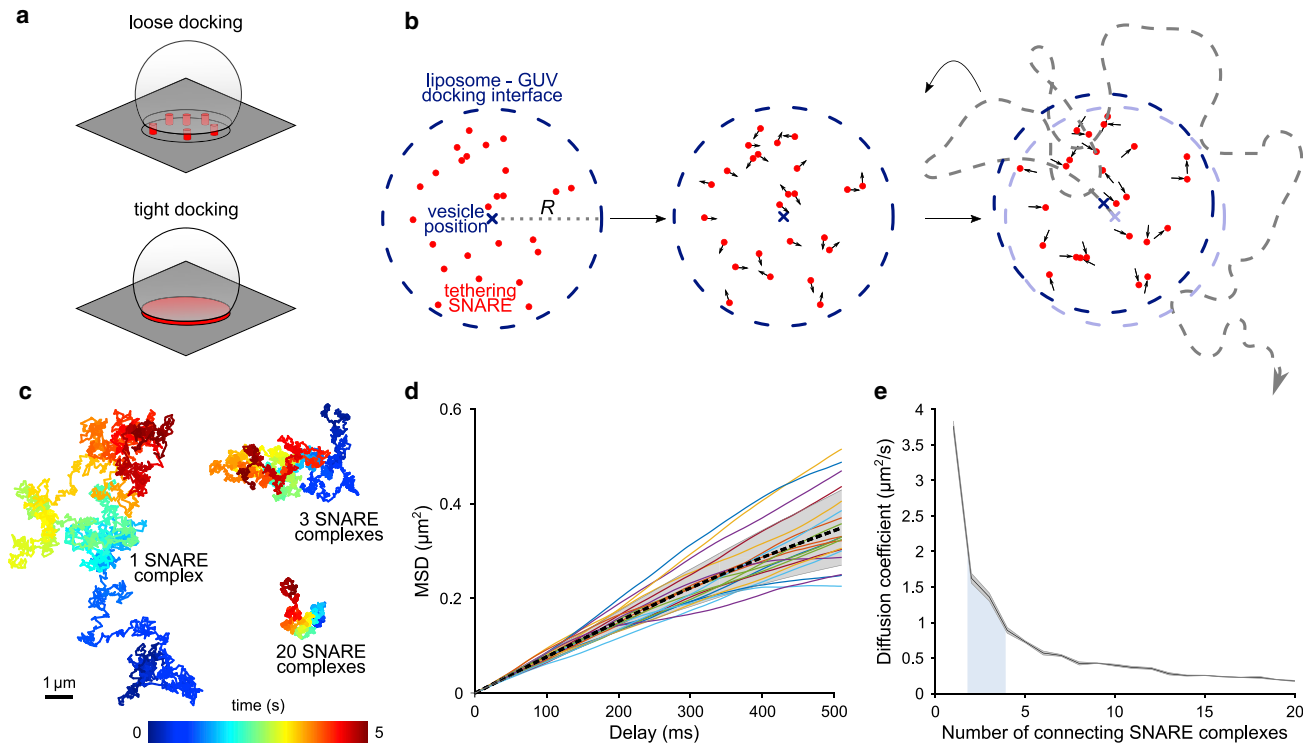

FIGURE 3 Simulation of diffusion of loosely docked vesicles tethered by multiple SNARE complexes. (*a*) Schematic illustration of a vesicle tethered by multiple SNARE complexes to GUV membrane (loose docking, SNARE complexes in *red*) and vesicle that is tightly docked on a GUV surface with interacting docking membrane interfaces marked in red. (*b*) Schematic illustration of the random walk diffusion simulation of SNARE proteins (*red points*) with liposome position determination (*cross*) and with a diffusional constraint *R* for SNARE proteins representing maximal contact area between LUV and GUV (*dashed blue line*). Liposome trajectory after multiple displacement steps is schematically shown with a gray dashed line. (*c*) Representative trajectories obtained in simulations with 1, 3, or 20 tethering SNARE complexes. (*d*) MSD obtained from 20 simulation runs with 20 tethering SNARE complexes. The mean is represented by the dashed black line and the standard deviation of the mean is shown by the shaded area. (*e*) Dependence of LUV's diffusion coefficient on the number of tethering complexes. The mean is represented by the black line and the standard deviation of the mean is shown by the shaded area around it. Each diffusion coefficient was determined in 20 independent simulation runs. The blue area below the graph shows the range of experimentally measured diffusion values for syb *Δ*84 and AA.

form a 5-s-long trajectory (see Fig. 3 *c*). Next, MSD curves were generated from the trajectories (Fig. 3 *d*), and diffusion coefficients for a varying number of tethering SNARE complexes were calculated (Fig. 3 *e*). The outcome of simulations confirms that the diffusion coefficient of a vesicle decreases with an increasing number of tethering SNARE complexes (Fig. 3, *c* and *e*). Diffusion speeds obtained in simulations and experiments let us conclude that loosely docked vesicles (mainly AA syb and *Δ*84 syb) observed with iSCAT are attached to the GUV with maximally 3–4 assembled SNARE complexes. Docked vesicles moving at the maximal speed, on the other hand, are found to be attached via two SNARE complexes. Vesicles attached with one SNARE complex were probably rejected from our analyses because of large fluctuations in the position perpendicular to the GUV surface and the lack of a ring-shaped amplitude pattern as seen in Fig. 2 *b*.

Next, we modeled the diffusion of vesicles that were attached to the GUV through tight docking interfaces by assuming a disk-like-docking interface that diffuses as a whole (see Materials and Methods). Here, we have used

an analytical approximation of the translational diffusion in the membrane (42,43) to calculate the theoretical diffusion coefficient of a tightly docked vesicle with a given docking interface radius (Fig. 4 *a*, see Materials and Methods for details). The resulting diffusion coefficients (Fig. 4, *b* and *c*) decrease with increasing interface size at a slower pace than in the case of a loose docking model (Fig. 3 *e*). Remarkably, diffusion coefficient values of the slowest vesicles containing syb mutants (i.e., potentially not hemifused, Fig. 2 *c*) correspond to the modeled interface radius of around 50 nm, which, in turn, correlates with maximal feasible LUV deformations based on electron microscopy studies (6,17).

DISCUSSION

Here, we utilized in vitro reconstitution using previously described SNARE mutants (6,17) to characterize recently discovered early membrane fusion intermediates (6,17). Employing iSCAT microscopy in this work allowed, for the first time, to our knowledge, for extended 3D-tracking
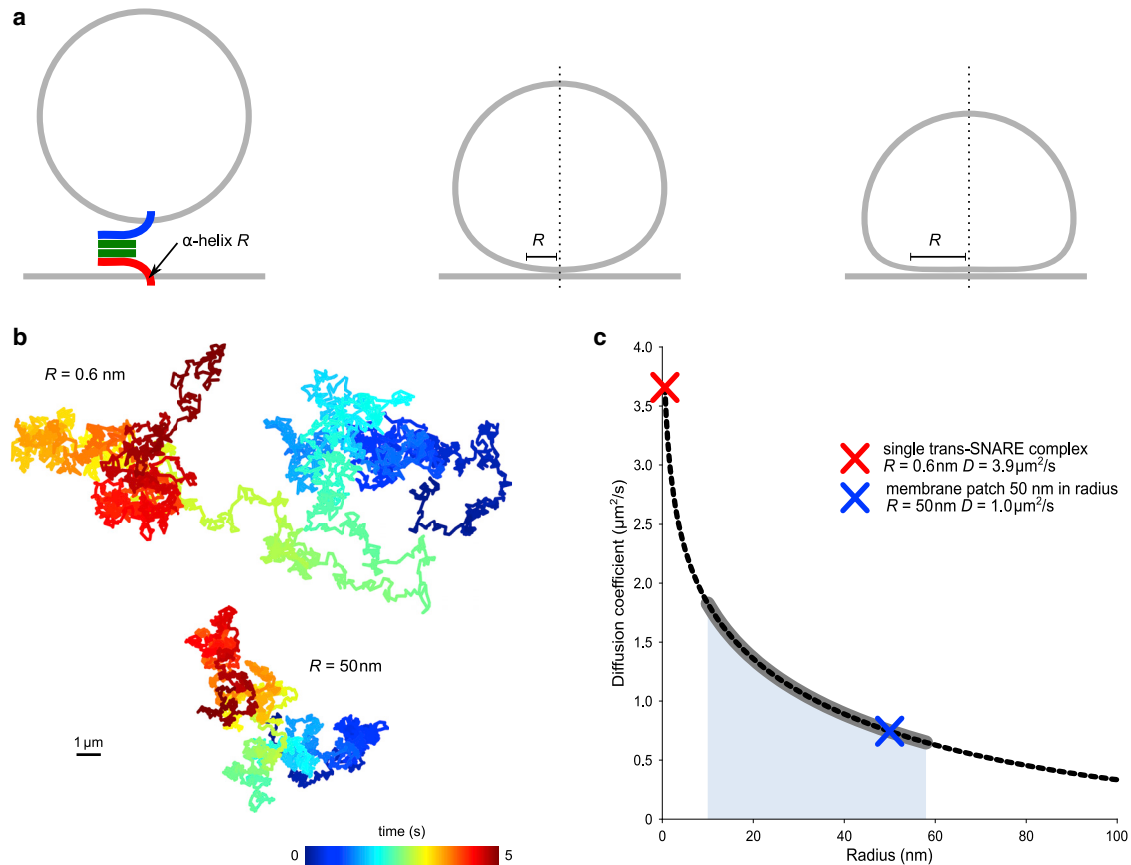

FIGURE 4 Modeling the diffusion of tightly docked vesicles. (*a*) Schematic illustration displaying different docking stages that can be captured by the model: point attachment by a single tethering SNARE complex, intermediate, and extended docking interfaces with varying radii R of the membrane interaction surface. (*b*) Example trajectories of vesicles over 5 s, moving with diffusion speeds obtained from the model (see (*c*)) corresponding to point attachment ($R = 0.6$ nm) and extended docking interface ($R = 50$ nm). (*c*) Analytical solution of the tight docking model (*dashed line*) with parameters (Table 2) corresponding to the experimental conditions in this work. Diffusion coefficient values of the trajectories shown in (*b*) are marked with crosses.

of vesicles' dynamics on large, free-standing membranes with very low curvature as typical for cell membranes thus avoiding disturbance by surface contact or edge effects that may occur in supported or pore-spanning membranes (33). With this approach, we were able to observe that docked vesicle's arrest at subsequent membrane fusion intermediate states (loose docking, tight docking, and hemifusion) is reflected in decreasing diffusion coefficients.

The loosely docked state, stabilized here by point mutations in the SNARE synaptobrevin, may serve as a model for partially assembled SNARE complexes in which progression of zippering is thought to be arrested by regulatory proteins (1,53). In our experimental system, we find that such loosely docked vesicles, on average, diffuse faster than other docked liposomes, which indicates less interactions between docked membranes. Moreover, the number of connecting SNARE complexes predicted by our model (up to 3–4) is in good agreement with current, albeit rather indirect, estimates for the number of SNARE complexes required for fusion (38,54,55).

Tightly docked membranes have only recently been observed in fusion reactions mediated by SNARE proteins (6), viral fusion proteins (56), as well as mitochondrial fusion proteins (57). Additionally, this state appears to be also independent of the continued presence of the tethering proteins because docking becomes irreversible upon SNARE complex disassembly (17). Moreover, development of tight membrane-membrane contact patch was also inferred from protein-free coarse-grain simulations (58), providing further evidence that it constitutes a true fusion intermediate. Taken together, it seems that tight docking is independent of the nature of the fusion protein and is thus an intrinsic feature of the bilayer. In this work, we detected a high proportion of vesicles with relatively large tight attachment interfaces, exceeding 10 nm in radius. Together with previous electron microscopy observations of large, flattened, interacting membrane patches (6,56,57), it suggests that once formed, expansion of such an adhesion interface can progress up to the point when further membrane deformation is not possible or when there is steric hindrance

coming from protein tethers. It remains to be established how the repulsive forces of the negatively charged membranes are overcome at close distance and also whether, and to which extent, diffusion of membrane constituents is hindered in the disk-like contact zone.

Do tightly docked intermediates represent fusion intermediates in living cells? Extended disk-shaped contacts were frequently observed in classical electron microscopy studies of secretory vesicles (59), but they were later attributed to fixation artifacts (60). However, more recently docked vesicles with subnanometer distance from the plasma membrane were seen in electron microscopy images of synaptic vesicles in neurons obtained with high-pressure freezing (61,62). Understanding the physical parameters governing this state such as adhesive and repulsive forces at the contact zone, the lateral mobility of molecules within and between the membranes, and the energy barriers leading from this state to nonbilayer intermediates, such as fusion stalks, will be instrumental for unraveling the mechanism of membrane fusion. The methodology applied here may be useful for analyzing the intermediate states of other fusion proteins such as those mediating mitochondrial or viral fusion.

SUPPORTING MATERIAL

Supporting Material can be found online at https://doi.org/10.1016/j.bpj.2020.10.033.

AUTHOR CONTRIBUTIONS

A.W., R.J., and V.S. designed the study. A.W. prepared all samples, performed confocal imaging, wrote code and performed numerical simulations, and analyzed and evaluated all data. S.S. prepared GUVs and performed and evaluated iSCAT experiments. R.G.M. contributed new analytic tools for iSCAT and evaluated iSCAT experiments. A.W., S.S., R.J., and V.S. wrote the manuscript.

Differential Diffusional Properties in Loose and Tight Docking Prior to Membrane Fusion

Agata Witkowska, Susann Spindler, Reza Gholami Mahmoodabadi, Vahid Sandoghdar, and Reinhard Jahn

Image background correction using image registration

For image background (BG) correction we developed a routine which we call Sparse In Time Affine Registration (SITAR).The procedure is briefly described in the following: Each frame is divided into 16 equally-sized boxes with 3-pixel overlap between all neighboring boxes. For each box, a stack of images (usually 25 with a spacing of 30 frames) is aligned by translation and scaling to register the images to the frame of interest (also called "affine mapping"). An optimization routine is applied to find the coefficients of the registered group of images to optimally describe the background of the frame of interest in this region. Finally, each pixel value in the box is divided by the estimated background value and multiplied by the mean value of the background box. The image is recomposed from the BG-corrected boxes without the overlapping regions.

Figure S1 Localization accuracy of determined LUV localization. (a) Localization error distribution for x and y directions of the trajectory shown in Fig. 2a. Bin width 0.5 nm. All positions with a fit error larger than 0.15 pixel size (corresponding to 9.54 nm) were neglected. (b) Determination of translational GUV dynamics. A GUV region (indicated in the snapshot) is selected to calculate the displacement of the same region relative to the GUV recorded 2 ms earlier in the video. Histogram presents displacements of such GUV translation. Color map encodes iSCAT gray values. Bin width = 6.3 nm; standard deviation = 8.

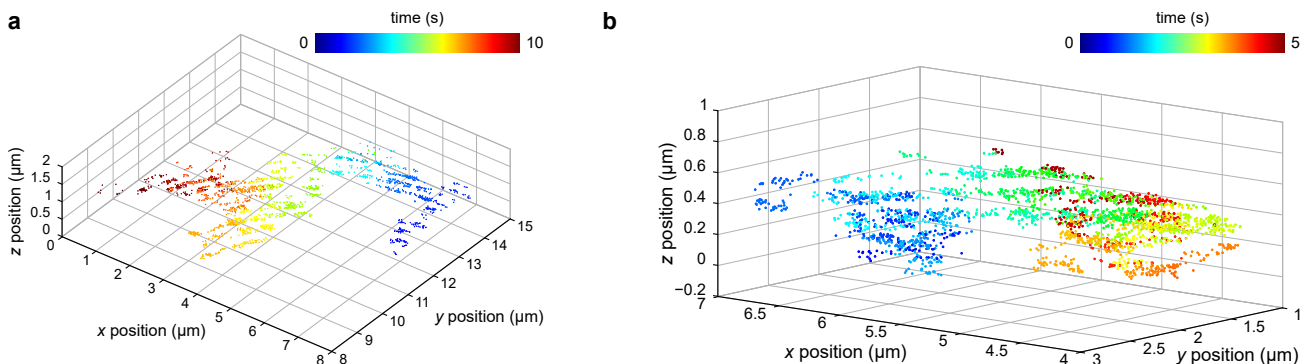

Figure S2 3D reconstructed trajectories of a docked liposomes. Localizations of Δ84 syb- (a) and WT syb- (b) liposomes docked on the GUV surface and tracked for 10 s (a) and 5 s (b), respectively. Point color encodes for the time evolution (see also Fig. 2a).

Determining the GUV center

To find the coarse and more accurate position of the GUV center (x_{GUV}, y_{GUV}), we applied two consecutive routines. For the coarse determination of the GUV center, the direction perpendicular to the fringes in small image segments was computed. To do so, the raw iSCAT image was divided into 16 segments and each segment was thresholded individually as shown in Fig. S3a. The Fourier transform of each binary segment (Fig. S3b) was approximated by an ellipse using image moments. The major axis of the ellipse was directed along the frequencies with high intensity and thus towards the GUV center. The eccentricity of the ellipse gives a measure for the strength of the directionality. Hence, a vector could be assigned to each segment with the direction along the major ellipse axis and the eccentricity as length (Fig. S3c). The intersection of all vectors determines the coarse GUV center with an accuracy on the order of a few pixels (1), depending on the number and quality of the GUV rings, which can in turn be affected by illumination inhomogeneities or strong scatterers in the field of view.

Figure S3 Coarse determination of the GUV center position from its iSCAT image. (a) iSCAT image of a GUV with 20 µm radius divided into 16 segments (2×2 µm²), each individually thresholded. (b) Segment-wise Fourier-transformed image. In each segment the distribution of the high-power frequencies can be approximated with an ellipse. (c) Raw iSCAT GUV image overlaid with red lines denoting vectors along the major ellipse axes each with a length determined by the ellipse eccentricity. The intersection of all vectors determines the coarse center of the GUV (red square).

To improve the accuracy, this center was used as the starting point for a second routine. Here, it was assumed that the path difference and the associated phase between the light reflected at the GUV surface and at the glass–water interface can be approximated with a parabola (1). In the parabolic approximation, the radial intensity distribution from the GUV rings is modulated quadratically as $I(r) = \cos(a r^2 + \pi)$, where r is the radial distance from the GUV center in the recorded image, and a is a constant factor. Binning the average intensity values in intervals with quadratic spacing starting from the assumed GUV center therefore results in a periodicity with a frequency determined by Fourier transformation. The position $r = 0$ for which the frequency has the maximum amplitude represents the GUV center.

The parabolic approximation is valid only in the small-angle regime, i.e. up to a relative phase of about 0.15 rad. For our experimental situation with a GUV radius typically between 10 and 30 µm, at

least 2.5 interference rings are present in this region, which is sufficient for finding the center with subpixel accuracy.

In the present example (Fig. S4a and b), we have plotted the average intensity versus the squared radial distance and the FT of the radial profile for a starting point ~3 pixel off the center (blue curve) and for the actual GUV center (red curve) in comparison. Although the routine for the coarse determination usually performs much better than 3 pixels deviation, this was chosen for illustration purposes and furthermore demonstrates that also in cases with a non-optimal starting point this routine performs well. In Fig. S4a it becomes clear that when the origin of the radial profile coincides with the actual GUV center, the periodicity is more pronounced and the corresponding peak frequency (marked with an arrow in Fig. S4b) has the maximum amplitude.

In Fig. S4c we have plotted the amplitude of the peak frequency around the initial center (in this case 3 pixels off) at (0,0). The distribution is smooth with only one global maximum, which represents the true center of the GUV. We determined this maximum iteratively using a MATLAB nonlinear optimization routine with a stopping criterion of 10^{-6} pixel accuracy.

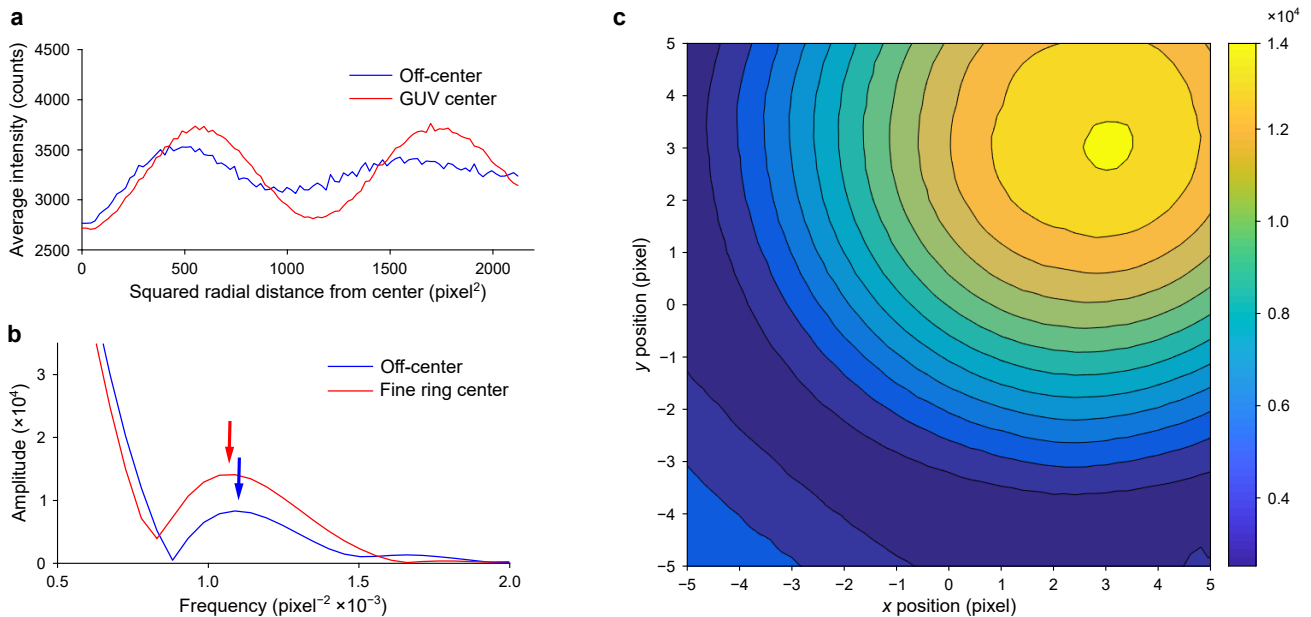

Figure S4 Fine determination of the GUV center position from its iSCAT image. (a) Average radial intensity profile of the GUV iSCAT image shown in Fig. S3c plotted against the quadratic distance from an assumed GUV center. For the true GUV center, the amplitude of the periodic intensity profile falls off much slower (red line) than for a radial profile with a center position about 3 pixels away from the GUV center (blue line). (b) Fourier transforms of the radial profiles shown in a) (with Hann window and zero padding). Note that the distance of 3 pixels used to calculate the off-center curves was chosen for illustration—the coarse determination routinely performs better than this. (c) Amplitude of the peak frequency from the Fourier transform as a function of the assumed GUV center position (with (0,0) corresponding to the coarsely determined position, in this case 3 pixels off). The position at which the amplitude is maximal corresponds to the fine GUV center position.

Unspecific attachment of liposomes on the GUV surface

To estimate the contribution of LUVs that are unspecifically interacting with GUVs (non SNARE-mediated interactions), we measured syb-LUV to GUV contact times (time from first contact that

appears as "docking" to "undocking") in a situation where ΔN complex is either absent (protein free GUVs) or is inhibited by preincubation with a soluble syb fragment (1–96, for details see (2)). This was done using confocal time-lapse microscopy of LUVs labelled with membrane dye DiD and GUVs with dye DiI (both from Thermo Fisher Scientific) in the same way as described in (2). These measurements show that unspecific interactions of LUVs and GUVs arising from random collisions are short-lived, in our hands not exceeding 300 ms (Fig. S5).

Figure S5 Prolonged docking of LUVs on GUV surface is SNARE specific. Syb WT-containing LUVs appear docked on protein free GUVs (black, N=209) or ΔN-GUVs preincubated with syb (1–96) (red, N=145) for only short periods of time, typically below 100 ms. Time from docking start to undocking was measured with time-lapse confocal microscopy (as in (2)). Boxes represent interquartile range, and whiskers below and above indicate full data range. Line in a box represents median and square point represents the mean.

Estimation of diffusional slowing down of LUVs induced by GUV proximity

In order to determine the effect of solvent and GUV proximity on the diffusion coefficient of freely diffusing LUVs, we employed a model of a vesicle moving parallel to a supported planar bilayer (3, 4). In this model diffusion coefficient $D_\parallel$:

$$D_\parallel = \frac{k_B T}{6 \pi \mu_s R} \times \beta_\parallel$$

is scaled with a $\beta_\parallel$ factor that describes increased hydrodynamic drag when particles diffuse parallel to a solid object:

$$\beta_\parallel = 1 - \frac{9}{16} \frac{R}{(R+h)} + \frac{1}{8} \left(\frac{R}{(R+h)} \right)^3 - \frac{45}{256} \left(\frac{R}{(R+h)} \right)^4 - \frac{1}{16} \left(\frac{R}{(R+h)} \right)^5$$

where R is the hydrodynamic radius of the vesicle and h is the separation distance between the vesicle and planar surface (GUV membrane in our case).

Diffusion coefficient and hydrodynamic radius of freely diffusing syb-LUVs (D_{free}) were measured in HEPES 20 mM (pH 7.4), KCl 150 mM buffer with dynamic light scattering (DynaPro Titan, Wyatt Technology) and were estimated to be 5.5 µm²/s and 44 nm, respectively. With these values diffusional slowing down of LUVs approaching GUV membrane could be estimated from the dependency (Fig. S6):

$$D_{\parallel} = D_{free} \times \beta_{\parallel}$$

Figure S6 Diffusional slowing down of LUVs induced by GUV proximity. Estimation of decrease in a parallel diffusion coefficient of a free LUV approaching GUV according to model of (3, 4).

Effect of potential SNARE clustering on simulation of diffusion of loosely docked vesicles

As SNAREs might also diffuse in small clusters, we have investigated the effect of the SNARE cluster size on the diffusion coefficient of a loosely docked vesicle. Increasing number of SNAREs in a single tether does slightly slow down docked vesicles (compare black and red lines in Fig. S7), although much larger effects have number of independently diffusing tethers independent of number of proteins within the tether.

Figure S7 Dependence of loosely docked LUV's diffusion coefficient on the number of independent tethers and number of SNARE complexes contributing to each tether. The mean is represented by the thick line and the standard deviation of the mean is shown by the shaded area around it. Each diffusion coefficient was determined in 20 independent loose docking simulation runs. Diffusion coefficients of clustered SNAREs were obtained by estimating their hydrodynamic radius and calculating diffusion coefficient of a single cluster as in (5). Data for single SNARE complex as in Fig. 3e.
Movies 1–3 Vesicles docked and diffusing on a GUV surface. SITAR background-corrected iSCAT videos of a docked and diffusing AA syb-LUV (Movie 1), Δ84 syb-LUVs (Movie 2), and WT syb-LUVs (Movie 3) on a GUV. Frame rate = 1 kHz, recording time = 1s, videos slowed-down 20×, frame size = 16.28 μm × 16.28 μm.
