QSM with any rim	25 (9%)	15 (6%)	10 (23%)	<.001 ^b	12 (6%)	13 (14%)	.012 ^b	8 (5%)	17 (12%)	.013 ^b						

Note: -n indicates number of lesions in each group.^a The appearance of lesion and lesion rim (if present) is described. The P value represents statistical significance for the χ^2 test of proportions, which was tested for groups as a whole (not per subject).^b P < .05.

ON-LINE FIG 1. Relationship between MSFC and quantitative R2*, frequency, and relative susceptibility values. Shown are the results of mixed-model regression (adjusted for age and sex) for prediction of the quantitative MRI index value by the Multiple Sclerosis Functional Composite z score as represented by a fitted-values plot. The open circles represent fitted values based on the fixed and random effects from the model, with each circle thus representing 1 subject and the size of the circle weighted for the number of lesions that particular subject contributed to the model. The regression coefficient for the fixed-effects portion of the model is shown in each panel, along with the P value for the significance of that coefficient. To place all quantitative values in an equivalent space, we converted all values to z-score units (based on the mean and SD from all lesions). A significant inverse relationship was found between R2* and MSFC and for a combined index of R2* + relative susceptibility and MSFC, though this relationship was heavily influenced by data from a small number of subjects with the worst MSFC scores.

ON-LINE FIG 2. The relationship between fatigue and quantitative R2*, frequency, and relative susceptibility values. Shown are the results of mixed-model regression (adjusted for age and sex) for the prediction of the quantitative MRI index value by the Modified Fatigue Impact Scale score as represented by a fitted-values plot (see Fig 4 and “Materials and Methods” for details). A significant inverse relationship was found between R2* and MFIS.
