## A. Further details of statistical analysis

We chose the Versatile test described in 2016<sup>1</sup> which is a combination test of 3 log-rank test statistics ( $Z_1, Z_2, Z_3$ ), each weighted differentially. The first is unweighted and so is the standard log-rank test, whilst the latter two are separately weighted according to either the overall survival or failure function, and hence sensitive to early and late effects, respectively. The test does not anticipate a particular functional form for the hazard ratio, but allows for any non-proportional treatment effect (whether early or late) to be more likely identified than a standard log-rank test would, whilst still maintaining good power under proportional hazards. The test statistic  $Z_m = \max\{|Z_1|, |Z_2|, |Z_3|\}$  was compared against a trivariate normal distribution with mean vector zero and a variance-covariance matrix based on the covariance estimates between the three test statistics. It is this correlation between tests that limits the effective degrees of freedom required to (considerably) less than 3, providing statistical efficiency whilst 'covering the bases' of possible outcomes.

We describe time-dependent features of the screening effect by estimating the hazard ratio and the absolute survival difference at the pre-specified time-points of  $t=5, 10, 15$  and 18 years (maximal follow-up was 19.3 years) using a flexible parametric RP model. The number of knots and subsequent spline functions were chosen based on the model with the lowest Akaike Information Criteria (AIC) when fitted to the MMS group, and then applied to the other groups. Knot placement was the default option, according to the centiles of the uncensored MMS group survival times.

The model was fitted using the Stata package `stpm2`.<sup>2</sup>

## Web Table 5: Sensitivity analysis for primary analysis

### Methods

Sensitivity analyses were undertaken for three particular issues 1) (non-)equivalence of data source 2) correlation of data within regional centres and 3) competing deaths.

1) Data-source: There was concern that there could be more comprehensive data in the MMS and USS groups than the no screening group, given the potential for more sources of information for these women. This analysis only considered data obtained or triggered from the receipt of electronic health records (eHR), where equivalence between groups could be guaranteed. This meant that not only data pertaining to OC death, but also any data pertaining to any reason for early censorship, from eHRs was used to create the necessary failure-event and time variables employed by the software. The primary analysis utilizing the Versatile test was repeated on data created according to the described criteria.

2) Correlation of data: Data may be correlated within centres. This could be due to systematic differences in delivery of the screen at the 13 centres or also due to regional socio-economic differences leading to variability in OC incidence and mortality outcome. The Versatile test cannot be modified to account for this. However, the standard Cox analysis on the primary outcome was a) fitted with the standard errors calculated using a 'cluster robust' sandwich estimator [Stata command `stcox` with model option `vce(cluster varname)`], and the effect on standard errors and significance was observed. In addition, b) a random effects flexible parametric model [Stata command `mestreg` or `stmixed`] was also be fitted to assess the effect a random intercept term for centre had on the mortality reduction estimate and standard error. Furthermore, this model allowed testing of the random effect variance, and hence the level of unexplained variability between centres.

3) Competing deaths: There is a possibility that the effect of 'competing risks' may impact on the primary outcome. These competing risk events may be death from another cause when the woman had ovarian or tubal cancer, or death from a related cancer (for example, endometrial or breast) that may not be reasonably considered as uninformative censoring. A competing risks model [Stata command `stcrreg`] incorporating the above events as competing risks was used to whether the Cox model primary outcome HR estimates were essentially no different to the sub-HRs from a competing risks model.

**Web Table 5**

1) Data source: eHR- equivalent only (Versatile test)					
	max $\chi^2$	p-value			
MMS vs no screening	0.54	0.596			
USS vs no screening	1.18	0.374			
2a) Regional Centres - cluster robust SEs					
	HR	se	L95% CI	U95% CI	p-value
MMS vs no screening	0.956	0.051	0.860	1.062	0.398
USS vs no screening	0.938	0.069	0.812	1.083	0.380
2b) Regional Centres - mixed survival model*					
	HR	se	L95% CI	U95% CI	p-value
MMS vs no screening	0.956	0.068	0.832	1.098	0.524
USS vs no screening	0.938	0.067	0.816	1.078	0.365
3) Competing risks - other deaths					
	HR**	se	L95% CI	U95% CI	p-value
MMS vs no screening	0.955	0.067	0.832	1.097	0.515
USS vs no screening	0.939	0.067	0.817	1.080	0.378

eHR=electronic health record. MMS=multimodal screening. USS=ultrasound screening. max  $\chi^2$  = maximum chi-squared values from the 3 weighted log-rank tests. HR=hazard ratio. SE/se=standard error. L95% CI=lower 95% confidence interval bound. U95% CI=upper 95% confidence interval bound.

\*test of random effect for RC: p=0.039 \*\* technically a sub-hazard-ratio
